Foreword

VOLUME 61 of the Transactions of The American Society of Mechanical Engineers contains the individual papers published during 1939 under the sponsorship of the Society's professional divisions and technical committees, including the contributions of the Applied Mechanics Division issued originally in a quarterly known as *Journal of Applied Mechanics*, and the 1939 Society Records and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and of its professional divisions and local sections and were published in monthly issues, eight being distributed as the Transactions of The American Society of Mechanical Engineers and four as the *Journal of Applied Mechanics*. Other papers published by the Society but not included in this volume may be located by means of the Index on page RI-49 at the end of this volume.

Because of the fact that material of which this volume is composed was originally issued periodically as Transactions, *Journal of Applied Mechanics*, and Society Records, three sets of page numbers will be found. Numbers without letter symbols are those of the eight issues of the Transactions, those with letter symbol A preceding the number refer to the pages of the *Journal of Applied Mechanics*, which follow, and those with letter symbol RI to the Society Records section, which concludes the volume.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on pages RI-45 to RI-48 of the Society Records and Index. Copies of the Transactions have also been set aside for sale.

The Society Records of the A.S.M.E. for 1939, which form a part of these Transactions, are the permanent records of the Society's activities for the year, including lists of committees. The Index provides a means of locating special A.S.M.E. publications and articles in *Mechanical Engineering* as well as those in the Transactions.

THE COMMITTEE ON PUBLICATIONS

Some Problems Related to the Preparation of Illinois Coals[1]

By L. C. McCABE,[2] URBANA, ILL.

The author discusses the mixtures of coal and mineral matter from Illinois mines and relates the problems encountered in cleaning them. He points out the need for and the method of separating the coal and refuse, and discusses the losses encountered in coal separation. Attention is called to the reduction of ash and sulphur and to the enhanced heating value of washed coal, the value of which is difficult to overestimate because of the resultant reduction of fly ash and sulphur fumes during burning. The author states that any effort directed toward the reduction of atmospheric pollution by fly ash and sulphur fumes through the use of better prepared fuel should be encouraged.

COAL preparation in Illinois has long been characterized by good hand picking and screening. In recent years it has come to embrace mechanical cleaning, dedusting, drying, surface treatment by chemicals and oils, and crushing.

The second coal washer in the United States was erected in Illinois in 1870.[3] Development for a number of years was fairly rapid, and in 1908 Illinois ranked first as compared with other coal-producing states in the total amount of washed coal. The washed-coal tonnage increased until 1917 and then rapidly declined until in 1929 only 527,000 tons out of a production of 61,000,000 tons were washed. In 1930 there was a revival of interest in coal cleaning which reached such proportions that in 1936 more than 6,000,000 tons were mechanically cleaned out of a production of 51,000,000 tons. In the period of six years (1930–1936) the amount of washed coal has increased from less than 1 per cent to approximately 12 per cent of the total production. Today there are 21 cleaning plants in operation in the state and three or four awaiting construction. It is probable that when these plants are in full operation, they will produce twelve or fifteen million tons of washed coal annually.

Important factors involved in the trend toward mechanical cleaning are the increased production from mechanized underground workings and from strip mines which do not lend themselves to careful separation of coal and refuse during loading, increased competition from oil and gas, the perfection of mechanical coal-burning equipment with exacting fuel requirements, and the adoption of antismoke ordinances by municipalities.

Selected coals chosen from the producing beds of the State will best illustrate the problems encountered in modern preparation plants in Illinois and at the same time demonstrate the benefits accruing to the coal consumer.

The modern washery is operated to eliminate noncoal material from the feed entering the plant. Carbonaceous and clay shales from the roof and underclay from the floor of the seam are loaded with the coal to some extent in all mines, but their removal in the cleaning process is relatively simple because their specific gravity is considerably greater than that of the coal. Occasionally, however, clays or shales disintegrate and remain in suspension in the wash water. As a result, the coal in the wash box becomes coated or "whitewashed" and clean-water sprays must be used to remove the coating and give the coal a clean appearance. Where the water supply is limited, as it is in some parts of Illinois, elaborate settling and clarifying systems must be utilized for settling out the suspended solids before the water can again be introduced into the cleaning system.

The bands, lenses, or veins of shale, pyrite, and "bone" which are commonly associated with coal beds may be broken free in mining or may remain attached to the coal. In the latter case the coal adhering to the impurity is frequently wasted unless the washery reject is crushed and recleaned.

Intimate mixtures of coal and mineral matter present the most difficult cleaning problem. This may be illustrated by a comparison of the washability characteristics[4] of two Illinois screenings from mines *A* and *B*, as given in Table 1; such a comparison can also be made from Figs. 1 and 2.

The ash content of the face sample from mine *A* is higher than the average for Illinois and the ash in the sample from mine *B* is considerably lower, but both mines produce raw screenings of about the same ash content. The workings in mine *A* are under a black-slate or a limestone roof and on a bone or a hard clay floor, conditions which permit little introduction of impurities foreign to the coal bed. Mine *B* has a friable shale roof and a soft clay floor, and a considerable quantity of these materials is loaded with the coal.

When cleaned at 1.50 specific gravity, the curves of coal recovery versus ash in Fig. 1 show a recovery of 80.6 per cent for coal *A*, while from Fig. 2, it is 81.6 for coal *B*. The ash content of the former is 9.5 per cent and of the latter 5.0 per cent. The refuse-reject curve shows the refuse from coal *A* to contain only 53.5 per cent ash while the refuse from coal *B* is 73.8 per cent ash. This would indicate a relatively large quantity of combustible matter in the refuse from coal *A*.

The ash-distribution curves best show the extent of the admixture of mineral matter and coal. The gentle warping of the coal-*A* ash-distribution curve, in Fig. 1, is indicative of the dissemination of ash through the coal. The sharp change in direction to the right in the coal-*B* ash-distribution curve in Fig. 2, reflects the presence of the free shale and clay which found its way into the coal during mining.

Separation of coal and refuse is difficult when large quantities of the feed have a specific gravity approaching the effective specific gravity of the separating medium. The ±0.10 specific gravity curves of Figs. 1 and 2 show that 15 per cent of coal *A*

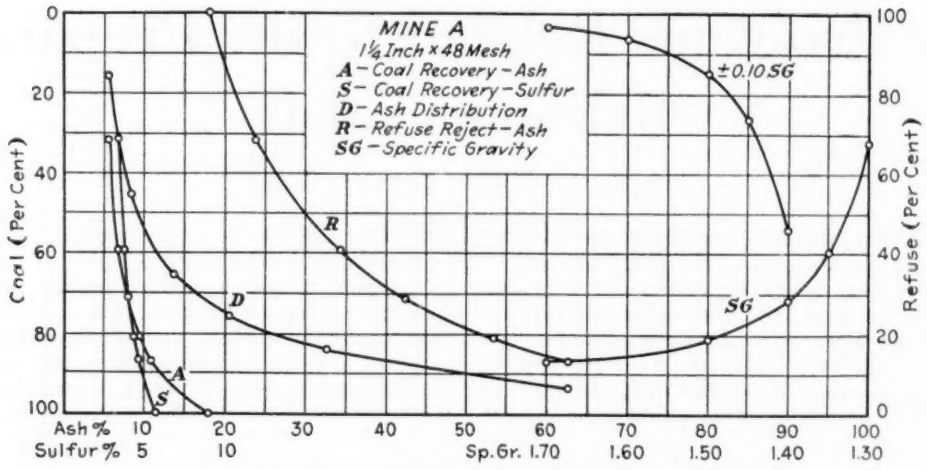

FIG. 1 WASHABILITY CHARACTERISTICS OF COAL FROM MINE *A*

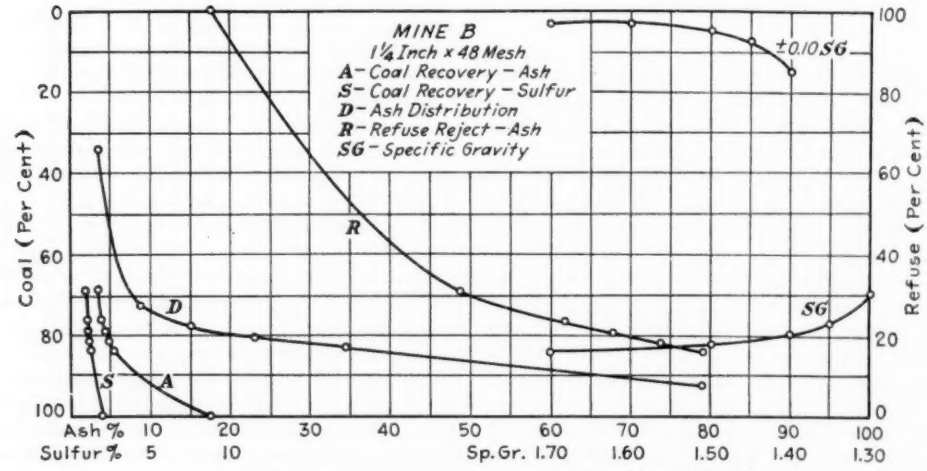

FIG. 2 WASHABILITY CHARACTERISTICS OF COAL FROM MINE *B*

and only 4.3 per cent of coal *B* is between 1.40 and 1.60 specific gravity. Because of the large quantity of material having a specific gravity near the separating gravity, coal *A* is a difficult coal to clean while coal *B*, with a relatively small amount of material of about 1.50 specific gravity, presents a simple cleaning problem. The use of specific-gravity–distribution curves makes it possible to select a specific gravity at which washing can be done most efficiently. Furthermore, they show that the possibility of efficient operation at one specific gravity does not assure similar efficiency at another.

Occasionally, in spite of a knowledge of the washability characteristics of the coal, considerations other than efficiency may direct the operation of a cleaning plant. The consumer, frequently without discrimination, objects to dull or slabby coal and to meet this objection a plant will operate to reject such coal, although it has a high calorific value. Sales departments may find that a washed coal having 7.1 per cent ash would be more readily marketed if the ash is reduced to 6.8 per cent. To obtain this reduction of 0.3 per cent in ash 1 or 2 per cent of coal may find its way into the washery reject.

For numerous reasons the tonnage losses in cleaning are relatively high. At some mines the feed may shrink 20 per cent or more in passing through the preparation plant. While the reject may contain little or no coal, it represents tonnage that formerly found its way into the market and must therefore be compensated for by increased price or expanded sales of washed coal.

TABLE 1 COMPARISON[a] OF RECOVERY, ASH AND SULPHUR PERCENTAGES IN COALS FROM TWO ILLINOIS MINES

	Ash						
Mine	Face sample	Unwashed screenings	Coal recovery	Float ash	Float sulphur	Sink ash	Sink sulphur
A	10.6	18.0	80.6	9.5	4.4	53.5	11.4
B	6.5	17.6	81.6	5.0	1.2	73.8	5.4

[a] Based on 1¼-in. to 48-mesh coal, dry basis, with 1.50 specific gravity

Wet-washing plants cannot effectively clean coal smaller than 48 mesh. In some instances it is removed from the larger coal by dedusting or by screening, but the most common practice in wet-washing plants is to remove it from the system with a thickener or centrifuge, or to permit it to escape to the settling pond.

The ash content of dusts from ten Illinois coals[4] recently studied ranged between 15 and 37 per cent ash. There is no ready market for such material and with few exceptions it is a waste product. It constitutes as much as 5 per cent of the tonnage in some mines.

In addition to tonnage losses, washing entails the loss of potential heat in the washery refuse. That the percentage of heat loss is not as great as the percentage of tonnage loss is apparent from Table 2, which gives a comparison of two coals in the unwashed and in the washed condition. The washability characteristics of coal from mines *C* and *D* are shown in Figs. 3 and 4,

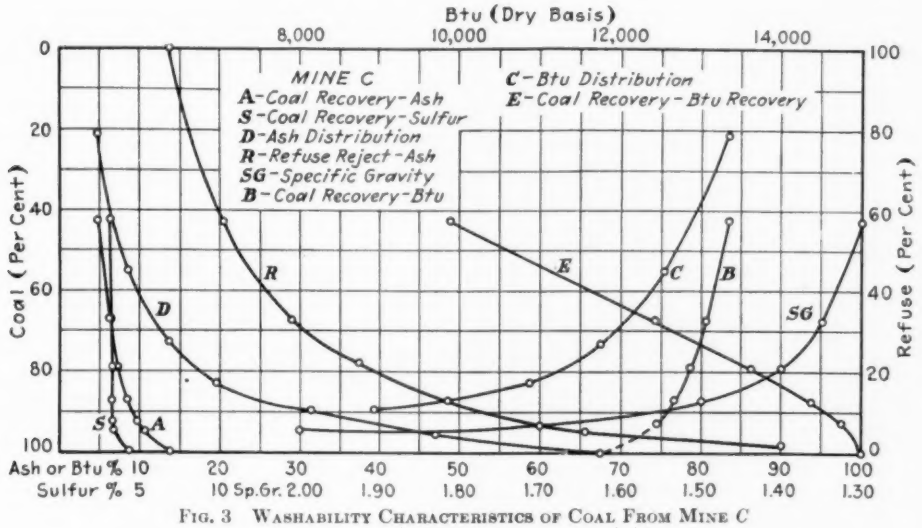

FIG. 3 WASHABILITY CHARACTERISTICS OF COAL FROM MINE *C*

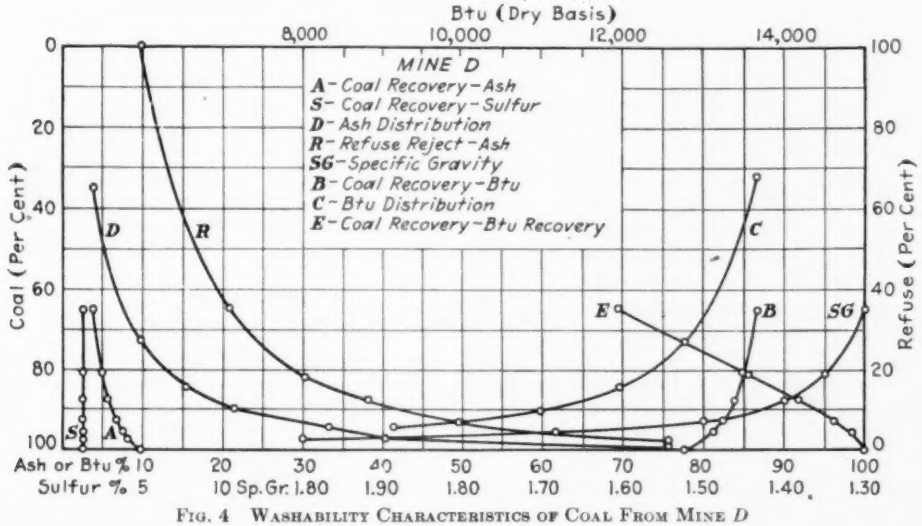

FIG. 4 WASHABILITY CHARACTERISTICS OF COAL FROM MINE *D*

TABLE 2 COMPARISON ON A DRY BASIS OF WASHED AND UNWASHED COALS FROM TWO ILLINOIS COAL MINES

Mine	Coal recovery, per cent	Ash, per cent	Sulphur, per cent	Heat value, Btu per lb	Btu recovered, per cent	Btu increase, per cent
C	100	13.62	4.5	11,756	100	...
	90	9.00	3.1	12,580	96	7.0
D	100	9.85	1.2	12,743	100	...
	90	6.50	1.0	13,300	94	4.4

respectively. When washed for a tonnage recovery of 90 per cent, 96 per cent of the Btu value is recovered in coal *C* and 94 per cent in coal *D*. The greater part of these losses of potential energy may be accounted for by the low calorific value of "bony" coal and pyrite which, in part, constitute the refuse.

Because of the reduction of its ash and sulphur content, a coal is enhanced in its calorific value by washing. Coal *C*, containing 13.6 per cent ash, 4.5 per cent sulphur, and 11,756 Btu per lb, as it comes from the mine, may be washed at 90 per cent recovery to produce a fuel with 9 per cent ash, 3.1 per cent sulphur, and 12,580 Btu per lb. Changes in the character of coal as a result of washing which are of interest to the consumer are 31 per cent reduction of sulphur, 34 per cent reduction of the ash percentage, and 7 per cent increase in calorific value. Coal *D* does not offer comparisons of the same magnitude because it has relatively low ash and sulphur content as it is mined. However, the heat value is raised from 12,743 to 13,300 Btu per lb by washing.

A discussion of the problems related to the preparation of Illinois coals would not be complete without some consideration of the distribution and varieties of sulphur[5] and their reaction to the cleaning process.

Sulphate, pyritic, and organic sulphur are the three varieties generally recognized. The sulphate form is thought to represent mainly the gypsum in the coal, but as the amount is usually less than 0.25 per cent it will be ignored in this discussion. Because of its yellow color, metallic appearance, and high specific gravity (4.95–5.1), pyrite is the most easily identified of the forms of sulphur. Organic sulphur is that part of the total sulphur which is neither chemically determined sulphate sulphur nor chemically determined pyritic sulphur.

The total sulphur content of most Illinois coals is high, averaging 4.37 per cent on an ash-and-moisture-free basis (3.4 per cent on the as-received basis). Fig. 5 shows the distribution of total sulphur, and Fig. 6 shows the minimum and maximum values for

[5] "Distribution of Sulfur in Illinois Coals and Its Geological Implications," by G. H. Cady, Illinois Geological Survey, Report of Investigations No. 35, 1935.

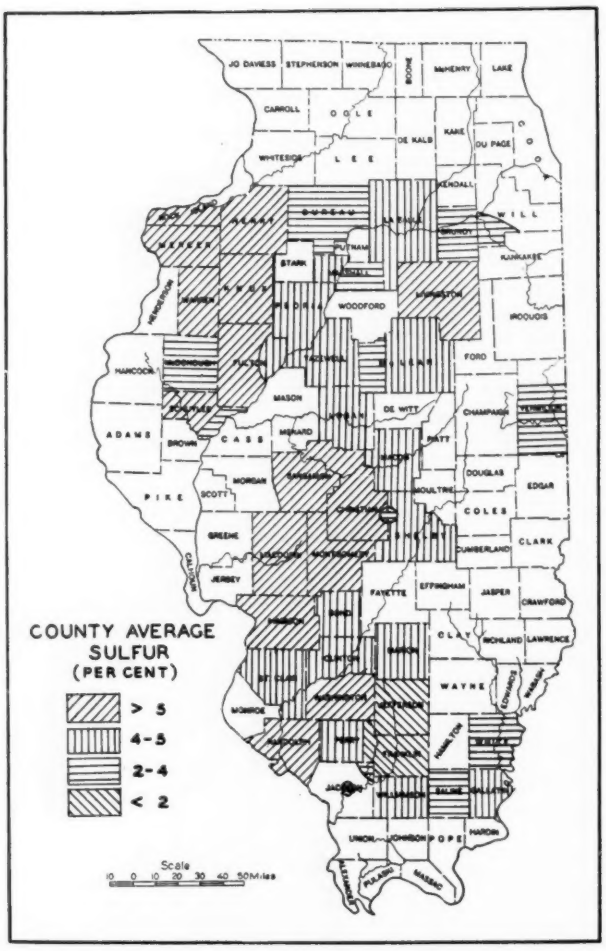

FIG. 5 COUNTY AVERAGE OF SULPHUR CONTAINED IN FACE SAMPLES OF ILLINOIS COALS ON AN ASH-AND-MOISTURE-FREE BASIS

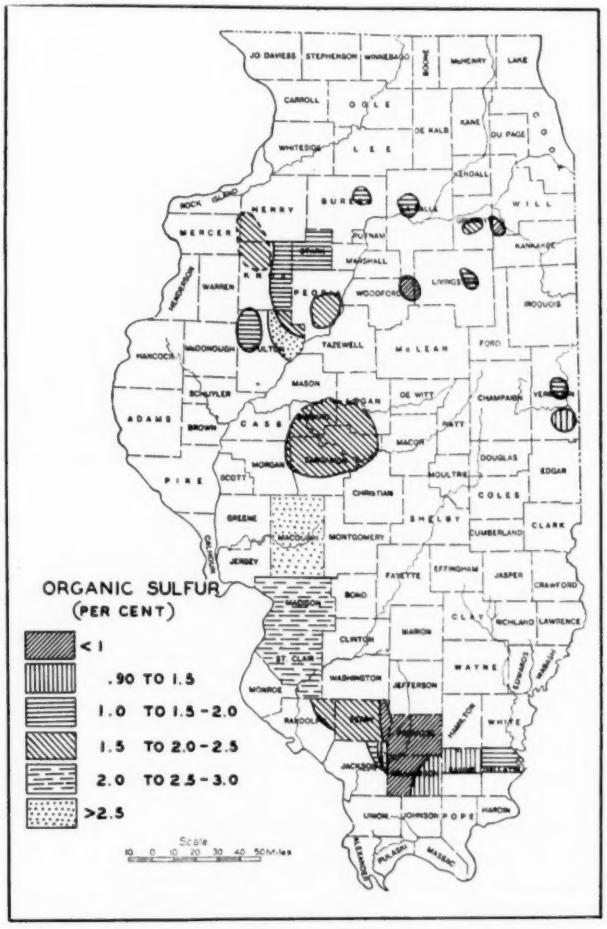

FIG. 6 MINIMUM AND MAXIMUM PERCENTAGES OF ORGANIC SULPHUR IN COAL FROM VARIOUS COUNTIES IN ILLINOIS

organic sulphur in the coal in various counties in the state,[6] information that is particularly useful in evaluating the possibility of sulphur removal by washing. The data for mapping sulphur distribution are from face samples and Cady[7] has pointed out that they do not tell the whole story in regard to the amount of pyritic sulphur present in the coal as more or less pyrite is discarded in collecting face samples. He concludes that the amount of pyrite discarded, if included in the face sample, would rarely increase the sulphur more than 2 per cent and commonly not more than 1 per cent. For practical consideration in pyrite reduction the amount of discarded pyrite need not be of concern as its specific gravity is so much greater than the coal that it is not involved in the economic limits of sulphur reduction.

There appears to be no reduction in the amount of organic sulphur in the washing process and in theory, should the pyritic sulphur be so concentrated as to be broken free in mining, and discarded in toto with the reject, the organic sulphur would represent the irreducible minimum of sulphur content. Actually it is not possible to remove all the pyritic sulphur, for much of it is disseminated through the coal in particles of microscopic size. In the high-sulphur coals, 15 to 35 per cent of the total sulphur may be removed by washing, but the low-sulphur coals are little affected, as shown for coal *D* in Fig. 4.

It was entirely relevant in discussing the problems of preparation to call attention to the magnitude of sulphur and ash reduction and to the enhanced heat value of washed coal. Greater fuel uniformity, less ashes, dust, and sulphur vapors are important corollaries. It would be difficult to overestimate the value to a municipality of the effective reduction of fly ash and sulphur fumes which can be brought about by the use of clean coal. Any effort directed toward reduction of atmospheric pollution by fly ash and sulphur fumes through the use of better prepared fuel should be encouraged because it is based on sound scientific premises.

Illinois coals can and are being burned smokelessly in equipment designed to raise the volatile matter to its ignition temperature before it passes into the stack. For the great number of domestic furnaces not particularly designed for the burning of high-volatile coals, installation of a conversion burner or stoker, or change to a processed coal appears to offer the only solution of the smoke problem without substitution of more expensive oil or gas.

Methods Employed to Remedy Water-Hammer Shock in Pumping Systems

By E. BRUCE BALL,[1] KILMARNOCK, SCOTLAND

This paper gives certain typical problems which have been encountered in English practice in pumping-plant installations, where surge conditions have been encountered, and the changes made to remedy them. The severity of the conditions and the effectiveness of the remedies are shown by pressure-recorder charts showing the line surges caused by the operation of automatic control apparatus.

The paper is the contribution of The Institution of Mechanical Engineers of Great Britain to the Second Symposium on Water Hammer.

THE problem of surge and water hammer, accentuated by the introduction of automatic control on complex centrifugal-pumping installations, has become increasingly serious. Many cases have been reported where severe pressure changes have occurred and, after investigation, almost complete elimination of the surges was effected.

Examples of wide divergency have been selected to illustrate the method of analysis and solutions applied. The first two cases deal with check-valve closure on short pumping systems and the third with gate-valve closures on a long column. Finally, an example is given where an air vessel overcame the objectionable pressure surge.

Case 1 Hydraulic Pumping Plant for Operating Elevators

The plant consists of two 10-stage 5-in-diam turbine pumps each delivering 350 gpm at 1155 ft pumping head running at a speed of 1460 rpm. The pumps are independent but their suction and delivery pipes are connected, and only one pump is operated at a time. The pumps are supplied through an 8-in-diam suction main from a tank approximately 55 ft above them, and deliver through a 6-in-diam pipe to two hydraulic cylinders controlling two elevators. Between the pumps and the elevators there are three accumulators which are equally loaded and independent; all three of them have choke valves which come into operation when the accumulators are nearly at the top of their stroke. One of the accumulators carries a tripping gear which stops and starts the motors driving the pumps. Connected immediately to the vertical delivery line of each pump there is a 5-in-diam check valve, a 5-in. to 6-in. taper pipe, and then a 6-in-diam gate valve. Fig. 1 shows a diagrammatic layout of the plant.

Operating Conditions. When the pumps were cut out with the elevators using water the check valves slammed violently. The whole pumping system shook and the noise gave rise to alarm. Furthermore, the gun-metal seat ring on one of the check valves had loosened due to this slamming.

To find the magnitude and nature of the pressures set up in the delivery pipe, pressure connections were made in the covers of the check valves to carry recording indicators which registered variations of pressure on a time basis.

Fig. 2 shows reproductions of cards from the two valves. That for valve no. 1 shows that the pumping pressure was 405 lb per sq in., and the maximum pressure recorded due to the valve slam 785 lb per sq in., a rise of 380 lb per sq in. or 94 per cent. The violence of the shock is apparent from the jagged nature of the diagrams. Valve no. 2 had the same pumping pressure and a maximum pressure rise of 190 lb per sq in. or 47 per cent.

Both cards show similar characteristics. On a primary surge pressure with a measured period of about 0.08 sec (calculated period 0.075 sec) is superimposed a secondary wave of high frequency the time history of which is complicated by the layout of the pipe system. A notable point is that on valve no. 2 the maximum pressure rise was only half that on no. 1. Although the valves were identical and the pumping conditions the same, there was a slight difference due to the cross connecting of the pipes.

Remedy. Fundamental experiments on, and critical analysis of, ordinary check valves had led to the conclusion that these were unsuitable for dealing with rapid reversals of flow and a type of check valve had been evolved which incorporated all the mechanical and hydraulic properties essential for dealing with difficult conditions. Mechanical improvement was given by a combination of inertia reduction, mass concentration, ideal suspension, and localized movement of the valve disk within a certain region of the stream, and hydraulic improvement was given by avoidance of cavitation and provision for forward and backward water streams within the body and around the valve disk.

In the system under discussion these specially evolved "recoil" valves were substituted for the original check valves and the effect may be seen in Fig. 3. These diagrams were taken under the same conditions as those in Fig. 2.

The rise in pressure over the pumping pressure is 12 per cent on no. 1 valve, an improvement of 85 per cent. No. 2 valve shows an improvement of 100 per cent as the rise in pressure does not exceed the pumping pressure. The noise and vibration due to slam had been entirely eliminated, so that a stethoscope was necessary to tell exactly when the valve closed.

Case 2 Automatic Pumping Plant for Intermittent Supply

A 6-in-diam single-stage centrifugal pump delivers 1000 gpm at 25 lb per sq in. into a closed vessel half full of air. A 6-in-diam pipe from this vessel supplies an intermittent demand used for process work. Due to variation in draw off the pressure in the tank varies and a relay gage on the tank operates the motor switch, cutting out the motor at the maximum allowable pressure and cutting it in again at the minimum limit. A check valve was placed on the discharge side of the pump in a horizontal position. The pipe between the pump and the tank is about 20 ft and the suction lift 3 ft. Fig. 4 shows a diagrammatic layout.

Operating Conditions. As in the first case, a violent slam occurred at the check valve when the pump was cut out. Pressure-time diagrams were taken on the outlet and inlet sides of the valve and these are reproduced in Fig. 5. The shocks were extremely

Contributed by the Hydraulic Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, in New York, N. Y., December 6–10, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until February 10, 1939, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

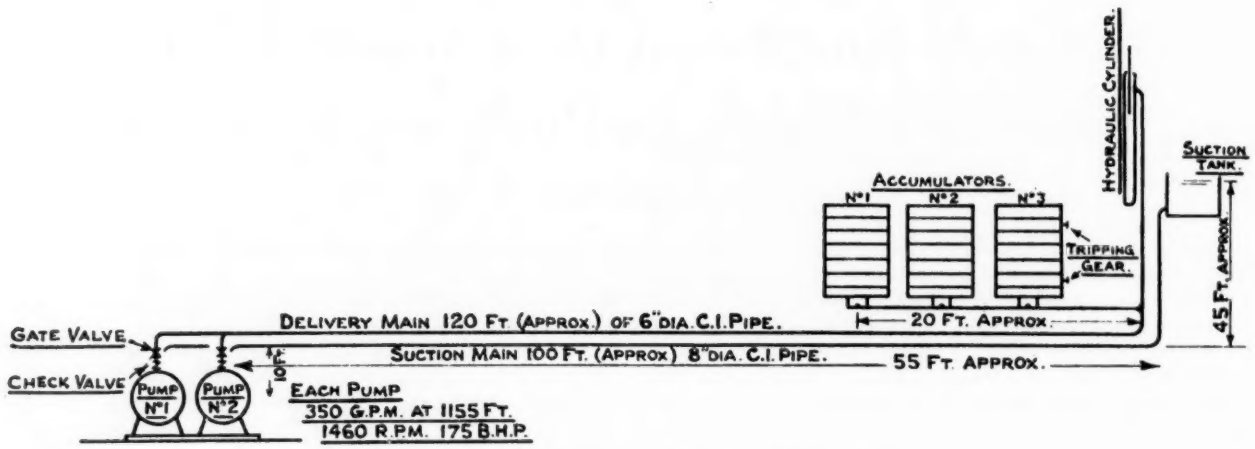

FIG. 1 DIAGRAMMATIC LAYOUT OF HYDRAULIC PUMPING PLANT

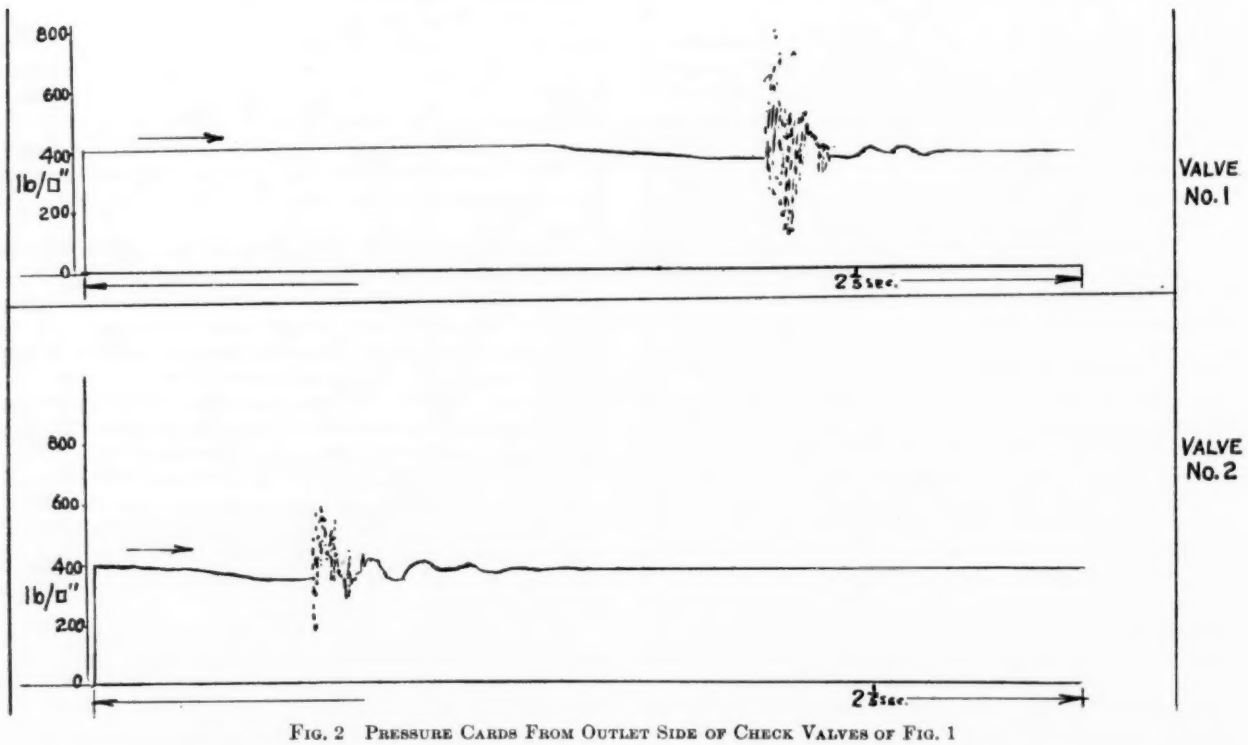

FIG. 2 PRESSURE CARDS FROM OUTLET SIDE OF CHECK VALVES OF FIG. 1

violent as shown by the jagged lines caused by the pencil jumping from the paper due to the vibration of the whole piping system and recording instrument. The recorded shock pressure on the outlet side of the valve was about 350 lb per sq in. and about 530 lb per sq in. on the inlet side.

An interesting point is that the shock pressures were about 50 per cent greater on the inlet side of the valve than on the outlet side. Confirmation of this apparently remarkable condition is provided by recorded cases of pipe fractures close to the inlet side of ordinary nonreturn valves.

Remedy. As in the previous case the check valves were replaced by recoil valves and the results of the change-over are seen in Fig. 6 which were taken under identical working conditions of pressure and pumping velocity.

The recorded surge pressure was 13 lb per sq in. on the outlet side of the valve and zero pressure on the inlet side. Thus 97½ per cent of the arresting shock was eliminated. The valve closed silently.

CASE 3 BOOSTING SYSTEM ON WATERWORKS SUPPLY MAIN

A general layout of the plant is shown in Fig. 7. Water from the reservoir is led to the suction side of an 8-in-diam pump which is set on a loop on the 15-in-diam main. Flow to the elevated tank is controlled by a 12-in-diam electrically operated gate valve on the downstream side of the pump. The 12-in. gate valve is closed first and when the "closed" limit switch is tripped the pumps are shut down.

Operating Conditions. During flow the pumping pressure was 390 ft on the downstream side of the gate valve. The valve is geared to travel 12 in. in 60 sec and, during closure, the valve traveled for 55 sec, or to within 1 in. of the shut position, before any changes were recorded by the pressure gages. Then the

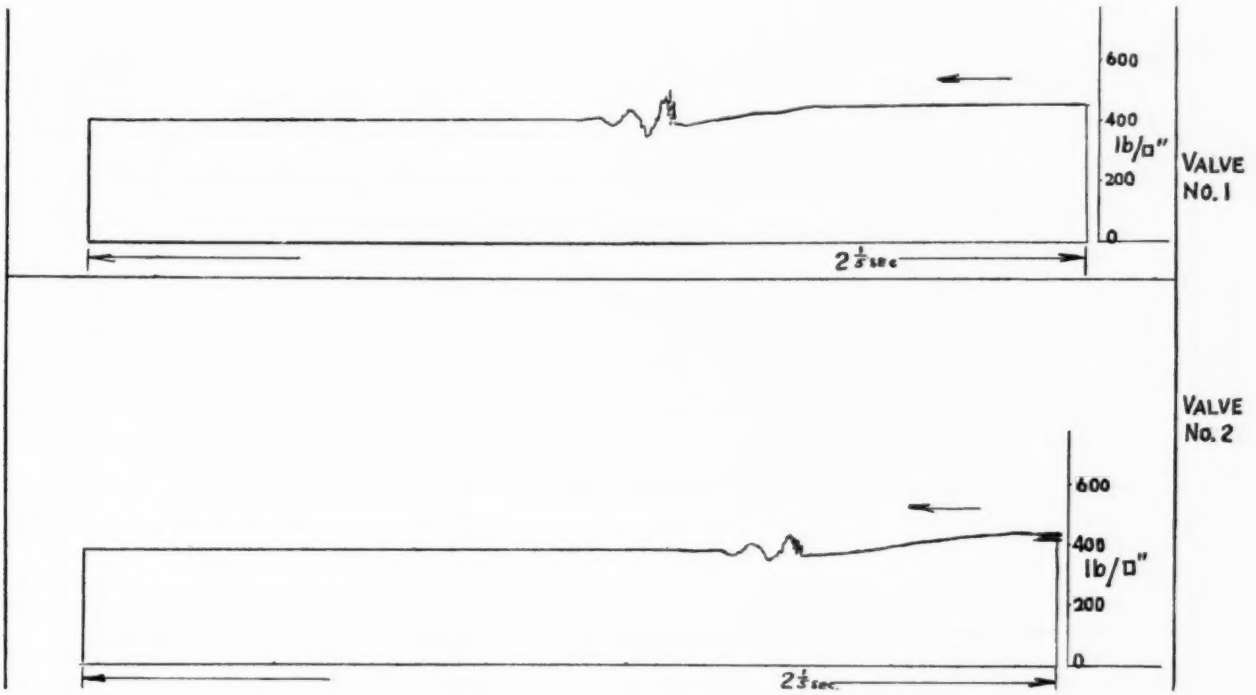

FIG. 3 PRESSURE CARDS WITH CHECK VALVES OF FIG. 1 REPLACED BY RECOIL VALVES

delivery pressure fell to 150 ft, rose to about 540 ft, and oscillated so rapidly that observations of any kind were impossible. The recording pressure gages were so agitated that the diagram was all jags, dots, and blots of ink.

On the delivery side of the valve, when closing down, the surge was a complicated series of pressure waves and reflections. Attempts to measure the period gave an average figure between 3 and 4 sec (which agrees well with the calculated value of 3.35 sec) for the fundamental surge, on which a number of erratic secondary waves were superimposed.

On the inlet side, when closing down, the surge exhibited a much less severe though similarly complicated series of pressure waves with a fundamental period of about 6½ sec. The estimated period was 6.9 sec.

The continued running of the pump aggravates the intensity of the surge downstream of the 12-in. gate valve during its closing operation. As the pressure is both maintained and built up, so that the difference of pressure between the two sides of the gate is increased, the result is that the jet velocity through the partially opened gate is increased. This has a driving effect, increasing the tendency of the column to travel away from the closing gate and still further increasing the fall of pressure. As the action is cumulative an abnormal depression is caused and, when the column recovers by reason of its elasticity, a pressure wave opposite in sign and of high intensity occurs.

A recoil valve had been installed originally in the plant between the pump and the electrically operated gate valve and when the pump was cut out, keeping the gate valve open, no shock or noise was experienced on either the delivery or suction mains and only a slight undulation, soon damped out, was noticed in the pressure gages. While this was entirely satisfactory, the previously outlined method of operating the plant was still desired.

Remedy. As pressure rise depends on time of valve closure, obviously the surge could be reduced by increasing the time of operation of the valve. The critical period, however, is the final part of the stroke and even doubling the time of closure would only approximately halve the surge pressure which would thus still be too severe. Also with this insufficiently extended closing time about 3000 gal of water would be put into the tank after the float gear had transmitted the signal to stop.

A valve was required that would occupy the same total time in closing, but would reduce the velocity in the main in direct proportion to the valve travel. While the spectacle-eye or follower-ring type of gate valve is an improvement in this respect over the disk type, to get the direct relationship required a ported follower-ring type was necessary, with the passage orifice so formed that as the valve closed the valve resistance and the pipe-line friction combined would retard the water column at a practically uniform rate.

Such a valve was made and installed and was successful in overcoming the undue surges. Although no actual test figures are available, the observed maximum peak-surge pressure does not exceed the pumping pressure.

REMARKS

The three cases described have been selected from a large number for their diversity of pumping conditions, pressure, and pipe layout and all are illustrative of the effect of valve behavior on a water column.

In general, a water system consisting mainly of long horizontal water columns at low pressure is sluggish in reversal, and a system, or portion of a system, consisting of short mobile water columns, or a system possessing some measure of elasticity, is rapid in reversal.

The fundamental relation determining the acceleration of reversal of a rigid water column is

$$\text{Acceleration} = \frac{\text{head}}{\text{column length}} \times g$$

where g is the acceleration due to gravity. In practice this relation becomes modified by elasticity and many other factors affecting the column behavior.

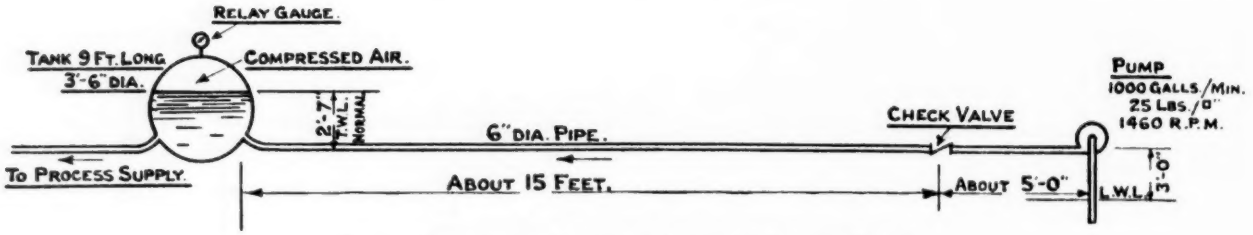

FIG. 4 DIAGRAMMATIC LAYOUT OF AUTOMATIC PUMPING PLANT

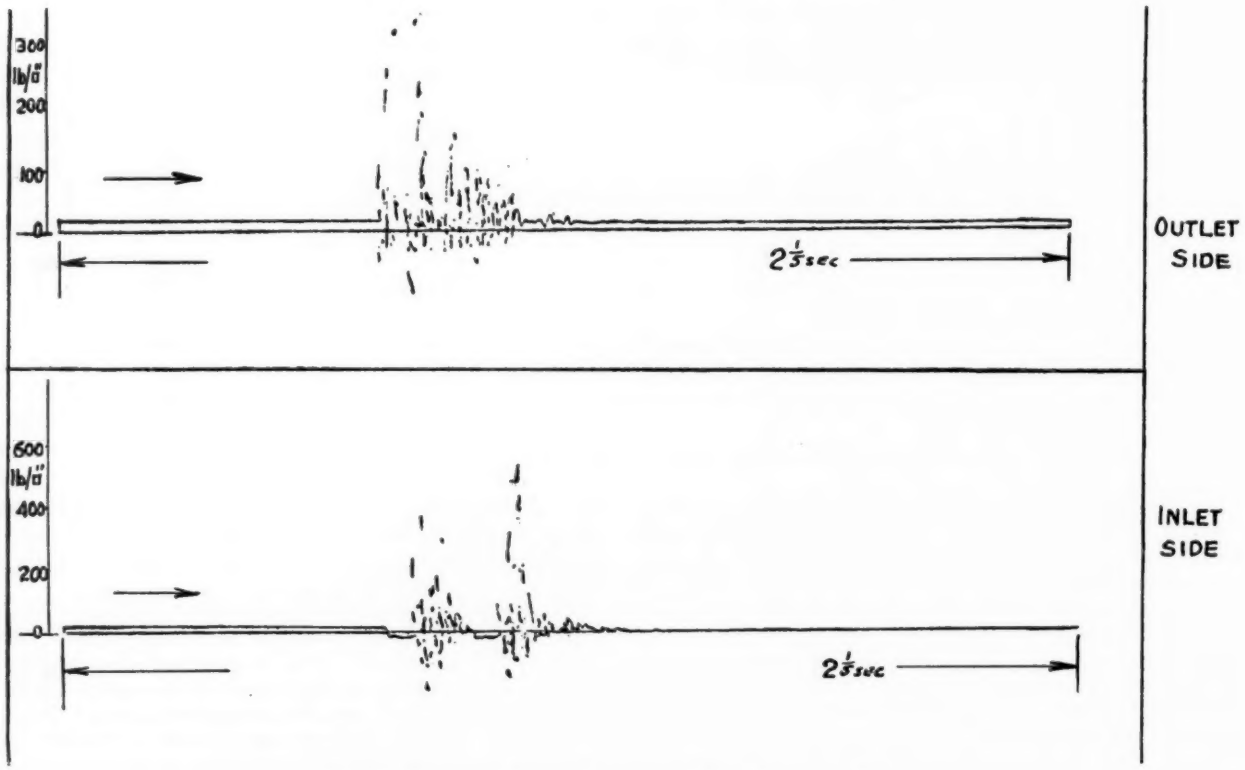

FIG. 5 PRESSURE CARDS TAKEN AT CHECK VALVE OF FIG. 4

A self-acting check valve depends for its operation only on the force due to gravity and, as the inertia of the parts must be overcome, the acceleration of the valve disk must be less than g. The water column is in contact with the disk, hence, if the column acceleration is greater than g and the disk acceleration less than g, it is obviously impossible for the valve to close more quickly than the column can reverse.

The criterion of perfect operation of a check valve is that the valve should reach its seat at the moment the water column is at rest. If the valve does this, any subsequent surge in the main is inherent in the system, cannot be cured by any valve, and must be remedied by other means. This is illustrated by the following case.

CASE 4

In a 6-in-diam pumping main, 18,500 ft in length conveying water at the rate of 83 gpm to a height of 396 ft, a recoil valve, placed on the delivery side of the pump, closed silently without any sign of slam when the pump was cut out. There was, however, a sudden drop of pressure equivalent to the friction head and then a surge varying from 525 ft maximum to 300 ft minimum. The normal pumping pressure is 450 ft.

When the pumps cut out the head conditions suddenly change and this change, not any arresting of backflow, causes the surge.

This type of problem may be solved satisfactorily by incorporating an air vessel in the pipe and, while absolute elimination of the surge cannot be expected, reduction of excess pressure to reasonable limits is possible by the use of a correctly designed vessel. In the case under discussion an air vessel 3 ft 0 in. in diam × 5 ft 9 in. high so reduced the surge that the maximum pressure never rose above 400 ft and the minimum never fell below 370 ft. Thus the original variation of 225 ft was reduced to 30 ft.

A properly designed recoil valve is a necessity in such an installation, as one effect of the air vessel is to increase the severity of the working conditions for the valve. The introduction of a free surface, in the air vessel and near the check valve, divides the water column into two lengths, viz., the main column and a short column from the air vessel to the pump. The short column then becomes exceedingly mobile and subject to rapid reversal of flow when the pump is shut down.

CHECK VALVES

Ordinary standard check valves meet all cases of sluggish water columns and frequently can deal sufficiently satisfactorily with cases where moderately rapid reversals of flow occur. More severe conditions can sometimes be met by fitting loaded disks to

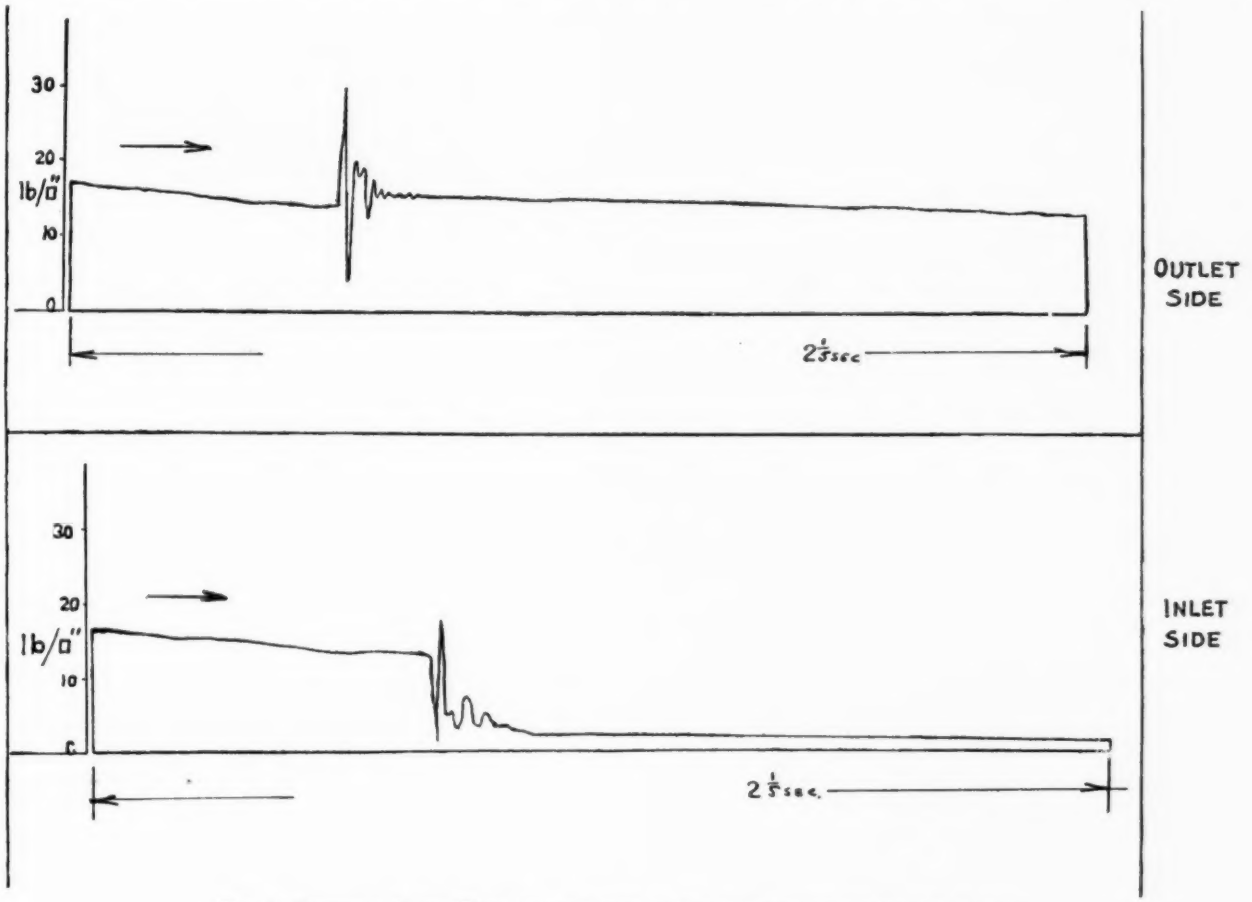

FIG. 6 PRESSURE CARDS WITH CHECK VALVE OF FIG. 4 REPLACED BY RECOIL VALVE

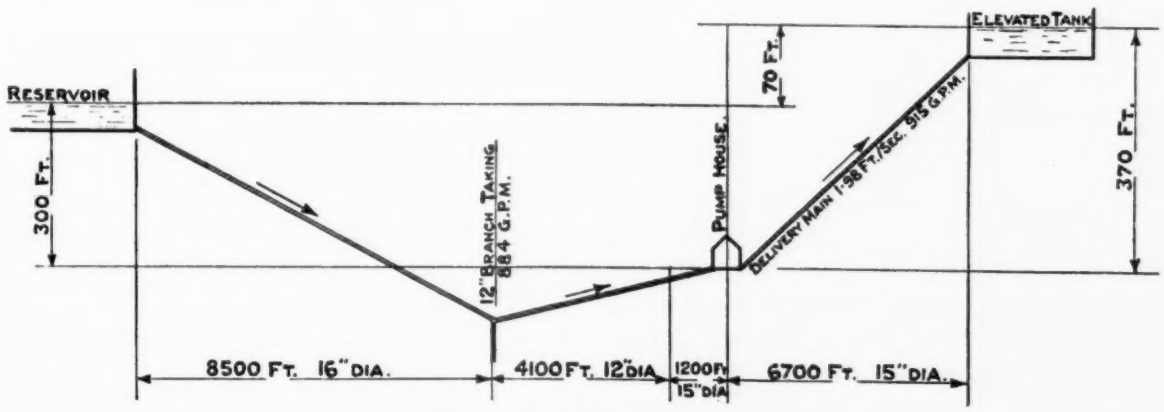

FIG. 7 DIAGRAMMATIC ARRANGEMENT OF PIPE LINE

otherwise standard types of check valves and occasionally so-called slow-closing or cushioned valves are installed. Apart from the heavy extra cost, experience with slow-closing valves proves that, in many cases when the conditions are really severe, the valve has been known to break down mechanically or become responsible for a fractured pipe. In other cases, the quantity of water lost during slow closing is either prohibitive or it is inconvenient to design the plant to accommodate the return water.

The check valve must, therefore, itself be capable of dealing with the rebounding water column.

A special elaborate plant on which exceedingly severe flow and return-flow conditions could be produced was installed in the hydraulic laboratory of Glenfield & Kennedy, Ltd., Kilmarnock, to investigate and develop the design of a recoil valve suitable for dealing with rapidly reversing water columns. Experiments were extended over a number of years and periodically the results were critically analyzed during the progress of the work.

It was found that the conventional type of check valve could be so improved by the application of scientific principles to every feature of the design that it could be completely transformed from a crude device to a highly responsive piece of apparatus eminently suitable for dealing with particularly mobile water columns.

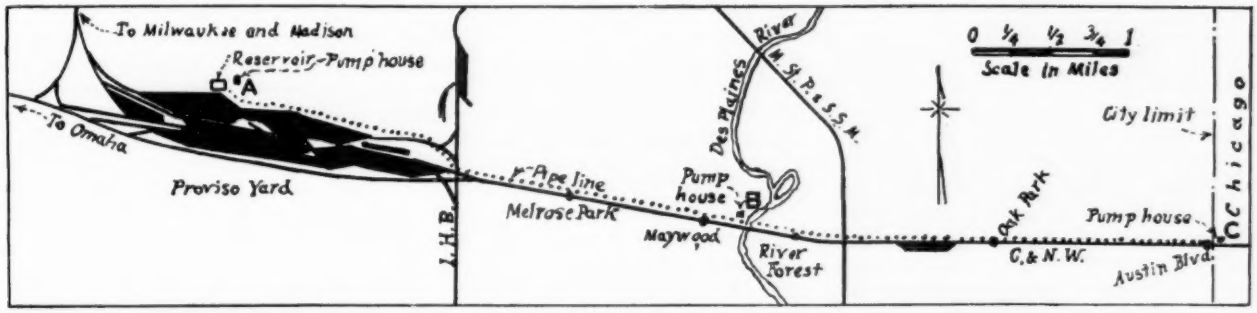

FIG. 1 MAP SHOWING LOCATION OF TRANSITE PIPE LINE FROM CITY MAIN TO RESERVOIR

Speed of Water-Hammer Pressure Wave in Transite Pipe

BY LEWIS H. KESSLER,[1] MADISON, WIS.

THE PURPOSE of this paper is to show a determination of the speed of travel of the pressure wave due to valve closure in a class-150, 14-in. cement-asbestos (Transite) pipe 34,237 ft long, serving the Proviso Freight Terminal of the Chicago and Northwestern Railway Company, and to extend these data to other sizes of Transite pipe by means of determinations of the modulus of elasticity.

At the request of the Railroad Water & Coal Handling Company of Chicago, Illinois (contractors), tests were made on February 9, 1937, on this pipe line, a plan of which is shown in Fig. 1. Water is metered and discharged from Chicago city mains through a float-control valve into an open 3000-gal tank in the pumping station at Austin Boulevard, Oak Park, Illinois. The pump suction pipe connected to the tank is at elevation 47.0 ft. This is considerably above the discharge at the city mains and the layout eliminates a possible cross connection. From the pump suction and discharge piping the line rises to a maximum elevation of 66.0 ft and then drops to a minimum of 44.0 ft at the Des Plaines River crossing near Vale, the booster pumping station (*B*) of Fig. 1. Twenty summits and sags occur between these pumping stations because the line on the right of way has its profile broken by passing above subways.

From elevation 44.0 at the Vale booster station, the line rises to elevation 66.0 at the motor-operated gate valve in the control house adjacent to the Proviso reservoir (see Fig. 2). The valve is normally operated by float control in the reservoir but in the tests described herein it was manually operated.

The pipe line was placed in service on January 6, 1937. However, presumably due to water-hammer pressure caused by closure of the motor-driven gate, leaks developed at several joints in the line. A 5-in. Snow Company flat-disk spring-loaded relief valve was installed on an 8-in. saddle and riser directly upstream from the valve. This was the situation when the writer and assistants were engaged to conduct tests to determine the adequacy of the relief valve in reducing water hammer.

The February tests indicated that the relief valve was lowering the pressure to safe limits, and a report was rendered on this basis to the contractors. The writer suggested that since little reported information was available on the characteristics and behavior of the pressure wave in Transite pressure pipe, this pipe line might be used to study the speed of advance of the wave front. The management of the railroad would not permit tests to be made without the relief valve because of the necessity for an uninterrupted water service. Service had been disrupted previous to the installation of the relief valve, and the railroad did not want to go through this experience again. However, the writer was permitted to make tests with the relief valve operating and to

Contributed by the Hydraulic Division, and presented at the Second Water-Hammer Symposium in cooperation with the American Society of Civil Engineers and the American Water Works Association, at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., December 6–10, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until February 10, 1939, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

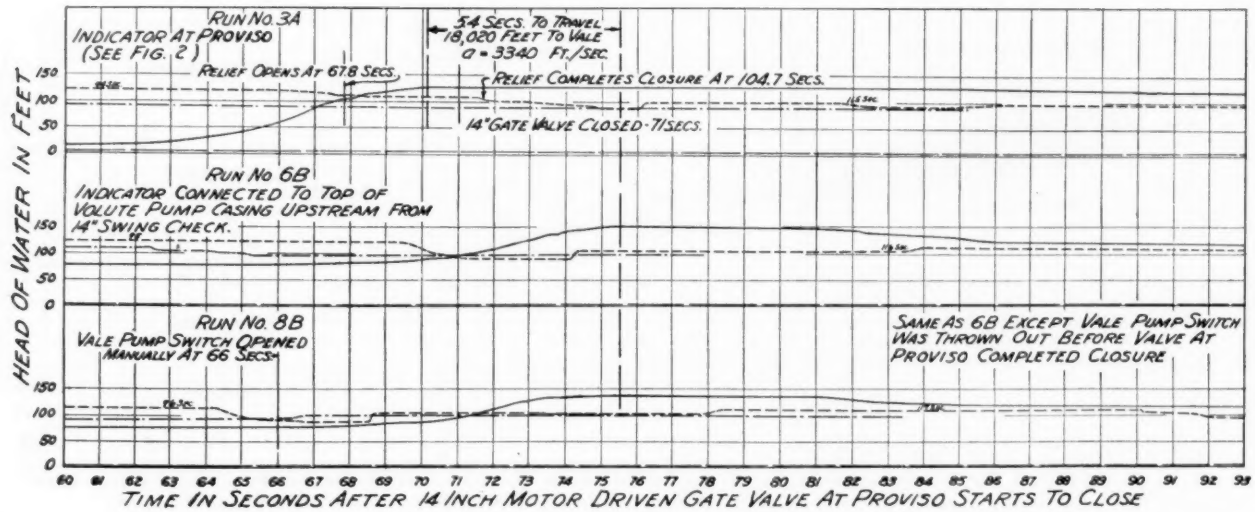

FIG. 3 TESTS OF AUGUST 27, 1937. PRESSURE-TIME DIAGRAMS ON 14-IN. TRANSITE CLASS 150 PRESSURE PIPE USED AS A PUMP-DISCHARGE MAIN

(Cards indicate advance of water-hammer pressure wave front from Proviso to booster pump at Vale, with 5-in. flat-disk-type spring-loaded relief valve operating at Proviso. Instant gate closure, V_0 = 3.38 fps, V_r = 2.16 fps.)

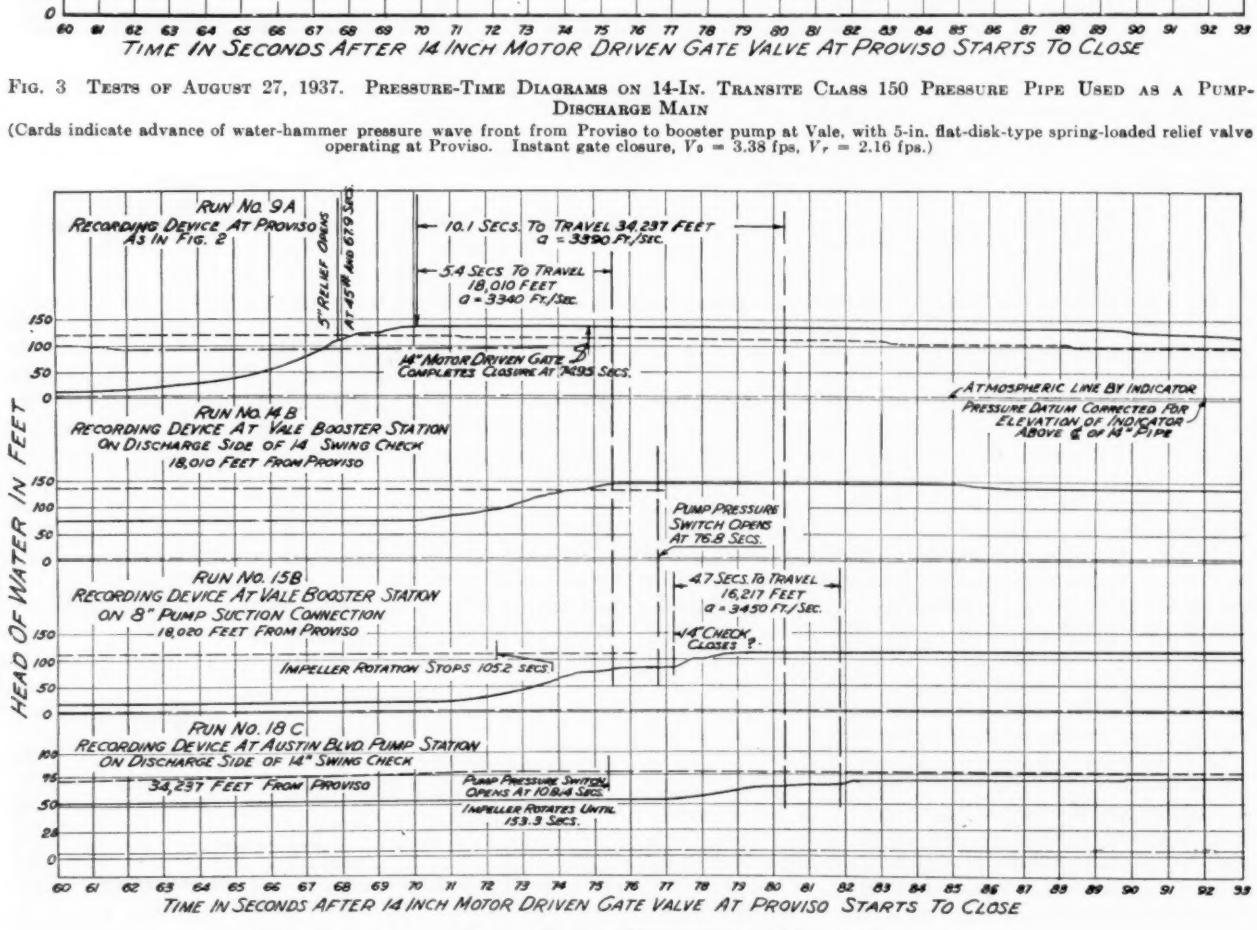

FIG. 4 TESTS OF NOVEMBER 14, 1937

measure the rate of travel of the pressure wave under operating conditions. These tests were made on August 27, 1937, and check tests were made on November 13 and 14.

Eight measurements of discharge were made by several observers using two 8-in. Neptune meters. The float control at the surge tank is sensitive and pump operation in the Austin Station causes no appreciable fluctuation in water level in the surge tank. Long-time observations showed the discharge to be fairly constant at 3.570 cfs or 1600 gpm. This result was checked against the head-discharge curves of the 6-L-1 Worthington centrifugal pumps. Incidentally a hydraulic-grade-line study using a coefficient of friction in the Hazen-Williams formula of C = 140, as suggested by the Johns-Manville Company, again checked the measured rate of discharge of 3.570 cfs. This discharge was reasonably constant for all tests.

There were available three possible methods of investigating the speed of the pressure wave: 1 By pressure-time diagrams showing the advance of the wave front as it progressed 18,020 ft from Proviso to the Vale booster station and 16,217 ft from Vale to Austin Boulevard Station.

2 By computation based on the hydraulic behavior of the relief valve with discharge characteristics as shown by tests in the hydraulic laboratory at the University of Wisconsin.

3 By comparing with field data the computed theoretical maximum pressure rise without the relief valve in operation.

The results obtained by these methods could be verified by tests to determine the modulus of elasticity of the cement-asbestos pipe. These tests were conducted in the materials-testing laboratory of the University of Wisconsin.

Advance of the Wave Front

Pressure-time diagrams were obtained by two methods. A Maihak high-speed engine indicator with chronomatic drum was used in the February tests. However, for this particular problem, it appeared that another type as used in the hydraulic laboratory at the University was more suitable. In the August and November tests a Crosby Diesel-engine indicator recorded the pressure history on a 24 × 4-in. rectangular card clamped to an aluminum drum which rotated at a uniform speed. The time history was recorded on the same card above the pressure trace by use of an electrically operated timer. In addition to the pressure-time cards, stop-watch and Bourdon test-gage readings were taken by five assistant observers.

In the tests of August 27, pressure-time cards were taken on the riser of the relief valve located 1 ft upstream from the motor-driven gate valve at Proviso. See Fig. 2. The recording device was taken to Vale booster station and four cards were taken on the top of the volute casing of the pump. In the tests of November 13 and 14 the location at Proviso, *A*, was used for four runs. Previous to these tests the railroad officials had the pipe line tapped on both sides of the check valve at Vale, *B*, and on the pump suction. A tap was also placed at Austin Boulevard Station, *C*, on the discharge side of the check valve. These additional connections to the pipe for pressure transmission permitted studies to be made of the advance of the wave front. All time was synchronized so that zero time was that time at which the motor-driven valve at Proviso began to close. The movement of the valve stem is uniform throughout the closure.

Figs. 3 and 4 are tracings of a few of the cards arranged to show the progress of the pressure wave caused by valve closure.

Table 1 gives the average values of measurements as determined in the August and November tests. Only one run, 13B, is not included since the card was damaged during the test. All time values shown in the table are from start of valve movement at Proviso to the maximum initial pressure rise at the respective stations.

Speed of Wave by Behavior of Relief Valve

The T. W. Snow Construction Company of Chicago loaned to the hydraulic laboratory a 5-in. relief valve and spring made to the same specification as the valve in use at Proviso. The relief valve was erected and tested on a setup practically identical with the Proviso layout and a similar spring setting and water pressures were used in order to obtain the coefficient of discharge of the valve for various ratios of lift to diameter. In the November tests at Proviso, the spring from the relief valve tested in the hydraulic laboratory was installed on the Proviso relief valve so as to eliminate a possible variable in spring behavior. Fig. 5 indicates the results obtained on the 5-in. relief valve, used in computations to determine speed of the pressure wave. The vertical lift of the relief valve was measured by means of a needle clamped to the valve stem. This needle recorded its vertical travel as a trace on a smoked glass clamped to the valve bonnet.

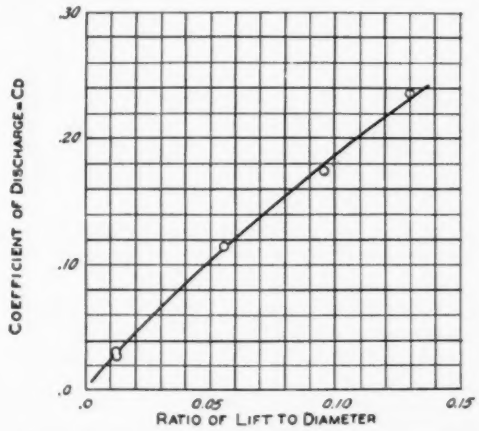

Fig. 5 Test Results on 5-In. Relief Valve at Hydraulic Laboratory of the University of Wisconsin

Indications were from data shown in Table 1 that the speed of propagation of the pressure wave was between 3340 and 3450 fps. Assuming the lower value of a, the time for one complete traverse of the acoustic wave $2L/a$ is 20.5 sec with L = 34,237 ft. From Table 2 it can be seen that the effective time of valve closure is between 15.25 and 16.4 sec. Instant closure occurs. The reason for the difference between the effective times of closure of the August and November tests is that the electrical control had been repaired during the interim between tests because some adjustments were necessary. In both cases the effective time of valve movement is less than 20.5 sec.

In this installation the fact that the relief valve opens and discharges water from the conduit means that the speed of the wave

[c] $T - t$ = effective time of valve movement

can be computed, providing the pressure rise and relief-valve characteristics and behavior are known.

The following nomenclature and the data in Table 2 are used in computing the speed of the wave.

NOMENCLATURE

- t = time from start of valve movement to beginning of pressure rise above H_0, sec
- T = total time of valve movement, sec
- H_0 = flow head or pressure head under flow conditions, 8.41 ft
- H = pressure head for surge conditions, ft
- h = increase in pressure head above H_0 or $H - H_0$, ft
- H_r = pressure head on orifice of relief valve, when discharging = H — elevation head of orifice = H — 8.17, ft. See Fig. 2
- Q_0 = discharge in 14-in. pipe for flow conditions, 3.57 cfs
- V_0 = velocity in 14-in. pipe for flow conditions, 3.380 fps
- Q_r = discharge through relief valve at head of H_r, cfs
- V_r = velocity in 14-in. pipe due to discharge through relief, fps
- A = actual area of 14-in. Transite pipe at Proviso = 1.059 sq ft
- A_r = area of 5.09-in-diam relief-valve orifice = 0.1415 sq ft
- c_d = coefficient of discharge of relief valve for respective ratio of lift to diameter. See Fig. 5
- a = speed of water-hammer pressure wave, fps
- g = acceleration due to gravity, 32.2 ft per sec²
- E = modulus of elasticity of Transite pipe, lb per sq in.

The discharge through the relief orifice and the velocity V_r may be expressed as

$$Q_r = c_d A_r \sqrt{(2gH_r)} \quad [1]$$

$$V_r = Q_r/A \quad [2]$$

Therefore the velocity which has been destroyed by the valve closure is equal to the difference between the initial velocity under steady conditions and V_r or

$$V_0 - V_r = \Delta V$$

According to the Joukowsky formula the pressure rise under instantaneous conditions is directly proportional to the decrement in velocity.

$$h = \frac{a}{g}\Delta V \text{ or } a = \frac{h}{\Delta V}g \quad [3]$$

The values of a computed by the Equation [3] are indicated in Table 2.

At this point it will be observed that the values of a shown in Tables 1 and 2 vary from 3210 to 3450 fps with a median of about 3335 fps. Using the equation shown in Fig. 6, values of E are obtained for all the values of a determined by hydraulic measurement, as shown in Table 3.

TABLE 3

	a, fps	E, lb per sq in.
From Table 1	3345	3425000
	3355	3500000
	3380	3600000
	3450	3900000
From Table 2	3210	3000000
	3360	3500000
Median	3335	3375000

With the assistance of Professor Wendt of the department of mechanics, University of Wisconsin, tests were conducted on 4-in. 150-lb standard Transite pipe. Compression tests were made on both wet and dry specimens and a cross-bending test was made. Later upon receipt of data from the Johns-Manville Company which indicated a reduction in the modulus of elasticity with increase in diameter, it was decided to test a section of the 14-in. 150-lb pipe installed at Proviso. In addition the Johns-Manville Company kindly sent to the laboratory a length of new standard 14-in. 150-lb pipe with Simplex couplings. Compression, tension, and cross-bending tests were run on these specimens and final results of tests are shown in Table 4. It will be observed that one test was made to determine the circumferential modulus of elasticity. This modulus agreed for all practical purposes with the moduli obtained by standard methods of testing.

Having presented the values of E as obtained by both hydraulics and mechanics of materials, it appears that a value of E of 3,400,000 lb per sq in. should be used for the class-150 lb Transite pipe of the Proviso tests. The value of a computed with this modulus is 3340 fps and this value is used in computing the theoretical maximum pressure rise that occurred before installation of the relief valve.

SPEED OF WAVE BY COMPUTED THEORETICAL PRESSURE RISE WITHOUT RELIEF VALVE

As mentioned in connection with Table 2, the effective time of the valve movement is less than one interval of $2L/a$ because only the last 22 per cent of the valve movement causes a pressure rise in the pipe line. Hence, without the relief valve, the entire initial velocity V_0 must have been destroyed by valve closure. The excess pressure head, due to water hammer, that must have occurred at Proviso was, therefore, $h = V_0 a/g$. With a taken as 3340 fps and V_0 as 3.380 fps, h = 350.5 ft. When gage elevation of 4.33 ft (see Fig. 2) is considered then H = 354.6 ft or 153.6 lb per sq in.

This figure is substantiated by Henry Westenfeldt, operator of the control-gate house and the water-treating plant at Proviso, who states that the pressure rise previous to the installation of the relief valve, as measured by him on the Bourdon gage, was more than 150 lb per sq in., which was the limit of the gage. The author calibrated this gage and found it accurate. This point is mentioned as another confirmation of the fact that the speed of the wave was more than 3260 fps which is the value corresponding to a gage reading of 150 lb per sq in.

Conclusions

Until further information is available, the author suggests that the value of the modulus of elasticity for computing the speed of propagation of the water-hammer pressure wave in Transite pipe be taken as 3,400,000 lb per sq in. A value of 3,400,000 can definitely be taken for the 4-in. and 14-in. sizes and it is believed there is no question but that the same value holds for all sizes of class-150 Transite pipe likely to be used in water service. As has been mentioned before, this value of 3,400,000 corresponds to a speed of the pressure wave of 3340 ft per sec in a 14-in. pipe. Fig. 6 shows the speed of wave computed for class-150 lb Transite pipe of from 4 to 24 in. in diameter, inclusive, using this value of E.

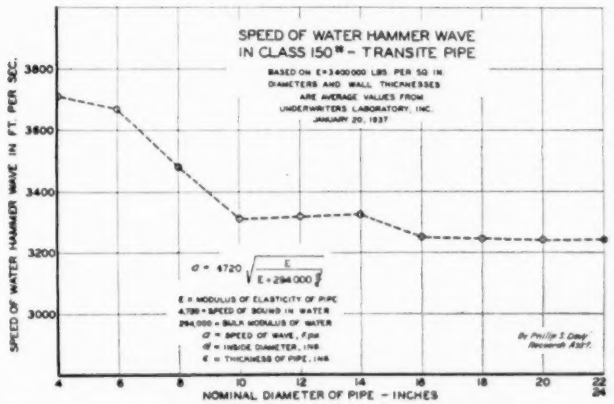

Fig. 6 Speed of Water-Hammer Wave in Class-150 lb Transite Pipe

Acknowledgment

The writer wishes to acknowledge the cooperation and assistance, in performing the test, of R. E. Coughlan, supervisor of water supply, H. W. Jensen, assistant division engineer, and H. Westenfeldt, water-treatment foreman, all of the C.&N.W. Ry. Co.; C. O. Congdon, vice-president, Railroad Water & Coal Handling Co., Chicago; Barton S. Snow, president, T. W. Snow Construction Co., Chicago; Merrill B. Gamet, instructor in civil engineering, Northwestern University; Gerard A. Rohlich, instructor in hydraulics, Carnegie Institute of Technology; E. R. Dodge, instructor in hydraulic engineering, University of Wisconsin; R. F. Zwettler, thesis student. Arrangements for tests were made through F. C. Huffman, assistant chief engineer of C.&N.W.Ry. Co., who also provided a profile of the pipe line and pump-discharge characteristic curves.

Prof. K. F. Wendt, department of mechanics, University of Wisconsin postponed some of his research work in order to supervise all tests on the cement-asbestos pipes. Prof. J. G. Woodburn, chief of department of hydraulic and sanitary engineering, University of Wisconsin, made the arrangements for financing this research project and gave valuable suggestions for the preparation of the paper. The men on W.P.A. research project no. 6605 in the hydraulic laboratory on water-hammer investigations assisted in the preparations for the field tests.

The Johns-Manville Company through their engineers, A. J. Maahs, E. F. Ries, and R. T. Walker provided all pipe required for test purposes and cooperated in every way possible.

The writer is especially indebted to Philip S. Davy graduate research assistant in hydraulics and sanitary engineering, University of Wisconsin, for his assistance in the analysis of test results and preparation of this paper.

Cavitation Characteristics of Centrifugal Pumps Described by Similarity Considerations

By G. F. WISLICENUS,[1] R. M. WATSON,[2] AND I. J. KARASSIK,[3] HARRISON, N. J.

Similarity considerations of hydraulic pumps and turbines can be obtained by comparing the known hydraulic performance of a given machine with the performance of other machines having geometrically similar waterways. The paper describes the application of this theory to the cavitation performance of centrifugal pumps and related machinery, and also introduces a characteristic parameter which, concerning cavitation performance, has properties similar to the specific speed with respect to other performance characteristics of such machines.

Introduction

THE WORK described in this paper had its origin at the Hydraulic Laboratory of the Metropolitan Water District of Southern California and the Pasadena Laboratory of the California Institute of Technology. The initial problem, concerning the evaluation of cavitation-test results on centrifugal pumps, was to work out a method of coordinating the results obtained at different speeds on the same pump. It was solved by applying the Thoma-Moody[4] similarity law for the cavitation performance of hydraulic pumps and turbines. This law essentially states that for changes in speed and proportional changes in the rate of flow through the machine, the absolute suction head above the vapor pressure of the fluid must be changed proportionally to the square of the speed of rotation, or to the first power of the total head of the machine, in order to maintain similarity of the cavitation phenomena in the machine. It can be expressed by means of the Thoma parameter

$$\sigma = \frac{H_{sv}}{H} = \frac{\text{Suction head above the vapor pressure of the fluid}}{\text{Total head of the machine}} \quad \ldots\ldots [1]$$

In other words, the cavitation behavior of a pump or turbine, relative to its normal behavior, will be the same if the Thoma parameter σ is held constant while speed and capacity are changed proportionally to each other. The law, as applied to centrifugal pumps, was verified at the Pasadena Laboratory with an unusual degree of accuracy. Fig. 1 shows the results of one experiment in which the test points obtained at different speeds of rotation practically all fall on one curve. Using the same results would form three widely separated curves if the drop in efficiency had been plotted against the suction head instead of the Thoma parameter. But the Thoma parameter cannot give any indications as to the influence of changes in the specific speed on the cavitation performance.

The concepts presented in this paper are but extensions of the fundamental ideas which have already been introduced by Thoma and Moody and which, concerning centrifugal pumps, were checked experimentally at the Pasadena Laboratory. Upon the suggestion of Professor Moody, the authors are also including in their derivations those of the Thoma parameter

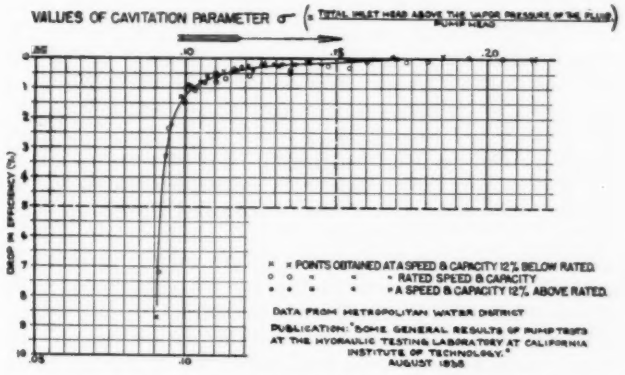

FIG. 1 TYPICAL RELATION BETWEEN INLET HEAD AND EFFICIENCY

and of the physical concepts underlying this whole field of investigation, thereby giving a more complete presentation of all questions involved.

Definitions

Our present knowledge of centrifugal pumps and related machines makes it necessary to base most considerations about their hydraulic behavior directly on test results. This means that in this field of engineering the most common and reliable method of evaluating the performance of any machine is to use the results obtained from tests on another machine of similar design and operating characteristics. This extension of test results, meaning application of conclusions to pumps and to operating conditions which differ in some way or another from the particular pumps and/or operating conditions for which test results are available, is generally made for some performance characteristics, such as capacity and head, by means of concepts like "unit speed," "unit capacity," and "specific speed." The purpose in the use of these concepts is to make test results independent of the particular size and speed of the test machine

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

so that they may be applied to similar machines of different sizes and/or different speeds.

Such extensions, however, are not yet in general use for cavitation tests, particularly in connection with centrifugal or propeller-type pumps. Therefore, the purpose of this paper is to introduce concepts similar to specific speed but applicable to cavitation characteristics only. These concepts will permit reliable extensions of cavitation-test results from one pump to similar pumps of different sizes and/or different operating conditions. It should be understood that, on the other hand, no attempt is being made in this paper to predetermine by theoretical means the cavitation behavior of pumps from their design features such as the cross sections of waterways and the like.

In order to avoid misunderstanding, definitions are given of the most important terms used in this paper. These definitions, however, are not intended to be complete, but merely sufficient for the present purpose.

1 *Cavitation.* Cavitation in this paper refers to that well-known behavior of centrifugal pumps which is caused when somewhere inside the pump the pressure drops to the vapor pressure of the fluid so that vapor pockets are formed in the stream, as a result of which the performance of the pump is materially impaired. The erosion which is often found in connection with prolonged cavitation is not considered.

2 *Suction or Inlet Head.* For investigations on cavitation phenomena it is most convenient to deal with the so-called "Net Suction Head," namely, the total suction head above the vapor pressure of the fluid pumped (including the velocity head in the suction pipe). The suction head thus defined will be designated by H_{sv}. The reason for this definition is that cavitation must be expected to commence when somewhere in the pump the static pressure has dropped to the vapor pressure of the fluid so that vaporization begins. This definition of the suction head automatically takes care of the very pronounced influence of temperature and vapor-pressure variations. Hence for most practical cases we need not include the temperature, vapor pressure, or nature of the fluid in cavitation formulas or charts, except in so far as these factors have an effect on the type of pump used.

Furthermore it is assumed that the net suction head H_{sv} is measured vertically from the shaft center line of horizontal-shaft impellers and from a suitably chosen central plane of vertical-shaft impellers. This definition of course is not rigorous because it is actually the suction head at the point of lowest pressure in the pump which should be used. Since the precise location of this point is not known, it would, strictly speaking, be necessary to adhere to Froude's similarity relation (fluid heads proportional to linear dimensions of the machine) whenever the vertical dimensions of the inlet passages become appreciable in comparison with the net suction head. This refinement, however, will not be considered in this paper.

3 *Cavitation Limit.* The cavitation limit of a pump may be defined satisfactorily in several ways, but the most important two are based on:

(*a*) The upper limit of capacity for a given net suction head and speed of rotation.

(*b*) The lower limit of the net suction head at a given capacity and speed of rotation.

The first is illustrated by Fig. 2 showing the conventional characteristic curves for two different inlet heads, while Fig. 3 illustrates the second by showing the pump head, or efficiency, plotted against the net inlet head for constant capacity and speed. It is clear that the curve shown in Fig. 3 corresponds to the σ curve shown in Fig. 1.

Both figures show examples by which the respective limits may be defined, but the following investigations will be valid regardless of the particular definition chosen, as long as the chosen definition is strictly complied with in comparing cavitation characteristics of various machines. The following investigations may be expected to maintain their validity to a reasonable degree, even where the pitting of the runner blades and not the influence of cavitation on the momentary performance of the machine is used as a criterion for the cavitation limit.

4 *Similarity or Similitude of Flow Conditions.* The flow conditions in geometrically similar pumps shall be called "similar" only if the machine and fluid velocities at similarly located points change from one machine to another by a factor which is constant throughout any two pumps compared. The velocity diagrams computed from the rate of flow, cross section of waterways, and from the peripheral velocities of the rotating parts are, therefore, similar at similarly located points. This definition, which follows standard engineering practice, does not take into account the changes which arise from the influence of viscosity and turbulence, i.e., from the changes in Reynolds' number, nor does it consider the fact that the roughness of the waterways generally does not remain geometrically similar with respect to the other dimensions of the waterways, so that the "relative

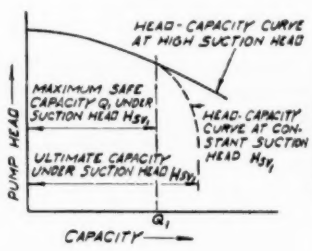

FIG. 2

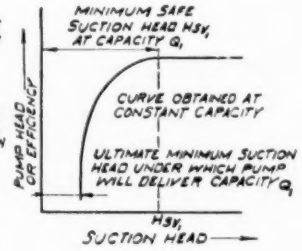

FIG. 3

roughness" is changed materially. The combined influence, however, of the changes in Reynolds' number and in the relative roughness is reasonably well known through test results with geometrically similar pumps of different sizes and/or different speeds, and it is to be expected that the influence of these factors on the cavitation behavior of a pump will be of the same order of magnitude as their influence on capacity, head or efficiency. This means that within the usual degree of approximation there is justification in neglecting the influence of changes in Reynolds' number and in the relative roughness on the cavitation performance of centrifugal pumps. While the validity of this approximation seems to be confirmed by practical experience, one should keep in mind that cavitation involves phenomena such as vaporization not present during normal pump operation, so that practical experience must be confirmed by more rigorous investigations.

Derivations

We are now ready to attack our initial problem, namely, that of extending given cavitation-test results to other pumps and/or other operating conditions.

The simplest form of such an extension is the well-known step from the performance of a model to the performance of the full-size pump, with the latter and the model operating under the same pump head. In this case the model and the full-size pump both will have to operate under the same net suction head, H_{sv}, in order to obtain the same conditions with respect to cavitation, i.e., either the same safety against cavitation or, if the pumps are cavitating, the same extent or influence of this phenomenon.

The characteristic of this simple step from the model to the full-size pump, both operating at absolutely the same head conditions, is that all machine and fluid velocities are equal to

each other at similarly located points in the two pumps, while all dimensions of the waterways are changed according to one fixed ratio.

The natural generalization of this method of extending given test results is to consider cases where, in addition to changing the waterway dimensions according to one ratio, all velocities at similarly located points are changed according to another fixed ratio. Flow conditions thus related have been defined previously as "similar," and it is in fact only under this condition of similarity of the flow conditions that simple and reliable conclusions can be drawn from the performance of one pump regarding the performance of geometrically similar pumps, or of the same pump under different operating conditions.

In order to include cavitation characteristics in such similarity considerations, it is expected that cavitation will commence when, somewhere in the pump, the static pressure has dropped to its natural lower limit, namely, the vapor pressure of the fluid in question. Under this condition the difference in total head between the suction pipe of a pump (corrected for elevation) and the point or region of the lowest pressure inside of the pump must be equal to the net suction head H_{sv}, as previously defined. However, in accordance with the given definition for similarity of flow conditions, all pressure or head differences inside of geometrically similar pumps will change proportionally to the square of the velocities as long as the flow conditions remain "similar." Since it is apparent that in any state of cavitation the net suction head H_{sv} actually exists as a head difference inside of the pump, the conclusion is that for similar flow conditions in similarly shaped waterways of centrifugal pumps the suction head above the vapor pressure (net suction head) is proportional to the square of the fluid velocities in these passages, i.e.

$$H_{sv} \text{ is proportional to } V^2, \text{ or } V \text{ is proportional to } \sqrt{H_{sv}} \quad [2]$$

where V may be any suitably chosen fluid velocity in the waterways of the pump.

This relation essentially expresses the Thoma-Moody law of similarity regarding cavitation conditions to which reference was made in the introduction. From this point on Thoma's method of extending given cavitation-test results is simply the following:

It is known that under similar flow conditions, as previously defined, the total head H of the machine is also proportional to the square of the fluid velocities. This means that according to relation [2] the total head H and the net suction head H_{sv} follow exactly the same law with respect to the velocities in the machine, i.e., H and H_{sv} are proportional to each other as long as the flow conditions are similar. For geometrically similar pumps, however, the flow conditions will be similar if the specific speeds are the same. Hence, if the Thoma parameter, $\sigma = H_{sv}/H$, and the specific speed of the pump are held constant, similarity is maintained with respect to the cavitation conditions, so that the influence of cavitation on the performance of the machine will remain the same. The relations

$$\sigma = \text{const} \quad \text{and} \quad N_s = \text{const} \quad [3]$$

therefore, express the desired condition under which cavitation-test results can be extended from one pump to a similar pump and/or similar operating conditions.

The last step in extending cavitation-test results is that from a given pump to another pump of a different specific speed. This problem is essentially the same as that of finding some theoretical background for calculating changes of σ as a function of the specific speed.

It should be understood that a rigorous solution of this problem does not seem to be within the reach of present-day fluid mechanics. However, useful approximations for such a solution are possible, and it is with such an approximation that the authors deal in this paper.

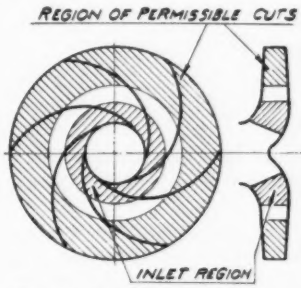

FIG. 4 LOW-SPECIFIC-SPEED IMPELLER

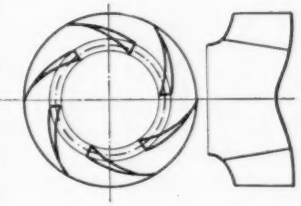

FIG. 5 HIGH-SPECIFIC-SPEED IMPELLER

As indicated in the introduction, the required relation between σ and the specific speed will be found by assuming that specific speed is changed by changing only the outside portions of the impeller, for instance, by cutting its outer diameter as shown in Fig. 4, leaving the suction passages of casing and impeller as well as capacity and speed of rotation unaltered. While it is true that the designer generally will not observe such a restriction on the design of the suction passages, the answer derived under this assumption will form the desired background for a theoretical relation between σ and N_s from which the effects of changes in the eye design can be measured and compared.

For the present the additional assumption is that changes in the outer waterways of the impeller, leaving speed and capacity unaltered, do not materially affect the flow conditions in the suction passages, i.e., in the region of lowest pressure where cavitation must be expected to commence. This assumption is quite accurate for impellers of the low-specific-speed type shown in Fig. 4, but is less accurate for high-specific-speed runners, such as shown in Fig. 5 because in this case it is no longer possible to consider suction and discharge passages separately from each other. For runners of specific speeds below 2000 (capacity through one eye in gpm) the assumption was confirmed experimentally at the Pasadena Laboratory.

It is clear that changes in the outer portions of the impeller, at the same capacity and speed of rotation, will primarily affect the pump head H (head produced by the pump) while, according to the authors' assumptions, the absolutely lowest pressure in the pump is not affected. Therefore, the net suction head H_{sv} which corresponds to a definite state of cavitation, will also remain the same. This means that such changes in the outer portions of the runner will influence the values of σ as well as of the specific speed N_s only by their influence on H. Hence, any relation between σ and N_s describing this particular form of change in the impeller must be such that resulting changes in the pump head H do not affect H_{sv}, while the speed of rotation N, and the capacity Q are held constant according to the definition of the change being considered. However, H_{sv}, N, and Q are, outside of H, the only remaining variables in σ and N_s, so that the above condition can be satisfied only if the pump head H cancels out of the desired relation between σ and N_s. This relation will therefore have to be of the form

$$\sigma = \text{const} \times N_s^{4/3} \quad [4]$$

or some power thereof. By substituting for σ and N_s their original expressions there is found

$$H_{sv} = \text{const} \times N^{4/3}Q^{2/3} \quad [5]$$

so that H no longer appears in the resulting equation

From the original assumptions and to the degree of their accuracy it follows that for this form of change in the specific speed, the constant in the last expressions cannot be a function of N_s or of H, but depends only on the suction qualities of the pump, particularly on the design of its inlet passages. For reasons of analogy with N_s this constant can be written in the form

$$\text{const}^{3/4} = S = \frac{N \times \sqrt{Q}}{H^{3/4}_{sv}} \quad [6]$$

which may be considered as a new form of cavitation parameter similar to σ but applicable in particular to the suction qualities of the inlet passages.

Naturally the assumption that changes in the discharge passages, and thereby in N_s, are without any influence on the flow conditions in the suction passages, cannot be strictly correct. Hence it is found that S actually will be a function of the specific speed so that, strictly speaking, the desired condition for the extension of cavitation-test results has now the form

$$S = \text{const} \quad \text{and} \quad N_s = \text{const} \quad [7]$$

which is essentially the same as the previously derived relation [3] where σ took the place of S. Therefore, from this theoretical point of view there exists no difference in physical significance between S and σ. From a practical point of view, however, such a difference does exist, because for moderate and low specific speeds, S will be very nearly independent of N_s. Hence for such specific speeds

$$S = \text{const} \quad [8]$$

is alone a sufficiently accurate condition for the desired extension of cavitation-test results from one pump to other pumps with similar inlet passages but of different specific speeds.

Returning later to the comparison between the parameter σ and the new parameter S, the authors now derive the latter by a straight similarity consideration quite similar to those leading to concepts, such as unit capacity, unit speed, and specific speed. This derivation, while offering nothing fundamentally new regarding the theoretical background of such quantities, will show that the validity of the new parameter S actually does not depend on the previous method of deriving the relation between σ and N_s, but has, in regard to cavitation characteristics, a significance very similar to the significance of the specific speed with respect to general operating conditions of centrifugal pumps.

This derivation starts again from the Thoma-Moody law on similarity of cavitation conditions in centrifugal pumps or turbines (see relation [2]).

For similarity considerations on cavitation or inlet characteristics it is natural to choose the eye diameter D_e of the impeller as the characteristic dimension of the waterways. The condition of similarity of the flow conditions demands that the fluid velocities V be proportional to the peripheral velocity of the eye of the impeller, which in turn is proportional to $D_e \times N$, where N is rpm.

Considering now a change in velocities and size from V_1, N_1, Q_1 (capacity), H_{sv1} and D_{e1} to a new combination V_2, N_2, Q_2, H_{sv2}, and D_{e2}, the following question is proposed: Which relation must be maintained between these operating conditions and dimensions in order to permit similar flow conditions in similarly shaped waterways of centrifugal pumps?

The condition of similarity of flow conditions demands that, according to relation [2]

$$\frac{V_1}{V_2} = \frac{D_{e1}N_1}{D_{e2}N_2} = \frac{\sqrt{H_{sv1}}}{\sqrt{H_{sv2}}} \quad [9]$$

and according to the usual condition of continuity in the waterways

$$\frac{Q_1}{Q_2} = \frac{D_e^2{}_1 V_1}{D_e^2{}_2 V_2} = \frac{D_e^2{}_1 \times D_{e1}N_1}{D_e^2{}_2 \times D_{e2}N_2} = \frac{D_e^2{}_1\sqrt{H_{sv1}}}{D_e^2{}_2\sqrt{H_{sv2}}} \quad [10]$$

From Equations [9] and [10] the condition for similar flow conditions may be written in the form

$$\frac{D_{e1}N_1}{\sqrt{H_{sv1}}} = \frac{D_{e2}N_2}{\sqrt{H_{sv2}}} = \text{const} \quad \text{and} \quad \frac{Q_1}{D_e^2{}_1\sqrt{H_{sv1}}} = \frac{Q_2}{D_e^2{}_2\sqrt{H_{sv2}}} = \text{const} \quad [11]$$

These two expressions, which may be designated by

$$S_n = \frac{ND_e}{\sqrt{H_{sv}}} \quad \text{and} \quad S_q = \frac{Q}{D_e^2\sqrt{H_{sv}}} \quad [11a]$$

correspond to the unit speed and unit capacity of centrifugal pumps, and are to be used in the same way for determining the scale ratio of similar inlet passages of two centrifugal pumps.

However, if it is desired to find the condition for similar flow with respect to the operation conditions only, i.e., without reference to the dimensions of the waterways, D_e must be eliminated from the Equations [11] or [11a]. From Equation [11a] is obtained by multiplication

$$S_n\sqrt{S_q} = \frac{N\sqrt{Q}}{H^{3/4}_{sv}} = S = \text{const} \quad [12]$$

This equation expresses the desired condition for similar flow conditions in similarly shaped inlet passages of centrifugal pumps under cavitation conditions. It is clear that the term "similar flow conditions" implies a similar extension of the field of cavitation (vaporization) in the pump. Hence the influence of cavitation on the performance characteristics, such as head or efficiency, will be the same for pumps with similar suction passages as long as Equation [12] is satisfied.

So far it has evidently been sufficient to extend the requirement of similarity of shape and flow conditions over the suction passages only, namely, from the suction pipe line to the point of lowest pressure in the pump. Similarity of shape and flow in the rest of the pump is required only to the extent in which this is necessary in order to maintain similarity in the suction passages. In other words, only those conditions in the pump, which can be expected to have a noticeable influence on the suction flow conditions, must be kept similar.

However, if the requirement of similarity over the whole pump is extended, then it is possible to eliminate the dimensions of the waterways from the expressions for S_n and S_q differently. In this case D_e is proportional to the impeller diameter D and therefore, ND_e is proportional to ND which is proportional to $\sqrt{H}$ (H = total pump head). Hence the condition S_n shown in Equation [11a] may be written in the form

$$\frac{\sqrt{H}}{\sqrt{H_{sv}}} = \text{const} \quad \text{or} \quad \frac{H_{sv}}{H} = \sigma = \text{const} \quad [13]$$

arriving thereby again at the well-known form of the Thoma parameter which was discussed before. The essential facts brought out by this second method of deriving the two cavitation parameters may be summed up as follows: Changes in the new parameter S necessitate corresponding changes in the suction flow conditions, while changes in the Thoma parameter σ do not necessarily require such changes but may be brought about by changing the discharge flow conditions only, e.g., by a change in the impeller diameter. For this reason the parameter σ will change as a function of the specific speed to the extent to which

the pump head changes with N_s, considering the other operating conditions as constant. The new parameter S on the other hand is influenced by changes in the specific speed but indirectly, i.e., only to the extent to which the inlet dimensions and flow conditions are influenced by changes in the discharge dimensions and flow conditions.

This leads to what is probably the most important practical difference between σ and S: For most comparisons of the cavitation behavior of centrifugal pumps of different specific speeds, it will be found that changes of S as a function of N_s only, are of a lower order of magnitude than its changes as a function of the design of the inlet passages. Hence it is generally sufficient to disregard the changes of S with respect to changes in N_s in comparison with its changes resulting from other variations in the design of the pump.

This is not true with respect to the σ parameter, where even for moderate changes in N_s the influence of the changes becomes equal to, or larger than, the influence of other changes in the design of the inlet passages. In other words changes of σ with respect to N_s must be considered generally as being at least of the same order of magnitude as changes of σ with respect to other design features and hence cannot be neglected.

Naturally, these two statements are true only if moderate changes in N_s are considered. For very large changes in N_s, which will affect the type of pump in question, the changes in the new parameter S with respect to N_s may be no longer negligible.

It should not be thought from the foregoing remarks that the authors wish to recommend replacing the Thoma parameter σ by the new parameter S in all cases. While it is true that for the comparison and prediction of cavitation characteristics of centrifugal pumps the parameter S seems to offer certain advantages over the parameter σ, the same thing is probably not true with respect to hydraulic turbines, where the total turbine head and the net suction head are more intimately related, so that a separate consideration of suction and discharge flow conditions may not offer a useful approximation. In connection with centrifugal pumps, the Thoma parameter σ will certainly be used in all cases where the enumerated advantages of the new parameter S do not come into play, as for instance in changing the speed of the same pump, or for comparisons between pumps of the same specific speed. In such cases the use of S would bring unnecessary numerical complications which are not present in connection with the numerically simpler parameter σ.

Since for these reasons the two parameters, σ and S, are likely to have parallel use in the same field of application, it will be necessary to give an analytic expression for the relation between the two parameters. This relation, which follows immediately from Equations [4] and [6], is

$$S = N_s \frac{1}{\sigma^{3/4}} \quad \text{or} \quad \sigma = \left(\frac{N_s}{S}\right)^{4/3} \qquad [14]$$

Finally it must be mentioned that for comparisons between single-suction and double-suction pumps, regarding their cavitation or inlet characteristics, the capacity of the double-suction pump should be divided by two when used in the specific speed and in the new parameter S. This merely means that only the rate of flow entering through one eye of the impeller is to be considered, which is natural for the desired comparison with single-suction pumps.

Examples and Applications

Using a numerical example it is assumed that a single-suction, single-stage pump, is tested at 1800 rpm, delivering satisfactorily 2100 gpm of cold water against a 215-ft pump head with a suction lift of 7 ft. The specific speed of this pump is $N_s = 1470$. For cold water, and at a moderate elevation above sea level the atmospheric pressure is equivalent to a column of water about 32 ft above its vapor pressure. The net suction head above the vapor pressure of the water, therefore, becomes

$$H_{sv} = 32 - 7 = 25 \text{ ft}$$

Now suppose it is desired to design a pump of the same specific speed, but running at 900 rpm and delivering 15,000 gpm against a 316-ft head.

Considering the first pump as a model of the second pump, it is possible to design the new pump from the first pump by "factoring," i.e., by changing all dimensions of the latter according to a constant factor. It is known that the new speed, capacity, and head conditions can be met by this procedure because the specific speeds are the same, and hence permit the use of geometrically similar pumps.

In this case, there is found the suction head necessary for operating the new pump against 316 ft from the suction head of the model while the latter was pumping against 215 ft by means of the previously discussed Thoma relation, Equations [3] and [13], so that the new suction head above the vapor pressure H_{sv2} is found as follows

$$\frac{H_{sv2}}{316} = \frac{25}{215}, \quad \text{or} \quad H_{sv2} = 36.7 \text{ ft}$$

Therefore, pumping cold water, the model pump as well as the full-size pump will have to work with a submergence of 36.7 — 32 = 4.7 ft in order to pump against 316 ft just as satisfactorily as the model has been pumping against 215 ft at 1800 rpm with a suction lift of 7 ft.

Of course, the scale factor to be used in "factoring" the full-size pump from its model can be found in a conventional way by means of a constant value of the "unit capacity" defined as

$$q_1 = \frac{Q_1}{D_1^2\sqrt{H_1}} = \frac{Q_2}{D_2^2\sqrt{H_2}} \qquad [15]$$

where Q is the capacity of the pump, D any suitably chosen linear dimension, usually the impeller diameter, H the total pump head and the subscripts 1 and 2 applying to the model and to the full-size pump, respectively. This definition is used in preference to the more common definition of the unit capacity $Q/\sqrt{H}$ because it is dimensionally more consistent. For this case, there is obtained from Equation [15]

$$\frac{D_2}{D_1} = 2.43$$

i.e., all waterway dimensions of the existing model have to be multiplied by 2.43 in order to obtain the corresponding dimensions of the new pump.

The next step would be to find what suction head would be required if the new pump were to be designed for 700 rpm instead of 900 rpm, still delivering 15,000 gpm against a head of 316 ft, i.e., if the specific speed were to be changed from 1470 to about 1142. As already stated, since a rigorous solution of this problem is not possible, a good approximation can be obtained by assuming that the inlet waterways of the pump are kept geometrically similar to those of the model, so that the change in the specific speed is brought about by a relative change of the outside diameter of the impeller (and of the discharge passages of the casing) with respect to the inlet dimensions. For this case it has been found that the new pump will work approximately under the same cavitation conditions as the model only if the value of S in Equation [12] is the same in both cases. In other words it is possible to "factor" all inlet waterway dimensions of the new pump from an existing pump with known cavitation

performance if S has for the new pump the same value as for the pump for which the cavitation behavior is empirically given.

In the present case it is found that for satisfactory operation of the "model"

$$S = \frac{1800\sqrt{2100}}{25^{3/4}} = 7360$$

but it is necessary to remember that the term "model" applies in this case to the inlet passages only, i.e., the previous model pump is no longer a model of the new pump as a whole.

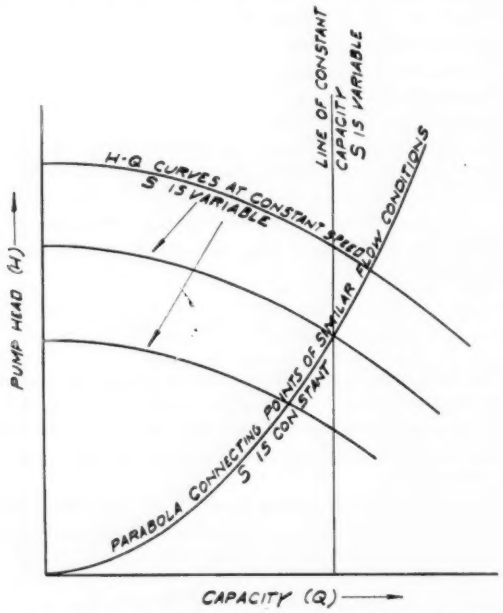

FIG. 6 BEHAVIOR OF S ON THE HEAD–CAPACITY DIAGRAM

If all suction passages of the new pump are designed by factoring from the previously considered model, the suction head necessary for an equally satisfactory operation of the new pump under the new operating conditions can be calculated from Equation [12] as follows

$$S = 7360 = \frac{700 \times \sqrt{15000}}{H_{sv2}^{3/4}} \quad \ldots\ldots\ldots [16]$$

where H_{sv2} is the required net suction head for the new pump. From Equation [16] it is found that $H_{sv2} = 26.5$ ft. This pump, pumping cold water will, therefore, operate satisfactorily with a suction lift of $32 - 26.5 = 5.5$ ft, compared with the submergence of 4.7 ft required for the pump of the same capacity and head running at 900 rpm.

The factor by which the inlet dimensions of the "model" have to be multiplied in order to obtain the corresponding inlet dimensions of the new pump may be calculated from Equation [11a].

Considering for instance the second part of this Equation it is found

$$\frac{D_{e2}}{D_{e1}} = \sqrt{\frac{Q_2}{Q_1} \times \frac{\sqrt{H_{sv1}}}{\sqrt{H_{sv2}}}} = \sqrt{\frac{15000\sqrt{25}}{2100\sqrt{26.5}}} = 2.64$$

which is the desired factor for the inlet dimensions. D_{e2} and D_{e1} are the eye diameters of the new pump and of the model, respectively. Evidently this procedure is exactly the same as that previously used in determining the scale factor for a new but completely similar design from the equality of the "unit capacities" of the two pumps in question, but here the suction head H_{sv} is used in place of the total pump head H. However, the factor thus determined does not apply at all to the discharge waterways of impeller or casing. Such a factor for the discharge waterways cannot be determined from the old model due to the change in specific speed. The outer portions of the new pump either have to be newly designed or factored from another pump of the proper specific speed. In this case it is left to the experience and general knowledge of the designer to decide how far the similarity with the model for the inlet dimensions has to be maintained and from which point on the discharge conditions become the controlling factor.

The approximations which were used in the previous examples (see Equation [12]), also permits the derivation of the following simple relations for pumps with geometrically similar inlet passages and flow conditions:

For N = const: H_{sv} is proportional to $Q^{3/2}$

For Q = const: H_{sv} is proportional to $N^{4/3}$

It is important to note that the changes of Q or N, considered here, must be accompanied by corresponding changes in the size

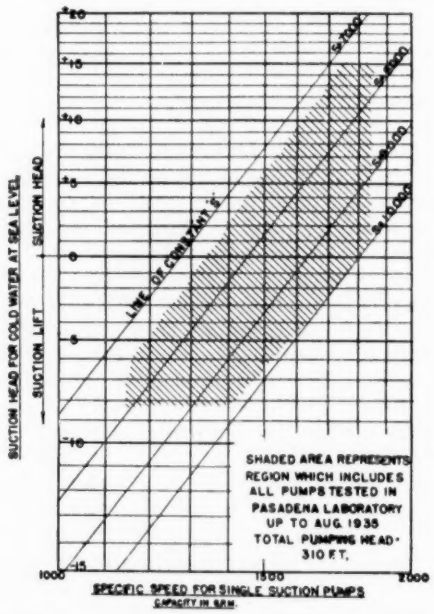

FIG. 7 DIAGRAM SHOWING RELATION BETWEEN SPECIFIC SPEED AND MINIMUM INLET HEAD FOR SATISFACTORY OPERATION
(Limit of satisfactory operation defined by 0.3 per cent drop in efficiency. See Figs. 1 and 3.)

of the pump in order to satisfy approximately the previous relations. These relations, therefore, generally cannot be true for changes of Q or N of one pump of definite size, because if either the capacity or the speed of a pump is changed without a corresponding change in the other, similarity cannot be maintained in the flow conditions in the pump. Therefore, changes in Q or N alone will cause (in the same pump) also changes in S, because the constant value of S can be obtained only if the flow conditions in the inlet passages are similar. This means that in general the value of S will vary along the conventional head-capacity curve of a pump (see Fig. 6). It will also vary if the capacity is held constant while the speed is changed. On the other hand, S will remain constant along any of the familiar parabolas in the head-capacity diagram along which the capacity is changed proportionally to the speed, thereby connecting points of similar flow conditions in the pump.

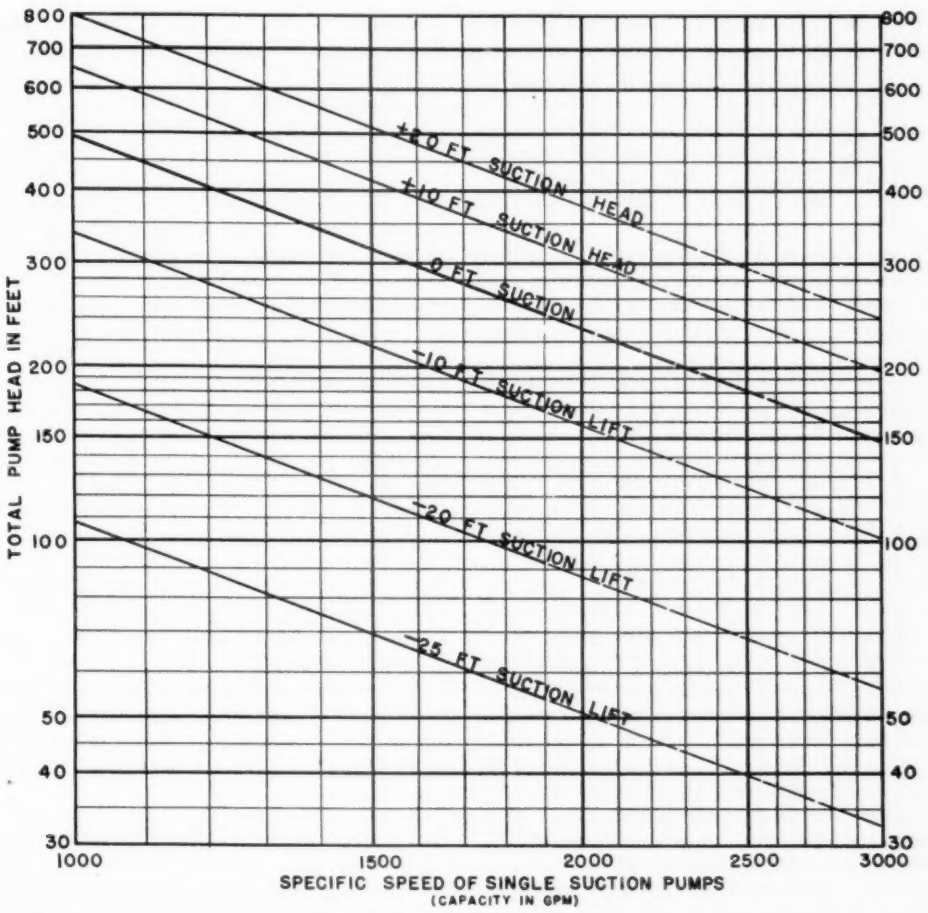

FIG. 8 FIELD OF EMPIRICAL POINTS IN THE S TO N_s DIAGRAM AND LINES REPRESENTING EXAMPLES OF CAVITATION LIMITS
(Empirical data taken from Pasadena Laboratory results and replotted from Fig. 7.)

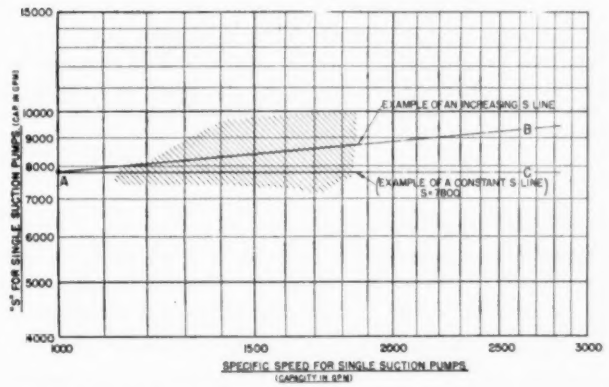

FIG. 9 EXAMPLE OF A CAVITATION LIMIT CHART FOR SINGLE-SUCTION, SINGLE-STAGE PUMPS PUMPING COLD WATER AT SEA LEVEL
(Computed on the basis of increasing S, line A-B in Fig. 8.)

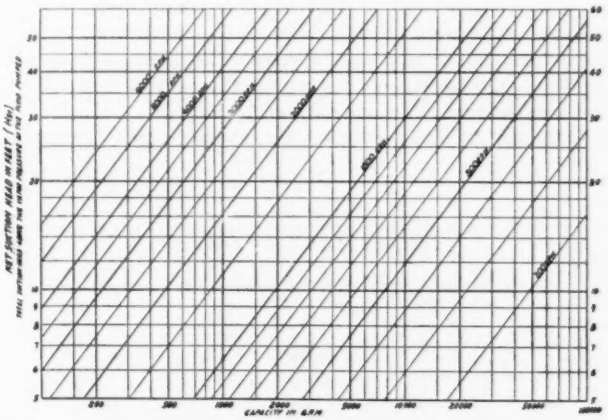

FIG. 10 SAMPLE CHART OF A CAVITATION LIMIT CHART FOR SINGLE-SUCTION, SINGLE-STAGE PUMPS
(Calculated on the basis of constant S = 7800.)

The question of the variations of S along the head-capacity curves as well as along the vertical lines of constant capacity is a most interesting and instructive one, but definitely exceeds the general scope of the present paper.

A rather startling verification of the practical usefulness of the new cavitation parameter S is shown in Fig. 7. In this figure the shaded area shows the range of net suction heads which is required for satisfactory operation for a rather wide range of specific speeds as well as pump designs.[5]

There has been plotted into this diagram lines of constant S values. The comparison shows an excellent agreement between the general slope of this area and the lines of constant S, showing

[5] "Some General Results of Pump Tests at the Hydraulic Testing Laboratory at the California Institute of Technology," compiled by the Metropolitan Water District of Southern California, August, 1935.

that the variation of the inlet heads with specific speed, as given by the law S = constant is generally verified by the pumps tested. It shows on the other hand that variations in design are reflected in corresponding variations in S regardless of the specific speed. In other words, according to these tests and within the range covered, S is practically independent of the specific speed, and dependent on other design features only. The upper limit of this comparison is at a specific speed of 1900 for single-suction pumps.

These test data also give an opportunity to illustrate how the new factor S can serve as a basis for comparing cavitation behaviors of a wide range of pumps, and for building up corresponding cavitation charts in a logically consistent manner.

Fig. 8 shows the region which is covered by the Pasadena Laboratory tests (see Fig. 7), but replotted so as to show S as a function of specific speed. Within this area lines can be chosen which would define cavitation limits for the pumps in question. The line A-B may be considered as an example of a limit chosen in this way. Using this line as a basis it then becomes possible to derive the cavitation limit chart shown in Fig. 9, which has been brought into the form of the familiar chart for double-suction pumps compiled by the Hydraulic Institute. The method of deriving the chart in Fig. 9 from the line A-B in Fig. 8 is based on Equations [13] and [14], which, in connection with line A-B, yield one definite value of H_{sv}/H for each value of N_s. The values of H_{sv}/H thus obtained, determine the points of intersection between the inclined lines of constant suction head and the vertical lines of constant N_s in Fig. 9.

Since in this example the chosen relation between S and N_s forms a straight line on the logarithmic diagram in Fig. 8, the resulting lines of constant suction head on the logarithmic chart in Fig. 9 also will be straight lines, requiring but two values of the ratio N_s/S for their complete determination. If, on the other hand, the S to N_s relation in Fig. 8 forms a general curve, then the constant-suction-head lines in Fig. 9 will also be curved and have to be determined more or less point by point.

In the special case, S = constant (line A-C in Fig. 8), a still more convenient form of the cavitation limit chart becomes possible. This form which is shown in Fig. 10, is really nothing but a nomographic solution of Equation [12], giving a value of S = 7800. The method of constructing this chart is conventional and does not require any special explanations.

Inasmuch as line A-C, on the average, falls below line A-B of Fig. 8, the resulting diagram in Fig. 10 yields more conservative values for the permissible inlet heads than those obtained from Fig. 9.

It should be noted that this paper, with all examples and charts, is concerned with specific speed and head limitations which are due only to the danger of cavitation (as heretofore defined), and does not deal with the additional restrictions imposed by mechanical and geometric limitations in the design of such machines. These restrictions will rule out the practical use of certain regions in the diagrams of Figs. 9 and 10, but intentionally have been disregarded in order not to confuse the principal issue of this paper.

Acknowledgments

The authors wish to thank A. H. Borchardt and M. Spillmann of the Worthington Pump and Machinery Corporation for encouraging these studies and for advocating their presentation before the Hydraulic Institute in December, 1937. Furthermore they are greatly indebted to Professor L. F. Moody of Princeton University whose repeated advice and criticism was an essential factor in arriving at the present form of presentation. They also wish to thank A. Hollander of the Byron-Jackson Company, R. M. Peabody of the Metropolitan Water District of Southern California, and others who have given their valuable comments. Finally they wish to emphasize the fact that this problem could not have been attacked with such confidence without the foundation formed by the previous work of Moody and Thoma, nor without the help of the experimental studies carried out at the laboratories of the Metropolitan Water District of Southern California and the California Institute of Technology.

Addendum

After the presentation of the preceding studies before the Hydraulic Institute, the authors learned from Professors L. Bergeron and P. Danel that the new cavitation parameter S had been used for some time in France, and was contained in a technical memorandum from Professor P. Bergeron to the Union d'Électricité, dated November 27, 1934. In this memorandum the new parameter has been given the very appropriate name "suction specific speed." The independent derivation and use of this parameter by the French engineers only confirms the authors' belief in its fundamental and useful nature.

Cooling-Tower Fundamentals and Their Application to Cooling Diesel and Gas Engines

By GUSTAVE J. BISCHOF,[1] NEW YORK, N. Y.

The size and cost of a cooling tower varies with certain conditions, some of which are inherent in the design, others are influenced by location and type of service, and still others may be fixed by the purchaser. In the last group are proper relation of water circulated and range of cooling for a given heat dissipation, the location of the cooling range in the temperature scale, and the relative size of the cooling tower compared to heat exchanger when both are operated as a unit. The purchaser is often unaware that reasonable modification of these factors may considerably reduce the size and cost of the cooling system.

Narrow cooling ranges with relatively high water circulations are conducive to optimum heat transfer, both from the standpoint of high temperature differences and high heat transfer coefficients in the heat exchanger.

The choice of the kind of engine-cooling system depends on many factors besides first cost, such as space requirements, operating cost, and trouble-free operation. The use of closed systems, while relatively high in first cost is often justified on the basis of yearly operating charges and low maintenance cost.

VARIOUS FORMS of equipment for evaporatively cooling water are so common that detailed descriptions are not needed in this paper. A brief outline, classified by nature of water surface and means of air movement, as shown in Table 1, is sufficient as a review. Some fundamental characteristics of evaporative water-cooling equipment are of importance to those responsible for its selection and use.

TABLE 1 CLASSIFICATION OF EVAPORATIVE COOLING EQUIPMENT

Name of equipment	Water distribution	Kind of water surface	Air movement
Spray pond	High-pressure spray nozzles	Drop	Lateral by prevailing wind
Spray-type atmospheric cooling tower	High-pressure spray nozzles	Drop	Lateral by wind and vertical by spray effect
Spray-type mechanical-draft cooling tower	High-pressure spray nozzles	Drop	Vertical counterflow by fans
Atmospheric deck cooling tower	Low-pressure distributors or troughs	Drop and wetted surface	Lateral by prevailing wind
Filled mechanical-draft cooling tower	Low-pressure distributors or troughs	Drop and wetted surface	Vertical counterflow by fans and baffled by filling
Combined spray-type tower and atmospheric-tube heat exchangers	High-pressure spray nozzles	Drop and wetted exchanger surface	Lateral by wind and vertical by spray effect
Evaporative surface	High-pressure spray nozzles	Drop and wetted exchanger surface	Vertical by fans

Evaporative cooling of water depends on these factors:

1 Large extent of water surface, either in drops or wetted surface.

2 The wet-bulb temperature, which is a function of the dry-bulb temperature and the relative humidity. The wet-bulb temperature is the absolute lowest limit to which water can be cooled evaporatively. In practice this temperature is only approached but never reached.

3 The quantity of air coming in contact with the water surface, its time of contact, and its relation to the quantity of water cooled, known as the air-water ratio.

4 The velocity with which the air scours the water surface.

In the spray types of equipment, nozzles operating at from 5 to 10 lb pressure finely break up the water to produce the desired drop surface, and the water remains in the air a comparatively short time in its unbroken fall to the bottom. Towers with filling or decks present a considerable wetted surface. In addition, the filling interrupts the fall of the water, thus increasing the time of contact of water and air. Table 2 shows the length of time for a drop of water to fall 30 ft with equispaced decks for interruptions. It appears that more than nine decks are not warranted by the gain in time of air contact and, remembering that decks offer resistance to lateral air flow induced by wind, it is not surprising to find that 30-ft-high atmospheric deck towers are standardized with about nine or ten decks. Filled towers are more expensive than spray types, but are more uniformly efficient over a large range of water-circulation rates. The water need not be finely broken up by pressure nozzles when filling is employed but only uniformly distributed over the top of the filling by means of low-pressure distributors or troughs. Spray nozzles dribble water without proper breakup when operating below designed capacity and hence, cooling falls off.

TABLE 2 VARIATION IN TIME FOR WATER TO FALL 30 FT WITH NUMBER OF DECKS

No. of decks	No. of falls	Total time of drop in air, sec.
0	1	1.36
1	2	1.92
4	5	3.05
9	10	4.30
14	15	5.25

In mechanical-draft towers, the filling is spaced more closely than in the atmospheric deck types, the height of filling being only from 12 to 15 ft out of a stack height of from 25 to 35 ft. The positive movement of air by forced- or induced-draft fans insures upward flow of air against filling and eliminator resistance quite independent of wind conditions. Spray types of mechanical-draft towers eliminate the considerable weight of filling and reduce the resistance against which the fans operate. On the other hand, they are subject to the limitations mentioned previously. Their proper field of application is where the ratio of

Presented at the Eleventh National Meeting of the Oil and Gas Power Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in Dallas, Tex, June 6–9, 1938.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until Feb. 10, 1939, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

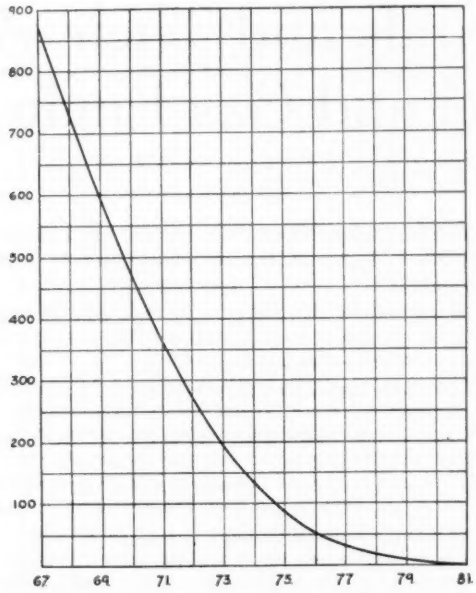

FIG. 1 HOURS DURING JUNE, JULY, AUGUST, AND SEPTEMBER THAT WET-BULB TEMPERATURES ARE EXCEEDED
(New York City observations.)

wet-bulb approach[1] to cooling range is rather high. Spray towers require from 20 to 40 per cent more stack area than filled mechanical types and also require higher air-water ratios. As the approach-to-range ratio decreases, indicating more severe cooling conditions, the size of spray-type towers compared with filled towers increases rapidly. This disparity in size and air-water ratio is accounted for by the short time the descending water is in contact with the counterflowing air, which prevents the air from taking up its full quota of heat and moisture. The discharged air has a considerably lower wet-bulb temperature than that of filled towers. Filling with its wetted surface acts very much like additional surface and baffled flow in a heat exchanger.

FACTORS INFLUENCING SIZE OF COOLING TOWERS

The cooling conditions in a specific situation which influence the size of a tower are: The design of the tower; the wet-bulb temperature of the location; the heat to be dissipated, which depends on the quantity of water circulated together with the cooling range; and the position of the cooling range on the temperature scale, which is fixed by the wet-bulb temperature and the approach of the off-tower water temperature to that wet-bulb temperature.

The wet-bulb temperature cannot be controlled. It suffices to say that the wet-bulb temperature to be chosen as the basis of tower selection should not be so high as to occur but a few hours per year, nor so low as to result in inadequate cooling over much of the hot season. The mean of the daily high wet-bulb temperatures of the hottest month of the year usually results in a suitable figure. A closer study of the wet-bulb conditions may be made from local weather-bureau data, which will indicate the probable frequency of each wet-bulb temperature during a year or a season. Fig. 1 shows the hours for June, July, August, and September in New York City that the wet-bulb temperatures shown are exceeded. It will be noted that 70 F wet bulb is exceeded about 475 hr out of a total of 2928 hr, over 16 per cent of the 4 months or $5^1/_2$ per cent of the year. A 75 F wet-bulb temperature is only exceeded about 88 hr in the 4 months, 3 per cent of the time or 1 per cent of the year, while 78 F wet bulb is exceeded only 15 hr in the 4 months, 0.5 per cent of the time or 0.17 per cent of the year. For most purposes 75 F wet bulb in this locality would be amply high, as it would be more economical to use city water to supplement the cooling tower for the remaining few hours or to operate at slightly higher temperatures, rather than to invest in excess tower size.

The design of the tower rests largely with the manufacturer and is, except as discussed before, beyond the scope of this paper. The choice of water quantities to be cooled and the cooling range to meet required heat dissipation, together with its position in the temperature scale is, however, subject to considerable choice on the part of the purchaser. Extensive experience in the cooling-tower field indicates to the writer that the purchaser is often unaware that modification of these factors may reduce the size of cooling tower considerably. These modifications depend to some extent on the requirements of the equipment which the tower serves, especially so in the case of condensers and heat exchangers. In general a larger tower calls for a smaller heat exchanger and vice versa, so that the selection of both tower and heat exchanger should be studied as a combined unit to obtain greatest economy. It therefore seems desirable to attempt an evaluation of the factors, aside from design, which influence cooling-tower size, namely: (1) Water circulation, (2) wet-bulb temperature, (3) approach of off-tower water temperature to wet-bulb temperature, (4) cooling range or difference between on- and off-tower water temperatures.

Fig. 2 shows the effect on mechanical-draft-tower size, i.e., the horizontal projected area inside of the stack, of variations in the amount of water circulated, wet-bulb temperature, approach to wet-bulb temperature, and cooling range. Each curve shows the influence of but one variant when others are kept constant. The horizontal scale gives factors for tower sizes and unity factor has been assigned to a 20 F cooling range, a 10 F approach to the wet-bulb temperature, and a wet-bulb temperature of 70 F. By assigning a suitable constant to convert area factors into square feet and developing a quantity-of-water-circulation scale in gallons per minute, all to conform with a specific tower design, this set of curves could be used to obtain the correct size of a mechanical-draft tower of such a design to meet any

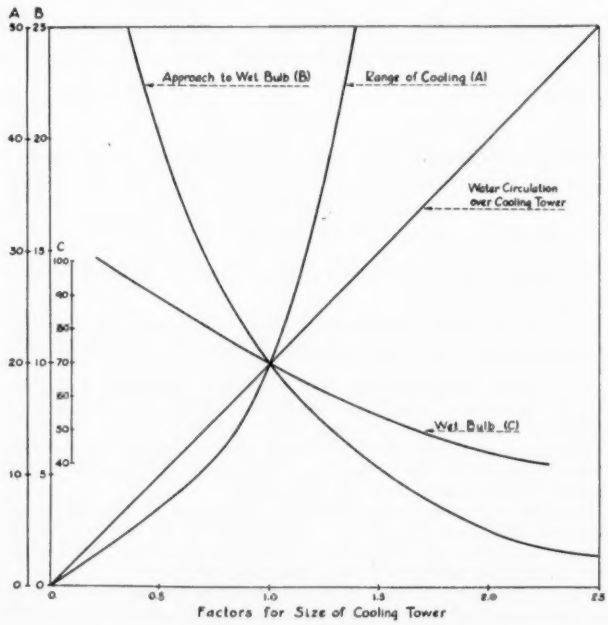

FIG. 2 EFFECT OF VARIANTS ON SIZE OF COOLING TOWER

[1] The wet-bulb approach is the difference between the temperature of the cooled water leaving the tower and the wet-bulb temperature.

conditions. The size of the tower is equal to the product of the four size factors times a constant.

For the present purpose, the curves are useful however, in showing how the size of the tower varies with the cooling conditions to be met. It strikingly illustrates how the purchaser can, by a wise choice of such cooling conditions as lie within his power of modification, obtain a reasonably sized cooling tower to give complete satisfaction at a reasonable price.

Analysis of each curve separately shows that:

1 The size of a cooling tower will be in direct proportion to the quantity of water circulated and cooled.

2 For equally close approaches to wet-bulb temperature, a low wet-bulb temperature requires a larger tower. The percentage of increase in tower size increases as the wet-bulb temperature falls.

3 For equal cooling ranges, the closer the approach of the temperature of the off-tower water to the wet-bulb temperature, the larger is the necessary tower size. Close approaches call for disproportionately large tower sizes.

4 Greater ranges of cooling, i.e., greater difference between on- and off-tower water temperatures, do not require proportionately larger towers. Hence it is more economical, for a given heat dissipation, to raise the on-tower water temperature and decrease the quantity of water circulated.

The curves of Fig. 2 are based for convenience on mechanical-draft towers. A similar set with but slight modification could be drawn up for an atmospheric tower which would have the same general characteristics but with the additional variant of wind velocity. In general all that has been said of variants in a forced-draft tower are equally true of an atmospheric tower.

Where water is scarce, or of such quality that treatment becomes imperative, the quantity of make-up water required is important. Water lost by evaporation is a direct function of the heat dissipated and is roughly equal to one pound for every 1000 Btu. To this amount must be added a constant driftage loss which depends upon the water circulation, the kind of equipment, and its design. In general terms and under average wind conditions a spray pond loses from 5 to 5 per cent of its circulation, an atmospheric tower from 1 to 1.5 per cent, and a mechanical-draft tower with proper eliminator system from 0.2 to 0.5 per cent.

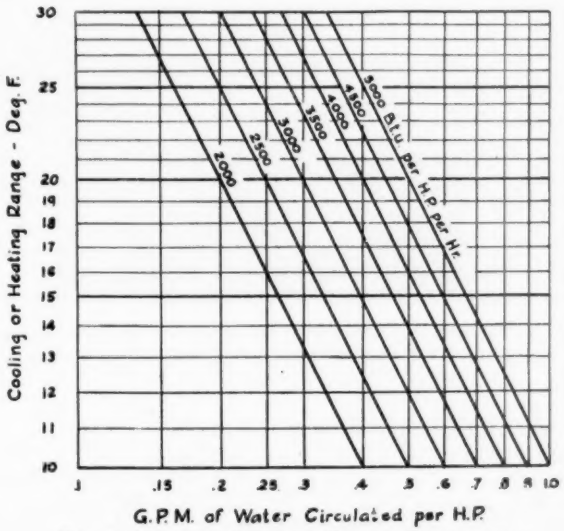

FIG. 3 RELATION BETWEEN COOLING RANGE AND CIRCULATION

(Problem: A Diesel engine of 1500 hp is to be cooled by removal of 3000 Btu per hp per hr. If the water is to be cooled through a 20-F range, how much should be circulated?

Solution: Trace horizontal line from 20 F to intersection with diagonal line of 3000 Btu per hp per hr. Drop vertically from intersection and read 0.3 gpm per hp. Then for 1500 hp, 1500 × 0.3 = 450 gpm.)

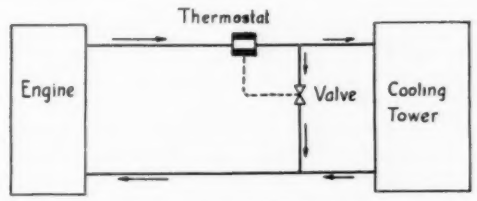

FIG. 4 THERMOSTATIC BY-PASS CONTROL

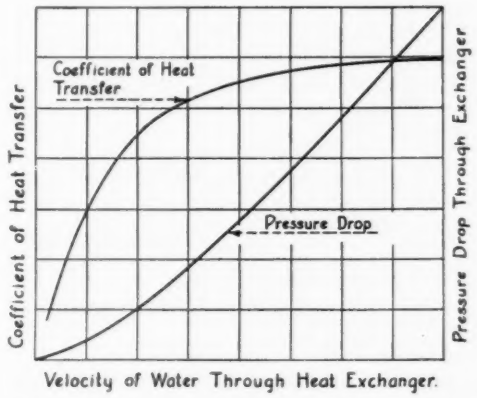

FIG. 5 VARIATION OF COEFFICIENT OF HEAT TRANSFER AND PRESSURE DROP WITH VELOCITY IN HEAT EXCHANGERS

APPLICATIONS TO DIESEL- AND GAS-ENGINE COOLING

Satisfactory oil- and gas-engine cooling is recognized as necessary for efficient operating and low maintenance costs. Determination of the proper amount of heat dissipation is the first consideration. Recent advances in engine design have enabled more of the heat input to be converted to energy at the crankshaft, thereby diminishing the heat lost to cooling water. Engine efficiencies have steadily risen from 28 to 39 per cent. A recent questionnaire sent to leading American Diesel- and gas-engine manufacturers disclosed that the heat to be dissipated by the cooling water varied from 1300 to 3500 Btu for Diesel engines and for gas engines from 3800 to 5400 Btu per bhp per hr. The figures depend upon design and whether or not exhaust manifolds and pistons are cooled. With such wide variations generalizations are dangerous but in the great majority of cases values for Diesel engines were between 2500 and 3000 Btu, while for gas engines they ranged from 4000 to 5000 Btu per bhp per hr.

A convenient chart for establishing circulation in accordance with cooling range and vice versa, when once the heat to be dissipated by the cooling water per horsepower per hour is determined is shown in Fig. 3. In general, ranges should be kept low, 12 to 20 F, and circulation of jacket water high so as to reduce thermal stress and secure turbulent circulation without dead pockets for steam formation and scale deposit. Partial recirculation is often advisable with thermostatic control, keeping off-engine water temperatures uniform without changing jacket-water circulation. This is done by means of by-passing the cooling equipment as illustrated diagrammatically in Fig. 4.

In recent years there has been a decided trend to the closed system of engine cooling. While the cost of the closed system is roughly three times the cost of the open system, the total yearly charges are more nearly the same.

The over-all rate of heat transfer through the heat-exchanger surface in closed systems depends upon the velocity of water in the tubes and around the tubes, the cleanness and nature of the

surfaces, and the mean temperature difference existing between raw water and jacket water. Maintenance of clean surfaces is an operating problem, while the kind of surface should largely be left to the manufacturer. Velocities, on the other hand, depend both upon the quantity of water circulated through the jackets and the arrangement of heat-exchanger tubes. Parallel tubes decrease the velocity and a series arrangement increases it. Fig. 5 shows the gain in over-all coefficient of heat transfer with increasing velocities and it also shows the increase in pressure drop especially at higher velocities. The nature of these curves indicates that due to relatively small gain in coefficient at high velocities and relatively large pressure-drop increases, there is a definite point beyond which velocities should not be increased. In practice, velocities may vary from 1.5 to 6 fps within the exchanger tubes.

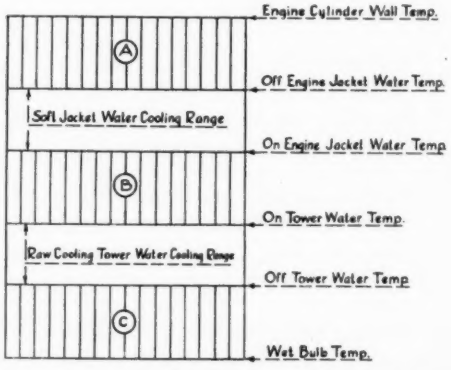

FIG. 6 STEPS IN HEAT DISSIPATION FROM ENGINE CYLINDERS TO ATMOSPHERE

(Temperature differences: (*A*) Engine cylinder wall and soft jacket water; (*B*) soft jacket water and raw tower water; (*C*) raw tower water and wet-bulb temperature.)

By increasing the quantities of water circulated the coefficients of heat transfer are not only increased but the cooling and heating range is kept narrow; an important consideration in obtaining the necessary mean temperature difference for heat transfer with reasonably sized exchanger surfaces. Heat dissipation from the engine cylinder to atmosphere takes three distinct steps as illustrated diagrammatically in Fig. 6: (*A*) from cylinder wall to jacket water, (*B*) from jacket water to raw water, and (*C*) from raw water to atmosphere.

The lower the wet-bulb temperature and the higher the permissible cylinder temperature, the greater is the total temperature difference available for these steps and hence the smaller the equipment may be. These top and bottom temperatures usually cannot be controlled, but by circulating larger quantities of both raw and soft water, which can be controlled, the ranges are narrowed leaving a greater temperature difference between hot jacket water and cool raw water (*B*).

EQUIPMENT FOR COOLING SYSTEMS

Scarcity or high cost of water and frequently problems of disposal necessitate recooling and reuse of water rather than running it to waste. A cooling tower saves about 95 per cent or more of the water. When soft water is available for make-up, open systems can be used. In such cases the jacket water itself is pumped through the engine and over some form of tower, after which it is recirculated through the engines. The choice of the particular type of tower depends largely on location and cost of ground space. In order of ascending investment costs are spray ponds, spray atmospheric towers, deck atmospheric towers and mechanical-draft towers. This also is the order of decreasing ground space required. Unless a pond of considerable extent already exists with cheap ground rent, spray-pond equipment, despite its low first cost, will prove expensive. At the other extreme, forced-draft towers, with their higher initial and operating costs, occupy small ground space (especially the filled induced-draft types), need no exposure, and are even adaptable for indoor use.

Heat exchangers used with cooling towers are of two kinds, the shell-and-tube type shown in Fig. 7 and the atmospheric tube type, placed directly in the base of a cooling tower as shown in Fig. 8. Table 3 compares the salient features of each type.

Radiators have found a wide application for cooling engines of small and medium size. They are particularly suitable for

Location	Directly in base of cooling tower and showered by descending raw water	May be placed indoors to prevent water freezing during periods of shutdown in cold weather

portable field engines and in some cases for indoor installations. As they do not employ the principle of evaporation, they are free from scale deposit and need no make-up water. On the other hand, they require the movement of a large amount of air and consequently high consumption of fan power. If off-engine water temperatures are to be kept below 160 F, under dry-bulb conditions exceeding 100 F, their size and horsepower requirements make them uneconomical.

The evaporative condenser was designed primarily as a combined cooling tower and condenser for refrigerant condensing, but it is also finding a field in Diesel-engine cooling. A photograph of one of the larger ones is shown in Fig. 9. It consists of a sheet-

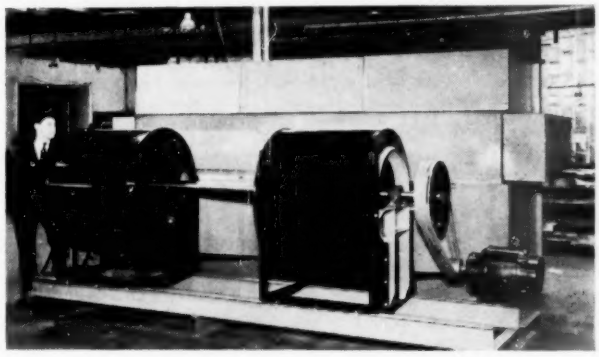

FIG. 9 LARGE EVAPORATIVE-CONDENSER-TYPE WATER COOLER (Courtesy of the Trane Company.)

metal shell through which air travels vertically driven by induced- or forced-draft fans. In the path of the ascending air are located a series of horizontal tubes carrying the soft water. These tubes have finned surfaces, and a spray-nozzle system discharges the raw water over the fins where evaporation occurs. Excess water collects in a pan from which it is pumped back to the nozzles together with the make-up water. The equipment is essentially an evaporatively cooled radiator requiring about half the amount of air necessary for a dry radiator. Jacket water is cooled through a 20 F range with off-engine water temperature between 140 and 160 F. The raw-water circulation is low compared with other types of heat-exchanger systems, being only about one third of the soft-water circulation.

The evaporative-radiator system seems well-adapted to engines of small and medium size, and forms a compact unit for indoor closed systems from which the moist air is discharged to the exterior through ducts. A serious disadvantage is the accumulation of insulating scale on the fins, resulting from salt deposits left by the evaporation of the raw water. Cleaning in place is out of the question and ordinary descaling methods cannot be used on fins. The finned sections must therefore be periodically replaced by spares while chemical descaling is applied to the fouled surfaces. Tubes without fins may be used where only hard untreated water is available for make-up, but this reduces the surface to such an extent that about 50 per cent more tubes are required.

ECONOMY OF CLOSED VERSUS OPEN SYSTEMS

The trend to closed cooling systems in preference to open systems has been so marked in recent years that the writer undertook to establish total yearly costs and analyze the components of these costs for both systems over a wide range of engine sizes. For the open system the investment covered a spray-type atmospheric tower mounted over a concrete foundation basin, all erected in place, together with a suitable pump and motor for water circulation. Cooling was from 115 F to 95 F at 75 F wet bulb. This resulted in a circulation of 0.3 gpm per hp. The closed-system investment included a much larger spray-type atmospheric tower, with atmospheric-tube heat exchangers mounted in the base, erected over a concrete basin foundation. Included also in the investment cost were a raw- and a soft-water circulating pump with motors. The jacket water cooling was much higher in the temperature scale (a permissible and desirable condition with closed systems), being from 140 F to 125 F, with both raw- and soft-water circulation at 0.4 gpm per

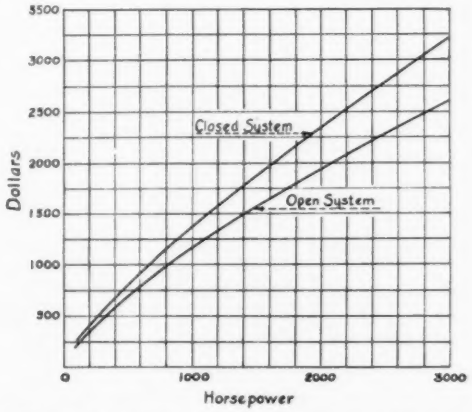

FIG. 10 TOTAL YEARLY CHARGES FOR OPEN AND CLOSED COOLING SYSTEMS FOR ENGINES

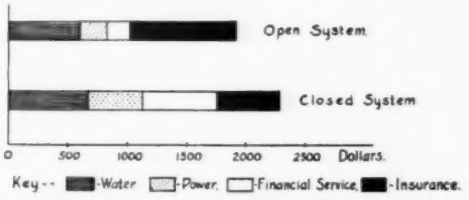

FIG. 11 COMPONENTS OF TOTAL YEARLY CHARGES

hp. No piping was included for either type of system. The investment costs, depending on size of installation serviced, varied from \$4 to \$1 per hp for the open system and from \$11 to \$3 for the closed system.

Fig. 10 graphically illustrates the variation of total yearly charges for both systems, servicing installations from 100 to 3000 hp.

Total yearly charges are composed of investment charges, operating charges (pumping cost and make-up water), and insurance. Investment charges as taken were based on 5 per cent interest on installation cost and yearly equalized depreciation payments for 10 years into a sinking fund compounded annually at 5 per cent interest. The operating charges assume operation for 3000 hr per year, make-up water costing \$1 per 1000 cu ft, and electric current at \$0.01 per kwhr. The insurance rates, were based on engines built since 1925, are for 3-yr premiums, and are the so-called "objective charges" to which is added a small insurance charge, not included.

Fig. 11 analyzes these components for a cooling system servicing a 2000-hp installation. It is interesting to note that while power charges, because of double pumping, and financial charges, because of larger investment, are materially higher for the closed system, the low insurance rates, due to its use, make total yearly charges only about 20 per cent higher than for the open system. The insurance component is a measure, in some degree, of the engine-repair costs but when other items associated with trouble-free and uninterrupted service are considered, it is readily seen that closed systems are economically justified unless very soft water or elaborate treatment is used.

Theory of Elastic Engine Supports

By S. ROSENZWEIG,[1] NEW YORK, N. Y.

It is obvious that the application of spring suspension to a foundation represents a great departure from the methods previously used. Instead of rigidly bolting down a machine, it is now installed so as to operate on a yielding structure. Instead of comparatively simple static laws, complicated dynamic conditions have to be considered. This paper presents the theory of the dynamic principles underlying machine operations. It is shown that not only capacity, speed, and weight of a machine must be considered, but also acceleration and free forces of reciprocating and rotating engines, irregularity of motion, inertia forces of individual parts, forced frequencies of operation, and natural frequencies of the subsoil.

Frequencies of Elastic Supports

THE SIMPLEST form of a vibratory motion can be demonstrated by the action of a spring, Fig. 1. A spring is loaded by a weight L and suffers a static deflection of d. An external force is applied to the loaded spring so as to displace the weight from its rest position C to some other position A. This external force is now removed and the weight oscillates between points A and B, due to the elasticity of the spring. These oscillations gradually die out, principally due to air resistance, till the weight stops at rest position C. The spring, elastically speaking, functions in identically the same manner as a swinging pendulum whose length 1 equals the deflection d of the spring. This analogous function is of great importance in the design of elastic suspensions.

The movement of the spring from C to A and C to B, designated x, is called the amplitude of the vibratory motion. By traversing the distance of $4x$ (from C to A, from A to B, and back to C) a cycle of the vibrating body is completed. The time required to complete the cycle is called the period, designated by T, and is usually measured in seconds. The reciprocal of T is termed the frequency of vibration, f, which indicates the number of periods that occur in a given unit of time, usually in cycles per second. For instance, if the frequency of vibration is ten cycles per second ($f = 10$), ten cycles are completed in one second with the duration of each cycle T being $^1/_{10}$ of a second.

The rate at which the spring oscillates has one particular value which is called its *natural frequency of vibration*. It is that frequency at which a system will vibrate after the external force which displaced it is removed. This natural frequency always remains the same, no matter how great or small the initial amplitude x of the spring or in the case of a pendulum the distance the pendulum moves from its rest position. Only the physical characteristics (wire diameter, outside diameter, etc.) of the spring or the load will affect its frequency and in the last analysis the static deflection d which is determined by both these factors. For an undamped simple linear system this natural frequency can be figured by the formula[2]

$$f = 3.13 \sqrt{\frac{1}{d}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

in which f is the frequency in cycles per second and d the deflection in inches.

The action of the spring under a momentary blow, as occurs, for instance, in a hammer installation, is of sudden and short duration. It may occur once or repeatedly, depending upon the number of blows that are struck; but from a vibratory standpoint, each blow produces an individual motion which gradually dies down.

In the case of rotary machines, such as motors and turbines, or reciprocating machines, such as steam and oil engines, there is

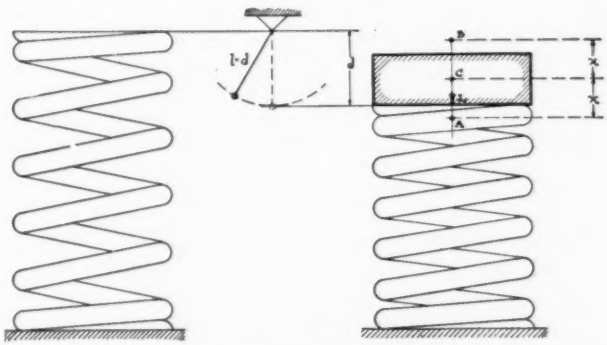

Fig. 1 Action of a Spring After Application of a Static Force

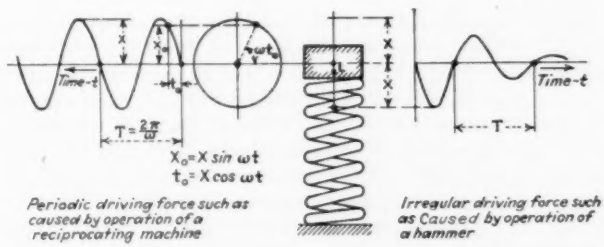

Fig. 2 Action of a Spring From Periodic and Irregular Forces

a periodically varying motion which reverses itself twice during each cycle and continuously repeats itself in all its particulars after a certain interval of time, called the *period of vibration*. To produce either motion, an external driving force, having a definite frequency called *forced frequency* is required. In the case of the hammer, it is provided by the blows struck on the anvil. In the case of engines, it is provided by the continuously rotating and reciprocating mechanism. The difference in the action of the irregular and periodic driving forces is apparent from Fig. 2 which shows the respective vibratory motions. Different physical laws apply to each. This paper will concern itself with the laws governing periodic forces produced by reciprocating engines.

[2] "Vibration Prevention in Engineering," by Arthur L. Kimball, John Wiley and Sons, Inc., New York, N. Y., 1932, p. 7.

Damping

Vibratory movement is always impeded by some sort of resistance. Generally speaking, this resistance is produced by what is technically termed either *absolute damping* or *relative damping*. Absolute damping, the more objectionable type, is usually caused by the sides of a foundation rubbing against other surfaces, such as earth, or soundproofing material against which the foundation is poured. This friction is usually not excessive since the foundation has a tendency to shrink away from the surrounding pit walls. An air space around the foundation is always preferable and, where it is provided, reduction in any vibratory transmission present will be noticeable. Relative damping is due to the quality of the substructure on which the foundation rests. All soils and, naturally, all organic shock-absorbing materials, such as rubber, felt, or cork, have a considerable damping factor under compressing action. Contrary to the still prevailing belief of many engineers, damping is decidedly harmful because it increases the transmitting effect of vibrations.

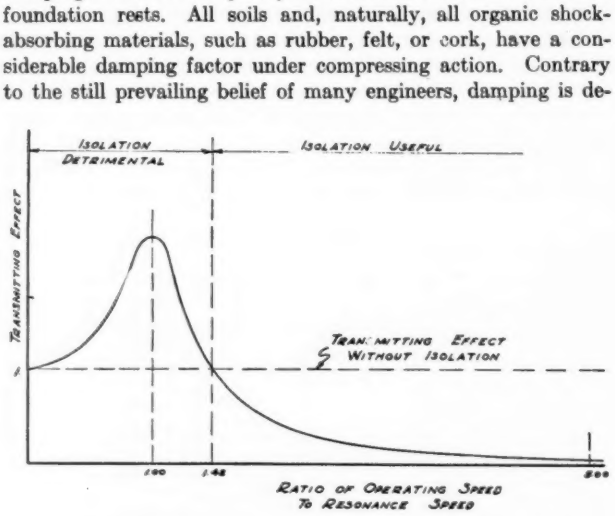

Fig. 3 Simple Form of Vibration-Isolation Analysis

Fig. 3 proves mathematically the correctness of this statement, which is equally well demonstrated by practical experience. Steel springs have a damping coefficient of less than one half of one per cent, a fact which contributes greatly to the excellent results obtainable with them as shock absorbers. Absorbing vibrations by means of damping implies dissipation of energy in the form of heat. It is energy irretrievably lost to the machine. This leads to a most important conclusion. When the operation of a machine sets up a vibratory motion in an adjoining structure, the energy used is spent for an entirely different purpose from that for which the machine is built. This energy is subtracted from the productive output of the machine. It is, therefore, profitable to regain as much as possible of this energy. A correctly designed spring suspension with a minimum of damping will save a considerable amount of this otherwise dissipated energy. This effect can be demonstrated most strikingly on large motors, where it appears as an appreciable increase in speed when motors are correctly isolated. No definite figures about actual savings are available; some prominent European engineers claim increase in power up to ten per cent. Damping, to prevent excessive movements, is of advantage only when the machine is operated near resonance speed, but better means than damping are available for this purpose to the designer of a spring-suspended foundation.

Power and Operating Amplitudes

The first complete analysis of vibration isolation was worked out by Soderberg.[3] A diagrammatical representation in its simplest form is shown in Fig. 3. The ordinates show the amount of the vibratory force which is transmitted to the substructure of an isolated foundation in comparison with a rigidly mounted foundation represented by the horizontal line 1. The abscissa is the ratio of the forced frequency (due to the operation of the machine and, often, corresponding with it's revolutions) to the natural frequency of the vibration absorber. For instance, if this frequency ratio is 4:1 the transmitted force is only about one tenth that of a rigidly mounted machine. When this ratio sinks below 1:42 there is a most astonishing result. The use of a so-called vibration absorber actually makes conditions worse. This is not just theory but has often been demonstrated in actual practice, particularly when the frequency ratio was in the region between zero and one. Many an engineer has assumed that, when a certain thickness of felt, cork, or rubber placed under a machine still permitted transmission of vibration, doubling the thickness of the isolating material would certainly improve conditions. To his astonishment, he found just the contrary to be true. The diagram clearly shows the reason for the failure.

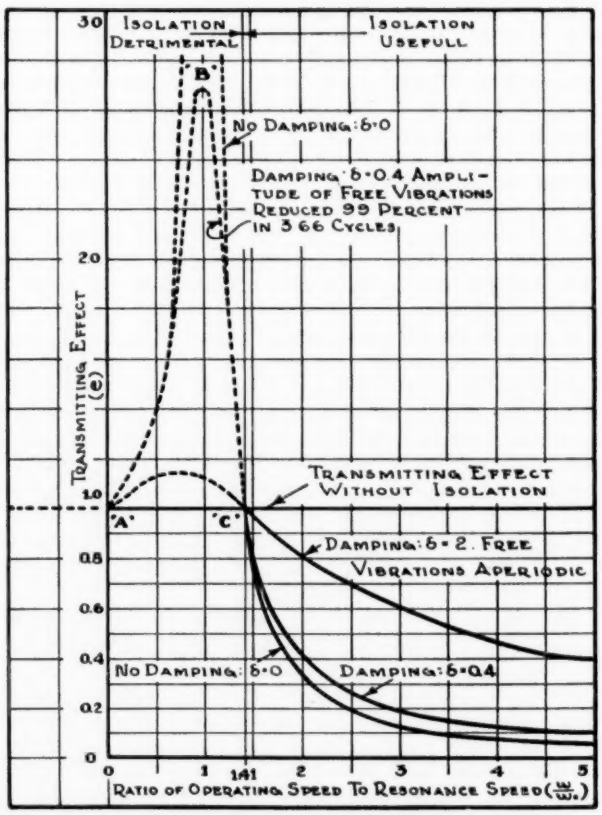

Fig. 4 Effect of Isolators With Different Degrees of Damping

This effect can also be clearly observed when standing on the floor adjoining a correctly isolated foundation. When starting and accelerating the engine, the frequency ratio is changed due to the varying speeds of the engine. A quickly increasing vibration transmission, which may be noticeable during the low-frequency region, will gradually diminish and suddenly disappear as a suitable frequency ratio is reached.

[3] "Vibration Absorbers," by C. R. Soderberg, *The Electric Journal*, vol. 21, April, 1924, Fig. 26, p. 162.

Another point in this diagram is of great importance. When the frequency ratio is one, i.e., when the two frequencies are alike, the transmitting effect is at a maximum, B. The system is now operating at, or passing through, what is called the *resonance speed of the system.* This is a dangerous condition if maintained, because large amplitudes of motion and excessive transmitted vibrations may be built up by comparatively small forces. This is the reason why soldiers are ordered to break step when marching over a bridge. To avoid disaster, the frequency of the combined rhythm of marching feet must not correspond with the natural frequency of the bridge.

In the next illustration, Fig. 4, the representation of Fig. 3 is repeated by curves showing the transmitting effect of vibration isolators having different degrees of damping. The curve $D = 0$ (zero damping), represents the result of isolation by means of steel springs, and the other curves illustrate the gradual decrease in efficiency as damping increases. This vibration-absorbing efficiency is more clearly represented by the curves

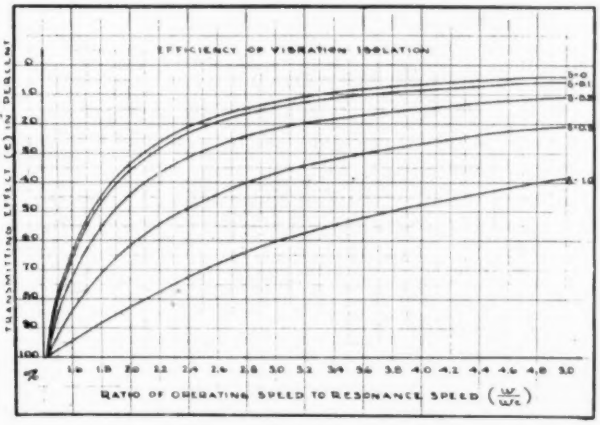

FIG. 5 EFFICIENCY OF VIBRATION ISOLATION

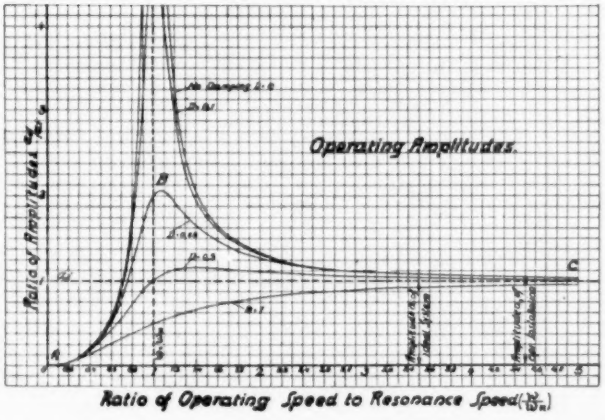

FIG. 6 RELATION OF ACTUAL OPERATING AMPLITUDES TO IDEAL CONDITIONS

in Fig. 5 where, for each degree of damping, it is plotted over the entire range of frequency ratios, varying between 1:42 and 5:1.

Therefore to make the force transmitted to the substructure as small as possible, the forced frequency of the operating machines must be large, compared to the natural frequency of the shock absorber, with a minimum of damping. This ratio should be at least 3:1, and in many cases, considerably more, depending upon local conditions and the magnitude of unbalanced force. It is clear that if this unbalanced force is small, a frequency ratio of 2.5:1 or 3:1 may be sufficient to make the transmitted vibratory force so small that it will not be noticeable. If, however, this force is great, an efficiency of the isolating medium of 80 to 90 per cent may not be sufficient. In such cases frequency ratios of from 5:1 to 8:1 are required.

With these facts established, it now becomes necessary to examine the movement which the running engine possesses when placed on a spring-suspended foundation. The operating amplitudes shown in Fig. 6 are all related and compared with the *ideal system.* The term, ideal system, refers to an imaginary system suspended in space and provided with an infinitely elastic suspension, i.e., no vibrations are transmitted. These conditions may be approached but can never be realized in actual practice.

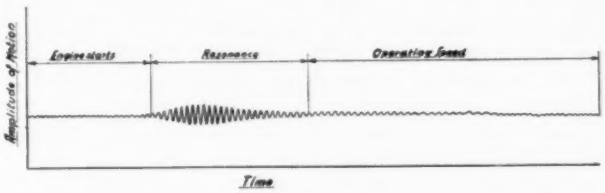

FIG. 7 AMPLITUDE OF MOTION OF FOUNDATION SYSTEM

The horizontal line 1 represents the operating amplitude of the ideal engine, obviously constant because the frequency ratio is infinitely large. This amplitude is, therefore, properly termed the *limit amplitude.* For the actual engine, in comparison, amplitudes are small for the low frequency ratios but gradually increase until they become large at resonance speed. From point B they decrease asymptotically until at point C they approach the amplitude of the ideal system.

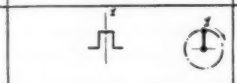
Some very interesting conclusions can be drawn from this diagram. It is possible that somewhat steadier engine operation is obtainable with an unisolated or incorrectly isolated foundation, as the range of curves to the left of the vertical 1.0 line indicates, though ordinarily on account of the resiliency of the subsoil, operation will take place along the 0.4 to 0.6 abscissa. But this causes excessive wear in the engine, reduced efficiency, and the annoyance which always accompanies transmitted vibrations. The benefits obtainable with a spring-suspended foundation are so great, physically and economically, that slight oscillation, hardly exceeding a few thousandths of an inch, is immaterial. That these operating amplitudes are negligible, is apparent from Fig. 7, representing the record taken from an actual engine. As shown, the amplitudes vary from the time the engine starts, passes through resonance, and attains operating speed. By making the springs in the isolator very soft, resonance speed will occur at a very low engine speed and therefore be passed through so quickly that the small increase in movement due to resonance is hardly noticeable.

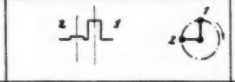
It is evident that a vibration isolation of 100 per cent with no oscillation of the operating system is impossible. However, for a frequency ratio of 5:1 and with zero damping, the amplitude of motion will be within 4 per cent of the ideal engine and vibration-absorbing efficiency approximately 97 per cent. This means that the motion of the mass would be virtually imperceptible and the slight vibration transmission would be well beyond the human sensitivity range, hardly detectable even by the finest instruments.

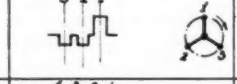
FOUNDATION AS A STABILIZER

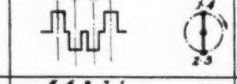
Unbalance and other inertia forces have the tendency to upset the equilibrium of the machine system, free forces tending to move it in a translatory direction and free moments in a rotational direction. Even in machines in which an attempt

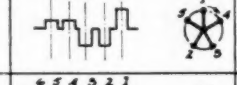
is made to provide perfect balance, as for instance for the primary and secondary forces and moments on six- and eight-cylinder Diesel engines of the four-cycle type, slight unavoidable changes in the manufacturing process will upset the theoretical calculations. These unbalanced forces in Diesel engines can be accurately measured. Their presence or absence depends upon

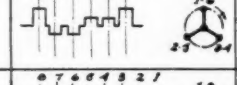


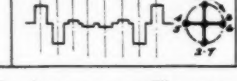












No. of Cylinders	Crank Sequence Diagrams	Unbalance	
		Free Forces	Free Couples
1		Primary and secondary forces unbalanced	Nil.
2		Secondary vertical force unbalanced	Primary couples unbalanced
2		Primary force unbalanced	Primary and secondary couples unbalanced
3		Nil.	Primary and secondary couples unbalanced
4		Secondary vertical force unbalanced	Nil.
5		Nil.	Primary and secondary couples unbalanced
6		Complete primary and secondary balance	
0		Complete primary and secondary balance	

FIG. 8 ANALYSIS OF UNBALANCE FOR VARIOUS CRANK ARRANGEMENTS

the number of cylinders and the crank arrangement, and their magnitude depends upon the design of the particular machine.

Fig. 8 shows the type of unbalance for Diesel engines of any given number of cylinders with specific crank arrangement. Operation of the engine will provide additional changes in the balance, such as variations in piston clearances due to unequal expansion, difference in the size of combustion chambers when bearings and connecting rods are adjusted, etc. It is, therefore, necessary to provide a stabilizing mass in the weight of the engine and foundation which will counteract the disturbing effect of free forces and moments. The calculation of the stabilizing mass is essentially the work of the mathematician backed by the experience of actual installations to check his calculations. The curves in Fig. 9 are the results of such calculations in which Q represents the stabilizing mass, a_0 the operating amplitude, and K a dynamic-balance coefficient which depends upon the perfection of balance in the engine. The coefficient K which can be calculated from the data furnished by engine manufacturers, governs the foundation weight for a given amplitude and, therefore, becomes also a concrete measure of the dynamic-balance quality of an engine's design and construction.

It should be noted that the results obtained from the curves given in Fig. 9 apply to the ideal engine and give, therefore, optimum conditions. Fig. 6 indicates that a close approach to the ideal engine, within 4 per cent, is possible by means of correct isolation by employing only minimum foundation weights.

The mathematical calculations which are the basis of Fig. 7 have been covered by Hartz.[4] An outline of these calculations illustrated by Fig. 10 is given here.

Using a single-cylinder engine which has a primary unbalanced force and a two-cylinder engine which, with cranks at 180 deg, has a primary unbalanced moment, the respective translatory and rotational movements caused by such unbalance are shown and can be mathematically calculated. In a mass system as represented by the ideal engine and its foundation, the moving masses, consisting of piston, piston rod, connecting rod, crank, etc., move relatively to the engine frame and the foundation to which it is rigidly bolted. Dynamics teaches that in such a system every movement of the revolving and reciprocating masses is counteracted by movement of the engine frame and foundation, which tends to maintain equilibrium by keeping the combined center of gravity S stationary. Let

m_1 = the combined revolving and reciprocating mass
r_1 = crank radius = displacement of m_1
m_2 = mass of foundation and stationary engine parts
r_2 = displacement of m_2 = a_0 in Fig. 9
m = $m_1 + m_2$ = total stabilizing mass
g = 32.2 ft per sec per sec

Therefore, if m_1 and m_2 move in counterphase to each other in such a way that S remains stationary, the law of gravitation is complied with if

[4] Vorschau auf die 75. V.D.I. Hauptversammlung in Kiel, H. Hartz, *Zeitschrift des Vereines deutscher Ingenieure*, vol. 81, June, 1937, p. 638.

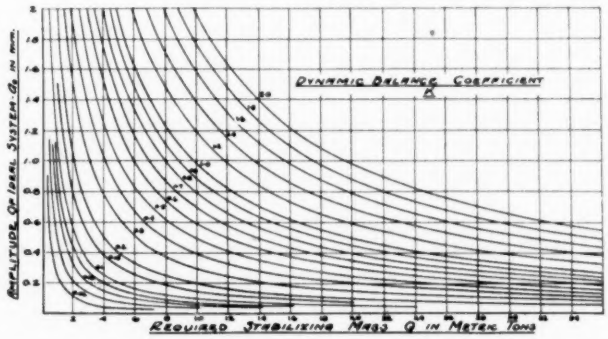


FIG. 9 RELATION OF STABILIZING MASS TO OPERATING AMPLITUDE

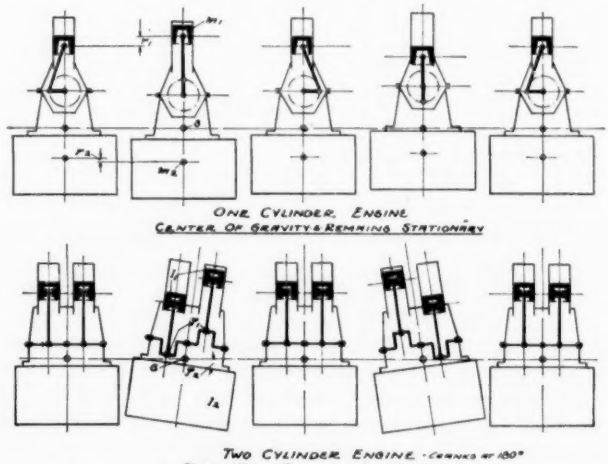

FIG. 10 ACTION OF RECIPROCATING AND STABILIZING MASSES IN ONE- AND TWO-CYLINDER ENGINES

$$m_1 \times r_1 = m_2 \times r_2 \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

(for the translatory movement). Since the free force of the crank mechanism is

$$P_{max} = m_1 r_1 \omega^2 = m_2 r_2 \omega^2 \ldots\ldots\ldots\ldots\ldots [3]$$

the dynamic-balance coefficient is

$$K = \frac{P_{max}}{\omega^2} = m_2 r_2 = m a_0 \ldots\ldots\ldots\ldots\ldots [4]$$

and, hence, the stabilizing mass becomes

$$Q = g \times K \times a_0^{-1} \ldots\ldots\ldots\ldots\ldots [5]$$

The formulas indicate that the stabilizing mass is independent of the revolutions or frequency of the engine. It is, therefore, a fallacy to assume that high-speed machines require heavier foundations than low-speed machines, or that the same machine can have a lighter foundation when it is being operated at a reduced speed. This may be illustrated by the following example:

P_{max} = 3000 lb (secondary free force)
n = 500 rpm
ω = 104.4

therefore

$$K = \frac{P_{max}}{\omega^2} = \frac{3000}{10900} = 0.275 \text{ and}$$

for

$$A_0 = 0.002 \text{ in.}; \quad Q = 32.2 \times \frac{0.275}{0.002} = 4430 \text{ lb}$$

for

$$A_0 = 0.004 \text{ in.}; \quad Q = 2215 \text{ lb}$$

An amplitude of 0.004 in. to 0.006 in. is unquestionably permissible with the flexible pipe connections generally provided

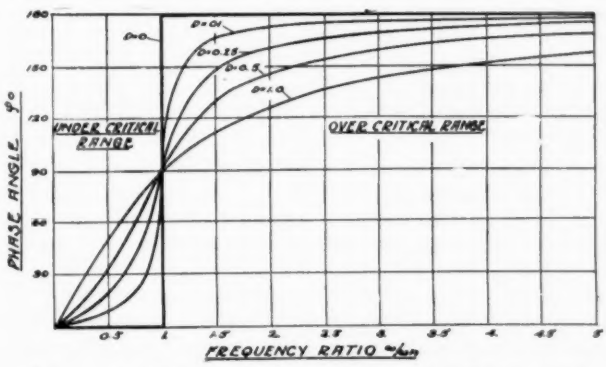

FIG. 11 VARIATION OF FREQUENCY RATIO WITH PHASE ANGLE

for Diesel engines. If the necessary foundation weight cannot be accommodated and greater amplitudes are desirable, the free force must be reduced by additional balancing.

The calculation of rotational movements provides greater difficulties because it is not simply a matter of weight in any shape for the stabilizing mass but also the inertia moment which requires consideration, and, therefore, the shape as well as the size of the mass is, in the final analysis, of principal importance. Hence, it can be concluded that by giving the foundation the proper shape, it will be possible to provide a relatively lesser stabilizing mass for free moments than for free forces. This will make it sometimes preferable in crowded localities to use an engine having an unbalanced moment, rather than an engine having a free force. The mathematical calculations are similar to those given for free forces, the only change being a substitution of inertia mass I for weight mass m, angular displacement φ_0 for amplitude a_0, and moment M for force P.

As the calculations apply to the ideal engine, which by definition is a system suspended in space, the amplitudes obtained for a given foundation weight will be slightly greater in accordance with Fig. 6.

It was previously shown that the disturbing reciprocating and revolving masses should swing in counterphase to the stabilizing mass to provide equilibrium and to satisfy Equation [2]. This is correct for the ideal engine where the phase angle between the two opposing masses is always 180 deg.

The conditions in the actual engine are somewhat different as Fig. 11 shows. Here again is a confirmation of all the previous lessons, that at low frequency ratios and with increased damping an increase of vibration transmission takes place; and for the low frequency ratio the phase angle is not 180 deg but 0 deg. In other words, the stabilizing mass is moving in the same direction as the disturbing mass instead of against it and there is increased vibration transmission. The phase angle is less than 90 deg below resonance (the vertical 1 line). It increases rapidly, a practically instantaneous change to 180 deg with zero damping. That is why with a foundation suspended on springs, the amplitude of motion is reduced so quickly (see Fig. 6). The mass becomes an effective stabilizing mass as the phase angle rather suddenly changes from zero to 180 deg. The greater the damping factor, however, the slower does the change in phase angle take place, an added indication of the disadvantage of damping.

CHOICE OF THE ISOLATING MATERIAL

It is a fundamental law that to retard the progress of vibratory waves, there must be interposed between the source of the disturbance and the structure on which it is mounted, a material which has a different mechanical resistance to sound conductivity. The mechanical resistance to sound conductivity (hereafter designated *R.S.* conductivity) is the product of the density of the material and the velocity at which the sound progresses through it.

TABLE 1 SOUND CONDUCTIVITY OF VARIOUS SUBSTANCES

Material	Sound velocity ft per sec v	Density, lb per in.^{3} d	Mechanical resistance to sound conductivity $v \times d$
Steel	17200	0.283	4860
Wrought iron	15500	0.278	4320
Copper	11700	0.320	3750
Cast iron	12400	0.260	3230
Lead	4150	0.411	1710
Glass	18000	0.094	1690
Concrete	16500	0.072	1190
Ash (with fiber)	15300	0.0272	416
Water	4700	0.036	169
Pine (with fiber)	11000	0.0145	159
Cork (with fiber)	1600	0.0086	13.9
Rubber	200	0.0442	8.84
Air	1080	0.000047	0.05

A machine is usually made of iron and steel, while the structure is composed of concrete and steel, all having a high *R.S.* conductivity as shown in Table 1. It is obvious, therefore, that for the purpose cited, a material has to be chosen from the bottom of the table. Air is unsurpassed as an isolating medium, but for obvious reasons can be employed only against lateral impact vibrations. Steel springs act admirably as isolators because of their shape, form, and heat-treatment possibilities.

In comparing the different materials shown in Table 1, it will be found that the density decreases fairly proportionally with the sound conductivity and, therefore, it can be stated that the more resilient a material the more suitable it is as a vibration absorber.

All materials deflect under a static load and follow a general law

$$c = \frac{dP}{dx} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [6]$$

which indicates that any increase in load P results in an increase in deflection x. In Fig. 12 (upper right-hand corner) are shown the deflection curves for three materials which are generally used as vibration absorbers—cork, rubber, and steel springs. Cork and rubber show a variable c curve. Rubber becomes harder and cork becomes softer as the load increases. The c curve of the steel spring is a straight line because it follows Hooke's law providing proportionality between load and deflection. K is then called the *spring constant* which denotes the number of pounds necessary to deflect the spring one inch. The formula may be written as

$$K = \frac{L}{d} = \text{const}$$

As is shown in Equation [1] for vertical vibratory motions, the deflection d controls the natural frequency of the isolator, and therefore, must have a definite value regardless of the weight it has to support. Hence it is important that the calculation

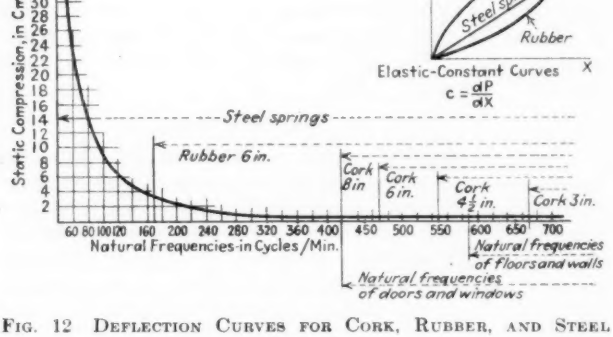

FIG. 12 DEFLECTION CURVES FOR CORK, RUBBER, AND STEEL SPRINGS

of such deflection in the isolator be made on a simple and reliable basis. The calculation of steel springs, based on modern practice employing the Wahl coefficient for the determination of deflection and stress, is very simple indeed. The large deflections necessary for maximum isolating efficiency are easily obtainable through the choice of the proper physical characteristics, especially with a coil spring which has a higher loading capacity per pound of spring material than any other type of spring usually applied for this purpose. Therefore the author adopted this type of spring for the most important and difficult isolation problems.

Organic materials do not show the simplicity and advantages of the steel spring which does not depend upon its material, but rather, upon its wire diameter, outside diameter, etc., which may be chosen at will, while the former are restricted in their use as their elasticity depends upon the material itself and only to a minor degree upon shape. This defect explains why organic materials cannot provide the necessary large deflections in the isolator for any reasonable thickness. The restrictions imposed upon them are clearly shown in Fig. 12, indicating the lowest natural frequencies that are obtainable for different conditions.

The curve shows the relation between the natural frequency of an undamped, single-degree system and the static deflection of the spring in accordance with the formula of $f = 188\sqrt{(1/d)}$ cycles per minute. Therefore, for a deflection of one inch, the frequency is 188 cycles per minute.

As stated, all the calculations given so far refer to static stresses. Isolators placed under operating machinery, also deal with dynamic stresses. The behavior of all materials, with the exception of steel springs, is different when stressed dynamically. On the basis of many experiments, it was found that the stiffness of cork and rubber is two to three times greater under a dynamic than under a static load and, therefore, their natural frequencies should be correspondingly increased over the values given in Fig. 12. Thus their useful employment range becomes still more limited.

Kimball[5] states, "Cork is not a perfectly elastic material, and tests show that it should be compressed three to four times as much as an ideal spring to produce the required frequency.... Considering its poor elastic qualities from the test standpoint, it is surprising how well it works in some applications....High-grade rubber is elastically much superior to cork, nor does it lose its resilience appreciably with time, as is commonly believed, unless cheap grades are used." Fig. 11 fully substantiates these statements in the light of most recent developments.

The considerations in this section so far are based upon a vertically acting force and, therefore, upon the use of a vibration isolator having what is technically termed *one degree of freedom.*

Since practically all foundation systems show six degrees of freedom, three in translatory and three in a rotational direction for the three space axes, the elastic suspension should be designed accordingly. Reference has been made to the analogous action of the spring and pendulum. By correct arrangement and construction of the isolators, this pendulum action can be used to provide the necessary frequencies, not only in a vertical direction, but also in a horizontal direction.

CONCLUSION

In conclusion it may be stated that from the standpoint of vibration control and for dynamic reasons, the following principal points must be observed in the design and arrangement of spring suspensions:

1 Large frequency ratio—at least 3:1
2 Minimum damping
3 Carefully calculated stabilizing mass
4 Correctly selected isolating materials.

ACKNOWLEDGMENT

The author wishes to give credit to the many engineers who have done such valuable work in developing and applying vibration isolation theories. It is impossible to mention all the names, but particular recognition is given to C. R. Soderberg, Westinghouse Electric Company; J. P. DenHartog, Harvard University; J. Ormondroyd, University of Michigan; A. L. Kimball, General Electric Company; E. H. Hull, General Electric Company; V. O. Knudsen, University of California; J. Geiger, Augsburg, Germany; and Ernst Lehr, Darmstädt, Germany.

Discussion

Some Data on Diesel-Electric Switching Locomotives[1]

J. P. Laux.[2] The percentage of availability mentioned by the author parallels quite closely the results which we have obtained with Diesel-electric switchers on the Lehigh Valley Railroad. We have found also that the locomotives of more modern design are giving better performance results than the older types. However, we do not find it necessary, as the author mentions, to hold locomotives out of service for 16 hr for monthly inspection—this work is done in 8 hr, thereby increasing the service availability of our Diesel-electric locomotive.

We have experienced some trouble with our Diesel-electric locomotives, due to design defects, which have now been corrected. The writer would estimate that the Diesel engine is responsible for about 75 per cent of Diesel-electric-locomotive failures, while the electrical equipment is responsible for the remaining 25 per cent.

The operating costs given by the author compare very closely with the cost of operating this type of power on the Lehigh Valley Railroad.

H. M. Rugg.[3] An official of one of the companies manufacturing Diesel-electric switching locomotives gave the writer some interesting figures regarding their operation. Speaking of the life of the locomotives he said, even considering the length of time they have been manufacturing and using these engines, they have yet to find any rule or any data which would allow them to estimate the length of life. Some of the locomotives have been in service constantly from 10 to 12 years with no indication of their passing out of service except for obsolescence.

In regard to economy, there were several items of exceptional interest. For instance, in 1936, class-1 railroads spent about 35 million dollars for fuel in switching service exclusive of the cost of moving the fuel to the point of usage and return of empties; Diesel-electric switchers will normally reduce this expense 75 per cent. In ordinary switching service each tank car of fuel oil covers as many service hours as 12 cars of coal.

Again, the railroads spent about 45 million dollars repairing locomotives used in switching service; Diesels will reduce this item approximately 50 per cent. They spent 16 million dollars for enginehouse expense caring for locomotives used in switching service. This includes cleaning fires, handling ashes, cleaning grates, watching, boiler washing, and government inspections of firebox and boiler. This service, he stated, on Diesels is practically negligible.

That same year they spent $3\frac{1}{2}$ million dollars for water to be used in switching locomotives. The Diesel practically eliminates this expense. In substituting Diesels for steam switching locomotives the capital investment will not be as high, as three Diesels will normally cover as many hours of service as four steam locomotives. Diesel switchers are normally available for not less than 8000 hours, or 330 twenty-four-hour days per year while steam switching locomotives are rarely available for more than 6000 hours per year.

From quite complete studies and this company's experience with Diesel power it is estimated that if class-1 railroads were to put 3000 Diesel locomotives into switching service, this number of Diesels—about 25 per cent of the present steam-switching-locomotive inventory—would cover approximately 50 per cent of the present switching hours and effect a saving in operating expense of 52 million dollars yearly. This saving would be sufficient to liquidate fully the investment in Diesel locomotives within five years and would permit the retirement, without replacement, of not less than 5000 old and obsolete steam locomotives with their current excessive operating cost, which should more than meet the cost of acquiring the Diesels. The full economy of Diesel operation will not become effective until Diesels completely supplant the steam locomotives in a given engine district, thereby eliminating the supporting services of steam that are not needed for Diesels, such as coal docks, water stations, track pans, and water-treating facilities.

A tremendous improvement has taken place during the last 10 or 12 years as the use of this type of equipment has advanced. Prior to 1924, single cars utilizing gas-electric power were the most common type of motor vehicle in railroad service. The engines used in these cars ranged from 150 to 175 bhp and most of them were gasoline engines. In the next six or seven years the size of the power units increased to as much as 900 bhp.

While use of the Diesel-electric locomotive in switching service began in 1924 with a 300-bhp engine, it was not until 1932 and 1933 that its application to both streamlined trains and switching service brought the special designs of high power. Now we have 1200- and 1600-bhp engines and, by combining various units, the most powerful locomotives ever built are being placed in service, the latest and largest being the two 5400-bhp locomotives for hauling the specially designed fast trains of the Union and Southern Pacific Railroads to California. Some of the locomotives already in service have covered more than half a million miles without a major overhaul.

R. Tom Sawyer.[4] Table 5 of this paper[1] gives comparative operating costs which are being substantiated every day by Diesel-electric locomotives built by the American Locomotive Company. Toward the end of the paper the author states: "In comparing the figures in Table 5 it is obvious that the three important items are fuel, enginehouse expense, and repairs; and in the case of all three items the steam-switcher costs are much higher than those for the Diesel switchers." The writer would like to discuss these three items.

Fuel. Railroads are asking why one locomotive burns more fuel than another locomotive of the same size; the locomotive that burns the most fuel is doing the most work—is using more of its brake horsepower. For example, an Alco 600-bhp locomotive in switching service will use from 5 to 6 gal of fuel per hr, while the same locomotive will burn 8 to 10 gal per hr in transfer service; in road service this same engine is using up to 32 gal per hr.

Enginehouse Expense. For steam locomotives this expense is justified, but for Diesels it is often a matter of bookkeeping or policy of management. The entire policy of the railroad may revolve around this one idea. If the steam and Diesels are mixed,

[1] Published as paper OGP-60-5, by John W. Anderson, in the April, 1938, issue of the A.S.M.E. Transactions, vol. 60, p. 221.

[3] Automotive Engineer, Birmingham, Mich. Mem. A.S.M.E.

[4] Sales Engineer, Diesel Locomotive Division, American Locomotive Company, New York, N. Y. Mem. A.S.M.E.

both using the same enginehouse, the enginehouse expense on the Diesels will be higher than if the same Diesels are placed in their own house, with steam locomotives eliminated from that section or yard. The road steam locomotives should be maintained at a main central enginehouse if possible, and the outlying yard engine-houses should preferably be closed when Diesel switchers are used. This allows a reasonable but low enginehouse expense for Diesels.

Repairs. The author pointed out that repairs deal with the entire locomotive, not just the Diesel engine. The entire locomotive must be built throughout so that it will have a large margin of safety on all parts. Alco Diesel locomotives today are coming well within the repair figures which are given in Table 5 of the paper.

The cost of repairs depends primarily upon two things: (1) The complete locomotive properly built for the service, and (2) railroad personnel and equipment.

Regardless of how good the personnel is, the locomotive will be costly to maintain if not properly built. We have certainly passed through an experimental era as pointed out by the author, but today we have learned how to build the heavy-duty Diesel-electric switcher; also, we have excellent cooperation with the railroad personnel and know how to hold maintenance costs to a minimum.

For example, we have learned that the mean effective pressure of a Diesel engine means nothing in so far as maintenance is concerned, while maximum pressures mean everything. The life of a Diesel engine also depends upon its temperature. We have learned by seven years of experience on the road that if an Alco engine has an exhaust temperature below 900 F, maintenance will be low. We have also found out that it is possible to obtain 900 bhp out of a 600-bhp engine simply by supercharging without increasing maximum bearing pressures and exhaust temperatures, thereby holding maintenance to a minimum and engine life to a maximum.

RALPH MILLER.[5] The writer would like to explain the manner in which figures on availability are obtained. Take as an example a certain railroad which now operates a number of 600-hp Diesel switches. These units work seven 24-hour days per week with the exception of eight hours out of service for I.C.C. inspection each week, making 6000 hours for 37½ weeks. At the end of that time the locomotive is taken into the shop for engine overhauling; heads, pistons, and rods are removed, main bearings inspected, the injection system is gone over, and all parts that show wear or defects which render them unfit for another 6000 hours of operation are replaced.

Now due to the deplorable condition under which nearly all the railroads conduct Diesel-engine maintenance work, both as to the actual work and supervision, the work I have just outlined will take from six to eight weeks, whereas if it were done by the engine-manufacturer's repair crew, or men of similar experience, it could easily be done in four or five days. Thus, in this case, if we have 37½ weeks of service and eight weeks out for work that should be done in five or six days that forces the availability factor down to nearly 80 per cent when it ought to be up close to 98 per cent, which latter availability is regularly obtained by the few railroads who have capable men in charge of maintenance.

We who were the pioneers in the development of Diesel engines for railroad service can truthfully say that it is one of the most difficult applications ever undertaken, primarily due to lack of proper maintenance personnel and supervision on the part of the railroads.

W. L. H. DOYLE.[6] The writer would like to ask the author this question dealing with one point discussed in his paper: Is there an indicated tendency on the part of some engine operators toward use of lubricating oils having viscosity characteristics other than those recommended by the manufacturer? The writer believes that it would be more logical to hold to the use of oils complying with manufacturer's recommendations, which are based on operating experience with the engines on the test floor and in a broad field of application.

F. H. DUTCHER.[7] The author does not mention benefits accruing from supercharging. If Diesel-electric switchers have been supercharged, have there been any beneficial or adverse effects on costs and on the general availability of these locomotives? The writer would also like to know if the percentage of Diesel-electric switchers, relative to steam locomotives, increasing.

AUTHOR'S CLOSURE

In the particular case referred to by Mr. Doyle, the engine manufacturer desired to use what the author would consider as an extra-heavy oil, but the railroad's experience with the oil was such that the railroad considered the lubricating-oil consumption too high and the general engine performance none too satisfactory. Therefore, contrary to the manufacturers recommendation, the railroad experimented with a lighter grade of lubricating oil; however, the oil used was only slightly lighter than the one recommended. After several months, the railroad returned to the use of the recommended oil, and gave the engine manufacturer comparative engine-performance data obtained with the two grades of oil. In this regard, the railroad used the same grade of oil in all of its engines, regardless of type or make.

With reference to Mr. Dutcher's first question, one manufacturer has built a number of Diesel-electric switchers with supercharged engines rated at 900 bhp; the rating of the engine without the supercharger being 600 bhp. These locomotives are mentioned in Mr. Sawyer's discussion of the paper.

The performance of the 900-bhp supercharged engines is, the author understands, better than that of the same engine when it was rated at 600 bhp with normal aspiration. Upon examination after service, the mechanical condition of the engine rated at 900 bhp was better than that when the engine was rated at 600 bhp and examined after a similar period of service; less evidence of heat was found, and the appearance of all the engine parts was better.

Table 5 of the paper can be referred to for a comparison of the cost of fuel for the 900-bhp and 600-bhp engines, which of course increases for the higher rated engine. Since it is the same size of engine, the lubricating oil, of course, doesn't change. Enginehouse expense is the same, supplies cost the same, and wages are the same. The figure for repairs has been increased slightly; however, the amount of the increase is, of course, purely arbitrary. The superchargers themselves require very little attention in service. The figures in the right-hand column of Table 5 of the paper for the 900-bhp Diesel can be taken as representative of supercharged performance. The first cost of the locomotive is very little more than for the normal 600-bhp rating; hence, the saving over steam is even greater.

Fig. 1 of the paper shows that the rated power of the locomotives in use is rising. Probably it is a fair statement to say that

[5] Chief Engineer, National Supply Company, Springfield, Ohio. Mem. A.S.M.E.

[7] Associate, Mechanical Engineering, Columbia University, New York, N. Y.

most of the locomotives going into service now and in the near future for switching purposes will be rated 900 bhp instead of 600 bhp, that is, for the normal switcher. The transfer locomotives carry a much higher rating.

Regarding Mr. Dutcher's second question, the author believes that Diesel-electric switchers are being ordered in preference to steam locomotives. A list of Diesel-electric locomotives placed in service in the last two years is to be found on page 223 of the June, 1938, issue of the *Railway Mechanical Engineer;* a chart accompanying this table indicates the rapid growth of Diesel-engine applications in railroad service, which chart can be used to augment Fig. 1 of the paper. A comparison of the number of steam and Diesel-electric switching locomotives ordered during 1937 can be made by referring to the table of locomotive orders to be found on page 77 of the January 1, 1938, issue of *Railway Age.*

Slag and Deslagging of Steam-Generating Equipment[1]

P. Nicholls.[2] Mr. Bailey does not state how many kinds of powders he has tried, but presumably he has tried at least the seven, which he describes. He makes a nearly neutral statement on the results of the tests, for as he says, it is not possible to duplicate results in such tests even if every effort is made to maintain conditions the same. Thus, it is doubtful whether the differences are caused by the chemicals or by other factors, but the tendency is to hope that beneficial changes are due to the treatment, and to give it the benefit of the doubt.

By what means might accumulations of slag on boiler tubes be prevented? First, and preferably, the particles of slag could be prevented from leaving the bed. Although it is known that with stokers, the weight of the slag carried out of the bed increases with an increase in the rate of combustion, yet it is also known that it decreases as the burning over the area of the bed becomes more uniform, and that holes or uneven burning are responsible for much of the trouble. Thus, there is a possibility at least, of reducing the slagging by insuring a better grade of fuel bed. In a pulverized-fuel furnace, the percentage of slag retained in the furnace can be, and has been, increased by causing the flame to impinge upon the slag bed, and there is the possibility that the ash that does pass to the tubes may have a lower fusion temperature than the average ash.

Second, the temperature of the particles of slag can be reduced so that they will not stick to the tubes. The method that has been employed has been to increase the height of the furnace and use slag-screen tubes, widely spaced, to cool the droplets before they reach the more closely spaced tubes.

Third, the ability of the droplets to adhere to the bare metal might be decreased. For a liquid to stick to a surface it must wet it. There are no data on the adherence property of slags, which property involves equally the nature of the slag and surface. There is of course a greater tendency for the slag to stick to a rougher surface, such as one that has been oxidized. As the surface of contact of the slag particle with the tube is cooled directly the particle impinges on the tube, there would appear to be some hope that this fact, together with the properties of the slag and the surface, could be utilized to prevent adherence; studies may disclose a type of tube surface to which the slag will not stick. It is claimed for some proprietary products that they coat the surface of the tubes, but no conclusive proof has been published that this is a fact.

The alkalies vaporize at relatively low temperatures and can condense on the tubes. That this occurs has been shown by analyses of slag taken from tubes. The inner layer was found to be rich in alkalies but the alkali content of the outer layers was less. The reason for this is that as the slag thickens the temperature of its outer surface becomes too high to permit the alkalies to condense. Whether a thin deposit of alkali would increase or decrease the tendency of slag to stick is problematical, but if alkali or anything else deposits, the nonsticking property of a special surface might be destroyed.

If the chemical does not volatilize, any action it might have on the slagging of the tubes would depend on its being carried out of the bed on the slag droplet. If the chemical combines with the slag, the properties of the slag would be changed. The change might be favorable with some slags and reduce the sticking ability of the droplet, but because the composition of slags varies, one chemical could not be expected to have the same effect on all slags.

It has been reported, but no experimental data can be offered in proof, that common salt thrown on a hot fuel bed causes considerable slag to fall from the tubes. This can be explained by the fact that the sudden fluxing of portions of the slag sets up mechanical strains in the deposit, or that the tentacles of slag around the tube soften so that they weaken and cannot hold the weight of the block. It is less likely that such actions would result if the chemical left the bed at a constant rate, as it would with a treated coal.

Additions of salt to a fuel bed, repeated at intervals, will loosen scale on boiler surfaces. This refers to thin scale and not to blocks of slag. The writer would ascribe this action to mechanical strain but, although he has seen it occur, he has not conducted controlled experiments. He would expect such action to be more definite with occasional heavy doses than with the application of a uniform treatment to the coal.

The writer's conclusion is that the only manner in which the treatment of coals with small quantities of chemicals could materially reduce the slagging of boiler tubes is that a coating of chemical might reduce the tendency of the slag particles to stick.

Maurice Ratel.[3] To eliminate slag it is better to prevent its formation rather than to try to get rid of it after its formation. It is the writer's opinion that slagging is due to a poor and nonuniform porosity of the fuel bed. It is well known that, in any fuel bed, some parts burn more quickly than others, and this is due to a deficiency of air supply in places caused by a varying porosity of the fuel bed. This condition occurs particularly with multiple-retort underfeed stokers where because of the feeding of the fuel by means of rams, a fuel bed is obtained that is more compact in sections in line with the rams, and which therefore produces stratification of gases. Parts of the fuel bed, specially along the center line of the retorts do not receive sufficient air so that coal is volatilized but not burned entirely. The tarry products driven off are drawn through the bank of tubes of the boiler and condense on the tubes to form a slimy product to which fly ash and unburned particles of fuel stick. Due to the effect of radiation from the burning fuel bed this coating hardens and often becomes a vitrified mass adhering solidly to the tubes.

To prevent slagging it is therefore necessary to eliminate this stratification of gases and this can only be done by obtaining a fuel bed of uniform porosity which makes possible proper air distribution.

The writer has accomplished this result with his improved

[1] Published as paper FSP-60-7, by Alex D. Bailey, in the April, 1938, issue of the A.S.M.E. Transactions, p. 209.

[2] Supervising Fuel Engineer, Bureau of Mines, Pittsburgh Experiment Station, Pittsburgh, Pa. Mem. A.S.M.E. Published by permission of the Director, Bureau of Mines.

[3] Ingenieur E.C.P., Bievres, France.

multiple-retort underfeed stokers and the results obtained have proved the correctness of the theory. To obtain good porosity of the fuel bed several series of stepped secondary pushers are used in each retort, with adjacent series working in opposite directions.[4] By these means a good porosity is maintained in every point of the fuel bed, and hence a better distribution of air and elimination of the stratification of gases.

The results are plainly proved by comparative tests of stokers using this principle with well-known multiple-retort stokers of American design.

Table 1 shows some test results, taken at random, in which boilers, coal, and other conditions are identical.

TABLE 1

	Ratel multiple-retort stoker		American multiple-retort stoker of modern design	
Dates, 1934	May 5	May 12	May 5	May 12
Evaporation rate, tons per hr	97	100	102	95
CO_2 at the time of readings, per cent	12	12	11	14
Temperature superheated steam	817 F	842 F	767 F	640 F
Temperature gas, boiler outlet	662 F	717 F	817 F	914 F
Temperature gas, economizer outlet	275 F	292 F	329 F	345 F

The differences in temperatures are most convincing. With the competitive stoker, temperatures of gases at the boiler outlet as high as 977 F have often been observed after operation for three weeks. Table 2 shows the results of another test with the Ratel stoker.

TABLE 2

Stoker lighted April 6, 1934		Stopped May 2, 1934
Evaporation rate, tons per hr	75	85
Temperature superheated steam	797 F	795 F
Temperature gas, boiler outlet	574 F	597 F
Temperature gas, economizer outlet	221 F	239 F

With the competitive stoker, after operation for 3 weeks, in addition to the high gas temperature at the boiler outlet, there was frequent clogging of the passages through the tubes which compelled shutdown at the boiler. All these troubles have been eliminated since the Ratel type of pushers were installed.

In regard to the use of sanding or water lancing to remove slag, it is the writer's opinion that neither of these methods should be used.

When lancing tubes which are at a relatively high temperature in comparison to that of the water used, sudden contractions occur which cause leaks and act on the structure of the metal rendering it brittle because of this mechanical action. Secondly, water combines chemically with the SO_2 contained in the gases of combustion, forming H_2SO_4 which attacks the steel of the economizer tubes. This action causes pitting and leaks if not the bursting of the tubes.

The sanding of tubes is always dangerous. When practiced, even very carefully, sanding causes a wear of the tubes which weakens them rapidly, and sooner or later, causes them to burst.

To summarize, the best way is to fight slagging and fouling of boiler tubes by proper regulation of the fuel bed and the combustion process.

Author's Closure

The author is fortunate indeed to have Dr. Nicholls' discussion of this paper as he knows more about the subject of treatment for the prevention of slag than anyone I know. Both he and Mr. Ratel have sounded a fundamental truth in saying that the best way to eliminate slag is to prevent its formation, but unfortunately with some coals this is impossible. It is hoped that ways will be devised for improving these fuels and removing some of their objectionable characteristics; washing these coals, in many cases, is particularly beneficial as it seems to remove those ingredients of the ash which are most conducive to slagging trouble.

Operating men will without doubt agree with Mr. Ratel that water lancing should be avoided if possible, and when it is necessary it should be carefully done. Unfortunately this treatment is necessary in many installations using slagging coals, even when firing conditions are the best. This applies to equipment fired with pulverized coal as well as stoker-fired.

The author is glad to take this opportunity to thank these gentlemen for their discussion.

Some Results From Research on Flow Nozzles[1]

Ronald B. Smith.[2] This progress report marks the first concerted effort in the United States toward the establishment of coefficients on standardized nozzles. In view of the experimental background established by research over the last ten years in Germany, Italy, Sweden, France, and other European countries on a standardized profile, now known as the I.S.A. shape, these efforts seem timely.

On the basis of the tests on various sizes of I.S.A. nozzles in smooth and rough pipe reported in Fig. 3, it is interesting to note that while the authors are justified in concluding that the coefficients of the twelve tests do not all fall within the tolerance band prescribed by the V.D.I., there are only four that exceed it and in none of these cases is the difference greater than 0.1 per cent. A comparison of the tests and the standardized coefficients is shown in Table 1. For each test the minimum and maximum coefficient above the limiting Reynolds number is recorded and then converted to include the approach velocity, so that a comparison can be made directly with the standardized data. The standardized tolerances are those of the V.D.I. corrected where necessary for roughness in the pipe. In this country, in fact in all the countries where the I.S.A. nozzle has been adopted, except Germany, the close tolerances of the V.D.I. are not used with the I.S.A. profile, but instead, the I.S.A. tolerances are employed. These tolerances allow ± 1 per cent for small-ratio nozzles increasing to ± 1.8 per cent for the larger ratios, with additions for pipe roughness. All the tests made on I.S.A. nozzles by the authors fall well within the I.S.A. tolerance zone; so, too, do the most recent investigations in Italy.[3] It is interesting to observe that the Italian studies, which were carried to Reynolds' numbers as high as the present work, indicated that, except for a few inconsistent tests at the University of Padova, the coefficients fell within the V.D.I. tolerance band, but the recommendation of the Italian standardizing body was for the adoption of the I.S.A. tolerance zone for reasons of manufacture. There is no evidence from the Italian tests of a continually rising coefficient above the limiting Reynolds number, and it seems to the writer rather difficult to generalize this conclusion on the basis of the limited data of Fig. 3.

The effect of upstream pipe roughness has been recognized for some time and generally treated by an adjustment of the coefficient and of the tolerance on the coefficient. The roughness effect is more severe on orifices than on nozzles and if the comparison between Figs. 3 and 5 is admitted it is more on the long-radius nozzle than on the I.S.A. The effect of pipe roughness has its influence mainly on the upstream velocity profile. A relatively rough pipe will have a more peaked distribution than a smooth approach with the result that the integral of the kinetic energy in

relation to the square of the mean velocity will be greater for the rough approach. As Pardoe[4] has shown, this brings about an increase in the discharge coefficient. This conclusion is opposite to that drawn by the authors but it is verified by Fig. 5 and in part by Fig. 4. Possibly for very high area ratios the effect of the initial kinetic energy on the coefficient is distorted, but on the basis of the results of Figs. 4 and 5 it is difficult to rationalize.

The investigation of the expansion factors of a nozzle is much to be desired. Will the authors please explain on what style of nozzle the present investigation was made and at what point the pressures were measured?

In regard to the pressure distribution upstream from the nozzle face, there does not appear to be uniformity between the results of the Bailey Meter Company and those of the Bureau of Standards with the long-radius nozzle. Inasmuch as the size of the static-pressure hole can influence the result it would be of interest to know the sizes that were employed. The upstream measurements by the Bailey Meter Company on the I.S.A. nozzles agree when plotted against diameter ratio with the results of Witte.[5] The indications from the tests of Table 3 are that the build-up in pressure at the upstream corner is from 40 to 45 per cent of the velocity head in the pipe for area ratios up to about 0.45. For area ratios higher than 0.45 the build-up is less. The explanation for this may rest with the fact that for area ratios above 0.45 the inlet curvature of the nozzle reaches to the pipe wall with a consequent influence on the direction of the approach velocity. A build-up of from 40 to 45 per cent is approximately the same as that found with orifices of equivalent area ratio.

On the downstream side of the long-radius nozzle the authors suggest standardizing the pipe-wall tap at 0.5 pipe diameter. When the tests of Tables 2, 4, 5, and 6 are plotted against area ratio for this location, the results are fairly regular up to diameter ratios of about 0.65, but beyond this point there is considerable inconsistency. This condition, as the authors suggest, is undoubtedly associated with the close clearance between the pipe and the nozzle wall. In view of the fact that the clearance is not fixed by the nozzle proportions, and because of its magnitude will undoubtedly be affected by roughness and other minor influences, would it not be a good idea to limit the use of downstream pipe taps to nozzles with a diameter ratio less than 0.65?

On the basis of the downstream-pressure measurements the authors have been able to ascertain the over-all pressure loss of a nozzle, concluding that this loss is proportioned to $1 - \beta^2$. It may be of interest to know that this result could have been predicted for both orifices and nozzles once the discharge coefficients were established. Consider the orifice installation shown in Fig. 1 of this discussion, and apply the momentum equation between plane 1 at the vena contracta and plane 2 on the downstream side of the diaphragm where the pressure recovery is complete. With the notation:

p_1, c_1 = pressure and velocity at plane 1
p_2, c_2 = pressure and velocity at plane 2
ρ = mass density
β = diameter ratio = D_1/D_2
μ = coefficient of contraction
φ = a discharge coefficient
G = mass flow

the conservation of momentum prescribes that

$$\frac{\pi D_2^2}{4}(p_2 - p_1) = G(c_1 - c_2)$$

[4] "The Effect of Installation on the Coefficient of Venturi Meters," by W. S. Pardoe, Trans. A.S.M.E., vol. 58, 1936, paper HYD-58-6, pp. 677–684.

[5] "Die Strömung durch Düsen und Blenden," by R. Witte, *Forschung auf dem Gebiete des Ingenieurwesens*, vol. 2, July, 1931, p. 245.

or upon simplification

$$\delta_2 = p_2 - p_1 = \mu\beta^2\rho(1 - \mu\beta^2)c_1^2 \quad [1]$$

Now the mass flow through the system may be represented by

$$G = \frac{\varphi \frac{\pi D_1^2}{4} \mu}{\sqrt{(1 - \beta^4\mu^2)}} \sqrt{(2\rho\Delta)} = \frac{\pi D_1^2}{4} \mu\rho c_1 \quad [2]$$

with the result that

$$\frac{\delta_2}{\Delta} = 2\varphi^2 \frac{\mu\beta^2}{1 + \mu\beta^2}$$

and the over-all pressure loss for the installation becomes

$$1 - \frac{\delta_2}{\Delta} = 1 - 2\varphi^2 \frac{\mu\beta^2}{1 + \mu\beta^2} \quad [3]$$

Equation [3] is the classical Carnot relation.

In Table 2 herewith, is shown a comparison between the calculated pressure loss from the Carnot equation and the losses measured by the authors as well as by other investigators. For nozzles a coefficient of $\varphi = 0.98$ and $\mu = 1.0$ was employed, whereas with orifices a friction coefficient $\varphi = 1.0$ and a contraction coefficient based on the A.S.M.E.-A.G.A. data and calculated on the basis of Equation [2] were used.

Authors' Closure

The authors are grateful to Mr. Smith for his extensive discussion of their paper, which, as stated in the introduction, is essentially a progress report. It is altogether probable that their final conclusions may differ from those given in these progress reports because of the inclusion of test data still being received, and from such discussions as Mr. Smith has given.

While it is interesting to have it shown that the tests on I.S.A. nozzles are within the I.S.A. tolerance zone, the authors are not sure whether to regard this as a compliment to the quality of the test work done, or as a critical comment on the uncertainty of fluid-flow measurements with nozzles in general.

In regard to whether the points in Fig. 3 do or do not tend to show a continually rising coefficient, it seems to the authors that there are only 3 which appear definitely to have reached a constant value. These are the two for $\beta = 0.70$ and that in brass pipe for $\beta = 0.80$. All of the others are either very definitely still increasing, or at least not definitely constant. While it is possibly unfair to the readers, it is nevertheless natural for the authors to be more or less influenced by other test data which are still in process of being prepared for publication. In many cases these tests yet to be reported have not indicated that a constant coefficient was reached, irrespective of the nozzle shape or pressure-tap locations, even when with water the differential pressure was carried up to over 50 ft.

The tests with steam reported in the paper were made on "long-radius" nozzles. The pressure-tap locations were approximately one pipe diameter upstream and one-half pipe diameter downstream. These distances were measured from the faces of the pipe flanges.

The authors do not have at hand a record of the pressure-hole sizes used by the Bailey Meter Company in their pressure-gradient tests. At the National Bureau of Standards the diameters of the pressure holes in the 4-in. pipe varied from 0.04 in. for the holes very close to the faces of the pipe flanges to 0.25 in. for the holes one pipe diameter and more from the flange faces.

It does not seem to the authors that Mr. Smith's suggestions of limiting the use of a downstream pipe wall tap to nozzles of a diameter ratio of 0.65 and under is desirable or practical. If this were to be followed it would most certainly have to apply to the use of corner taps because that tap is even farther under the shadow of the nozzle throat. There are three other possibilities: (1) To place a limit on the width of the annular space between the inner surface of the pipe and the outer surface of the nozzle. This would be possible because it is seldom if ever necessary for the wall of the nozzle throat to be very thick. (2) To make use of the tolerance of ± 0.25 pipe diameter in locating the downstream tap so as to have it nearer 0.75 than 0.5 pipe diam. (3) To use a somewhat shorter nozzle. In justification of this alternative, attention is called to the fact that as stated in other reports, the committee is conducting tests with other shapes of nozzles than the I.S.A. and the long-radius as defined in the first paper.[6] These tests are still going on, but a report on them will be made at the earliest possible time.

The Friction of Reciprocating Engines[1]

E. S. Dennison.[2] Near the end of his paper the author states: "It is of interest that the friction-mean-pressure values obtained in the present test do not differ widely, either in value or trend, from those obtained by Taylor[3] with a somewhat similar engine." In both cases, friction expressed as mean effective pressure was found to vary in almost linear relation to the mean (gage) pressure exerted on the piston crown. The similarity in results is of special interest because of the difference in the method of applying pressure. Taylor maintained an almost uniform pressure during the cycle, while the author refers his results to the mean during a compression cycle, maximum gas pressure being about 10 times the initial. The results, taken together, form a useful check. The direct proportion between gas pressure and piston and ring friction, found by Taylor, evidently is not much upset by a change over to fluctuating conditions such as are found in an operating engine. Moreover, this proportionality seems to extend to the region of actual combustion pressures, since the author's maximum was in excess of 500 lb per sq in.

Attempts are sometimes made to identify the friction of pistons and rings either as fluid (i.e., due to an oil film), or as solid or Coulomb friction. The present results show the friction force to be proportional roughly to (1) gas pressure and (2) speed. The first result is inconsistent with film lubrication; the second is contrary to the law of solid friction. Evidently no simple classification of this type of friction is possible at the present time.

Conclusions regarding piston and ring friction, based upon the author's data, have to be made on the assumption that journal-bearing friction at a given speed is constant irrespective of load. This is true only as an approximation. It is unfortunate that the author did not attempt to segregate journal friction from the total. Division of "mechanical" loss into the portions contributed by bearings, pistons, and rings, respectively, is essential in any thorough investigation of the subject which the author undertook.

C. W. Good.[4] About eight years ago the writer tested an

engine to determine the probable variation in friction losses due to the change in direction of heat flow through the cylinder walls. The following procedure was used to determine the effect of the change of heat conditions in the engine operating under its own power as compared to that with the engine being motored by the dynamometer: With the engine operating under stable conditions, the ignition and fuel were shut off, the dynamometer was changed over from a generator to a motor as rapidly as possible, and a succession of load readings were taken for a few minutes. The supply of cooling water was also shut off at the time the ignition was cut off, the purpose being to retain the heat in the engine during the test. It was found that the friction increased at a decreasing rate with time, indicating, as the writer believes, that the cylinder walls on the inside were cooling down as the heat flowed to the water jacket, with the result that the oil film on the walls became more viscous. This fact is pointed out in order to indicate the effect of the temperature gradient in comparing test results where the engine is operating under its own power.

As you increase the combustion pressure, you are putting more heat into the cylinder walls. That means a higher temperature gradient through the walls to the water, which in the author's tests was maintained at 180 F. Therefore, it is quite possible to conceive that the oil would be getting thinner and thinner for successive points along the author's curves and the writer is inclined to believe that this is a fairly good reason for the slope of the author's curves, although the writer has no definite research results other than the previously mentioned observations with which to prove it. Further, there is probably a higher inside wall temperature as you go up along the curve. That would mean high oil temperatures on the walls, which would mean less friction due to the decrease in oil viscosity.

G. B. Karelitz.[5] There are two main sources of mechanical friction in engines, that is, the journal bearings and the piston rings. One might regret that no attempt to estimate the friction in bearings has been made, because that is one part of the friction which can be estimated, probably even tested separately—Dennison's paper[6] gives the necessary data. Does the author know what proportion of the total friction is attributed to the pistons and what proportion to the bearings?

Curves drawn originally by the author but not included in the published paper have an upward bend at the lower speeds, characteristic of friction in bearings.

When it comes to the friction in pistons, we encounter difficulties in spite of the number of papers written and reports made on the physics of piston rings. We do not know what happens under a piston ring during engine operation. The pressure behind the piston ring could be measured, but this does not mean that the metal-to-metal pressure on the cylinder would be known. There may be pools of oil or gas between the rubbing surfaces, in which case part of the load would be carried by the very thin liquid film and part by the metal-to-metal contact. Under the circumstances there is no way to guess what would be the coefficient of friction between the piston ring and the cylinder wall.

This is similar to what happens in a journal bearing on a railway car. In a railway motor axle bearing, which carries about 40 lb per sq in. on its projected area, the coefficient of friction is usually rather low, only about 0.75 per cent. However, if a speck of dirt were to come into the clearance, the friction would increase immediately. The part of the load carried on the liquid film is lost, with the result that solid friction takes place and the friction increases to 2 or 3 per cent, or even higher.

The same thing may happen under a piston ring in an internal-combustion engine. The total pressure behind the piston ring must be balanced by the wall. However, we do not know how much of this pressure is carried by an oil film, gas film (which may act very well as a lubricant), metal-to-metal contact, or a speck of carbon. The amount of pressure carried by these various factors will influence the coefficient of friction to a marked degree.

Harte Cooke.[7] A method used some years ago by the writer for determining friction losses in steam engines might prove of interest in discussing this paper,[1] inasmuch as the same method could be used to investigate friction losses in internal-combustion engines. The writer used the method while testing a 2500-bhp engine which had heavy flat gridiron valves. In determining the indicated horsepower at no load, indicator cards were taken as rapidly as possible for 30 min, the average mean effective pressure from which permitted the calculation of a good average no-load indicated horsepower. It then became the problem to determine how to allocate the various friction losses.

It looked as though the heavy flat gridiron valves would require a lot of power. An assumption was made to determine the distribution of the friction losses. The coefficient of friction of all rubbing surfaces outside the valve chamber and cylinder was taken as X, while the coefficient of friction of the piston rings, piston, and valves was taken as $2X$. The loads on all the bearings were obtained, and, with the coefficient of friction assumed, the friction losses of the engine were determined. If the calculated horsepower was 250 and the result of the writer's estimate gave 322 horsepower, the ratio of these two horsepowers was the ratio between the assumed and actual coefficients of friction. Then, when the writer knew the coefficient, he calculated the horsepower for the various parts of the engine.

The writer found that the valves, which were heavily loaded and unbalanced, took very little power because the stroke was short, whereas the piston rings, which had natural tension pressure of 3.5 lb per sq in., accounted for one of the principal losses, because while the pressure was low the distance traveled per minute by the pistons was very high.

A similar method could be applied to allocate the friction losses in an internal-combustion engine. The engine could be motored to determine the total friction and pumping losses, after which the head could be taken off and the test repeated to eliminate the pumping losses. The test could be again repeated with the pistons out of the engine to determine the shaft friction. The trouble will then be the determination of the friction loss of the piston rings, which will vary because of differences in their natural tension and differences in pressures under the various rings at all load conditions. Tests at full load on internal-combustion engines could be conducted and the pressures behind the piston rings determined, from which the friction losses and friction horsepower could be determined. However, these pressures, the coefficients of friction, and the friction losses could be calculated in turn, and the latter checked with the actual losses.

There is another method available for determining the friction losses in a Diesel engine: Using quarter, half, and three-quarter load as abscissas and fuel consumption as ordinates, draw a line for the total fuel consumption for the various loads and project it until it cuts the base line. From this intersection a fair estimate of friction losses can be made.

Referring to the balancing of pressures behind and in front of piston rings, the writer on one occasion took some steam-engine

[7] Mechanical Engineer, Diesel Engine Division, American Locomotive Works, Auburn, N. Y. Mem. A.S.M.E.

rings, which were 1 1/2 in. thick and had a 2-in. face, and cut a groove in the face near each edge, after which holes were drilled from the bottom of the grooves to the space behind the rings. This was done to balance the rings by cutting down excessive pressures which might occur behind them. These rings stayed in place which gave the writer reason to believe the pressure behind and in front of rings was balanced.

There are many uncertainties to consider when trying to determine piston friction losses, such as clearances, improper adjustment of rings, face conditions at the rings, quality of lubricants, and pressures behind the rings. It is essential that operating data be obtained relative to these factors, all of which bear on piston friction losses and the answer to which would be of inestimable value to engineers interested in the subject.

LOUIS ILLMER.[8] In the next to the last paragraph of this paper, reference is made to a paper[9] published by the writer, and states that in the author's tests no sudden building-up of ring-pocket pressures was found conforming with the writer's deductions.

The paper under discussion does not break down the frictional losses sufficiently to permit a direct check of a phenomenon of this kind. In fact, the results are masked by failure to separate bearing, gear, and other losses from the piston-ring losses, as such.

The writer's hypothesis did not deduce any sudden building up of pocket pressure, but rather an accumulative or gradual self-loading pressure that progressively increases at higher piston speeds. It is only at maximum speeds that the ratio of piston-ring drag to total frictional losses becomes a significant factor. The ring width and its side fit may exert a considerable influence on the intensity and distribution of pocket pressure, but neither is specified in the author's paper.[1]

When replotting the reported test points (after deducting for pump work), the graph lines do not converge as stated; instead they may justifiably be drawn in substantial parallelism. When taken thus, the total drag including bearing and piston losses, may be evaluated as

$$\text{FMP} = \left(\frac{P_{cyc}}{8.2} + 2\right) + \frac{\text{RPM}}{275} \quad \ldots\ldots\ldots\ldots [1]$$

where P_{cyc} = mean cyclic pressure acting behind the piston, lb per sq in. gage.

The accompanying bearing and valve-gear losses usually constitute the major portion of this FMP value. While the paper under discussion affords no appraisal of such bearing losses, a rough separation thereof may be arrived at by assuming that the piston-ring loss becomes substantially equal to the bearing losses when running normally without supercharging under full-speed conditions at $P_{cyc} = 50$. Accordingly, the following expression may be taken as an approximation for such bearing losses on a power-stroke basis in terms of pounds per square inch of piston area

$$= \text{abt } 5 + 1/3\ \sqrt[3]{(\text{RPM})}\sqrt[3]{(P_{cyc})} \quad \ldots\ldots\ldots\ldots [2]$$

When resorting to such interpolation, the piston and crosshead drag may be determined by subtracting Equation [2] of this discussion from Equation [1].

As applied to the test conditions prevailing in the paper[1] under discussion, the corresponding first pocket pressures have been worked out in accordance with the equations laid down in the writer's paper.[9] Fig. 1 of this discussion plots the resulting values, assuming the rings to be 1/8 in. wide and their side faces snugly fitted. It will be observed that such estimated pocket pressures start to build up at different speeds in a proportionate relation to the supercharging pressure used, that is to say, the bore-contacting pressure of the first ring is not directly responsive to the initial manifold pressure alone but to piston speed also.

Going a step further, by dividing the remaining unit piston-ring drag by the pocket pressures plotted in Fig. 1 of this discussion, some idea may be gained regarding the prevailing friction

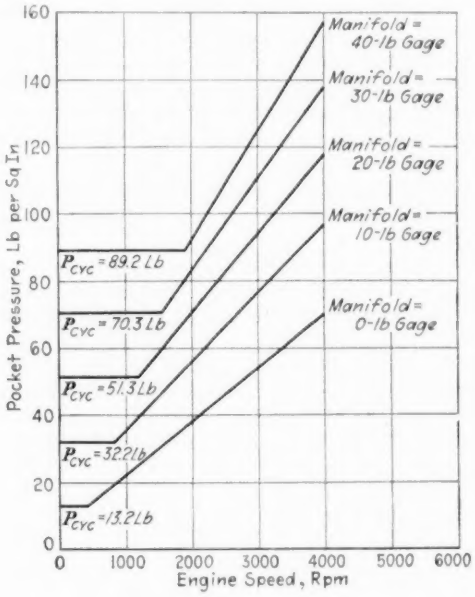

FIG. 1 ESTIMATED POCKET PRESSURES P_r

coefficient f_{exc} that applies to the first ring. Without elaborating on this aspect, it is found such coefficient takes on the following characteristic

$$f_{exc} = 0.08\ [5\sqrt[3]{\text{RPM}} - (80 - P_{cyc})] \quad \ldots\ldots\ldots [3]$$

This finding applies after the oil film has partially broken down and the frictional ring drag starts to increase directly with augmented pocket loading. The numerical value of Equation [3] of this discussion is dependent upon both the P_{cyc} and rpm factors, and when plotted reaches a common abrasive maximum value of $f_{exc} = 0.08$ at around 4000 rpm. The rpm factor evidently bears a relationship to the rate of accumulative pocket-pressure rise. Actually f_{exc} never drops to zero, but at a moderate P_{cyc} value goes over into an oil-borne-film condition for which the coefficient is relatively low. Although the rated engine speed was 3600 rpm, all the reported tests were for some undisclosed reason restricted to 3000 rpm.

According to Fig. 1 of this discussion, the estimated ring-pocket pressure rises from 13 to 70 lb per sq in. between 500 to 4000 rpm for nonsupercharged conditions. If the alleged accumulative action did not actually occur, the maximum ring-friction coefficient, because of its lowered bore-contacting pressure, would have to be correspondingly increased to about $5.4 \times 0.08 = 0.43$. Such an excessive value would be entirely unreasonable under well-lubricated high-speed conditions.

Therefore, the writer believes that the author's tests, as far as they go, tend to prove rather than disprove the existence of an accumulative pocket pressure. Furthermore, it is questioned whether his supercharging method does constitute a rational basis for fixing upon ring-pocket behavior, particularly where the bearing and incidental fixed-gear losses cannot be sufficiently broken

down to allow of definitely segregating piston-ring drag. In any event, no accurate deduction can be drawn from combined piston and bearing measurements where the latter factor remains inherently large.

B. J. ROBERTSON.[10] There are many inconsistencies arising from the conventional method of obtaining friction horsepower by motoring an engine with an electric dynamometer. A compression-ignition engine of the precombustion-chamber type in the laboratories at the University of Minnesota gave the following results during dynamometer tests at full load and 850 rpm: Brake horsepower = 42; friction horsepower = 24; fuel consumption = 0.445 lb per bhp-hr; fuel consumption = 0.283 lb per ihp-hr; brake mean effective pressure = 74.3 lb per sq in.; friction mean effective pressure = 42.3 lb per sq in.; and indicated mean effective pressure = 116.6 lb per sq in. It is quite evident that the fuel consumption per indicated horsepower hour is impossibly low, so that it may be presumed that the friction horsepower as determined by motoring is too high.

Moore and Collins[11] report a friction mean effective pressure of 5 lb per sq in. due to the friction produced by the air passing from the main chamber to the antechamber of a compression-ignition single-cylinder engine. The nozzle between the precombustion chamber and the main clearance chamber of the engine was $^1/_4$ in. in diameter so that the friction losses due to air movement in and out of the precombustion chamber would undoubtedly be much greater than in the N.A.C.A. engine.[11] It seems probable that the density of the gases passing through the precombustion-chamber nozzle would be somewhat greater when the engine is motored than when it is operated under power, and that the power loss when motoring the engine is excessive because of greater density.

Another source of discrepancy between the friction losses while motoring and under power is found by reason of the heat rejected to the water jacket while motoring the engine. The expansion line falls below the compression line, producing a compression loop. The mean effective pressure of this loop in the engine with a five-to-one compression ratio tested by Moss[12] was given as slightly over 1 lb. A high compression ratio with correspondingly high air temperatures during the friction run should increase the area of the compression loop.

Moss[12] also reports that the friction losses in the single-cylinder Benz engine were twice as great when operating under full power and full spark advance as when the engine was motored. The discrepancy between the friction losses of the two previously mentioned engines when tested by the motoring method, indicates that there is a great need for further investigation along this line. The method employed by the author would yield valuable additional information if applied to engines of different types.

The author emphasizes the effect of the high pressure of the piston rings against the cylinder walls. The excessive friction and consequent wear produced by the high pressure of the top piston ring against the cylinder wall is indicated by the familiar ridge found in any used engine immediately above the highest point to which the ring travels. The depth of the wear at the extreme top is greatest with high-compression engines. It is undoubtedly true that the lubrication between the ring and the cylinder wall is poorest at the top position, but the hypothesis that excessive pressures against the cylinder wall are responsible for wear is borne out by the excessive clearance found at the mid-stroke position on some aircraft engines. Side thrust of a rather short piston itself is very likely responsible for this condition. Excessive side-wall pressures which are caused either by rings or by piston skirts may be expected to result in excessive wear.

Just what pressures exist behind the top ring at high speeds is not known. The work done by Professor Ford and the writer on a slow-speed engine,[13] indicates that there is, without a doubt, a time lag in transmitting the pressure to the second ring groove. The two curves in Fig. 2 of this discussion represent pressure behind the top ring and the pressure behind the second ring. It will be noticed that the pressure behind the second ring is very nearly constant for the compression and expansion strokes, while the pressure behind the first ring shows a wide fluctuation. At high speeds there may be a lag in transmitting the cylinder pressures to the top ring groove also. Until information is available on the ring-groove pressures at high speeds it seems necessary that friction tests be made with pressure variation in the cylinder approximating those occurring when the engine is operating under load. The author's method employs cylinder pressures that fluctuate in a normal manner.

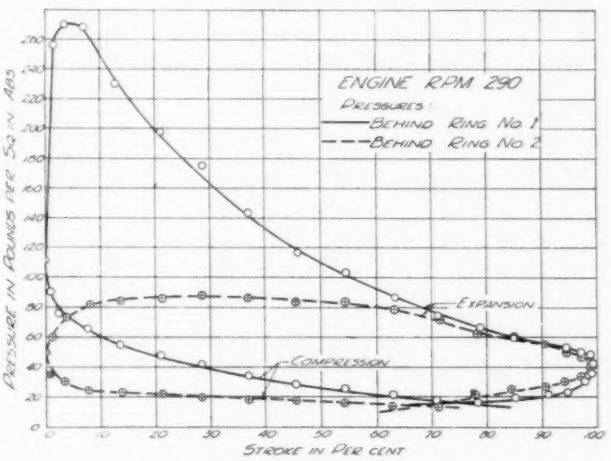

FIG. 2 COMPARISON OF PRESSURES BEHIND THE FIRST AND SECOND RINGS OF AN INTERNAL-COMBUSTION ENGINE

Fig. 8 of the paper[1] indicates that there is lag in the transmission of the pressures to the rear of the rings, because the curves of mechanical friction versus speed become flatter with increased mean pressures on the pistons.

It is reasonable to suppose that the friction of the individual rings will be proportional to the pressure in the respective ring grooves. Tests made by removing the first ring to evaluate the friction on the second ring, etc., do not give the true picture because the gas pressures in the combustion chamber are then transmitted directly to the second ring and the pressures produced by it are very nearly the same as those that existed behind the first ring when it was in position.

Mechanical friction is a large fuel consumer in many types of internal-combustion engines. The difference between the losses in different types is so great that a more complete understanding of the contributing causes is greatly needed.

Author's Closure

Messrs. Dennison, Karelitz, and Illmer have mentioned the failure to separate piston and journal-bearing friction. It is regrettable that this was not done. It was felt that it would be a mistake to make any structural changes in the engine until the work was completed, and for this reason it is impossible at present to furnish data on bearing clearances, ring pressures, and the separation of mechanical losses. It is hoped that these figures may be presented in a later paper.

Professor Good noted the effect on friction of change in piston and ring temperatures, and suggests that this is one of the reasons for the decrease in slope of the curves of friction mean pressure, both in relation to speed and also to indicated mean effective pressure. This is very likely the case. In fact, this is one of the reasons that the compression-expansion cycle, as described, was used in this investigation.

Mr. Cooke's suggested method of determining Diesel-engine friction losses by plotting fuel consumptions over a load range might well be used in the case of a constant-speed injection engine, particularly where the fluid-pumping losses are known or can be determined. For carburetor engines, however, the effects of change of mixture proportionality and fluid-pumping losses with load variation are believed to be so serious as to make this method unsatisfactory as a means of determining mechanical friction losses.

Mr. Illmer's discussion states his belief, and gives his reasons therefore, that this paper tends to prove his hypothesis of a building-up of piston-ring-pocket pressures at high speeds. He also notes that the maximum speed reported by the author was 3000 rpm. As was stated in the paper, it is regretted that the equipment available for this work was not capable of higher speeds.

When the results as given in the paper are examined in connection with the work of Taylor, which has already been mentioned, and with the discussion of this paper by Professor Robertson, particularly with respect to his suggestion of increased pocket-pressure lag with increased speed, Mr. Illmer's conclusion would seem, in the author's opinion, to be unwarranted.

In Mr. Taylor's investigation a constant air pressure was maintained above the pistons, which would tend to result in constant pressure, subject to blowby, back of the several piston rings. If his figures are replotted to give the relation of friction mean pressure to rpm for any constant air pressure, the resulting curve will be seen to have substantially the same shape as those presented in the paper, except that the Taylor curve has a somewhat higher and more constant slope.

The author believes that this bears out Professor Robertson's idea of increased lag, and a consequently lower mean ring-pocket pressure as speed is increased.

Income Versus Production[1]

Comfort A. Adams.[2] The writer has for some years been well aware of the trend pointed out so clearly in the diagrams, although never before has he seen such complete statistics over a long period. The logic of the situation, as the writer sees it, is briefly as follows:

1 Every dollar that goes into the savings or investment pocket beyond the need for capital, means that much less demand for consumer products, which are the only ultimate products of industry.

2 Since the receivers of interest and dividends, as a whole, spend a much smaller percentage of their income on consumer products than do the recipients of wages and small salaries, it is obvious that the larger the interest-and-dividend end of the nation's income, the smaller is the demand for consumer products, and the more unstable is the whole economic structure.

However, it was not intended to tell the author what he already knows, but merely to indicate a vital interest in the article, which to the writer's mind touches the sore spot of the whole economic order.

John B. Coleman.[3] From the data given in Table 1 of the paper the writer has prepared the chart shown in Fig. 1, herewith, in which the incomes of the various groups are plotted as percentages of the group incomes in 1919. The assumption is made that the 1919 income was reasonably fair in amount and in distribution and, according to the writer's recollection, this was so since almost everybody that wanted work was working, incomes were high, people were spending money, and profits were good. What really happened was that from 1919 to 1929 a much larger share of the goods produced went into profit and overhead. The additional profit must have been on the order of twenty-five billion dollars in that ten years, and this provided the surplus money which was invested in foreign bonds and certain "monuments to imbecility," that served no useful purpose.

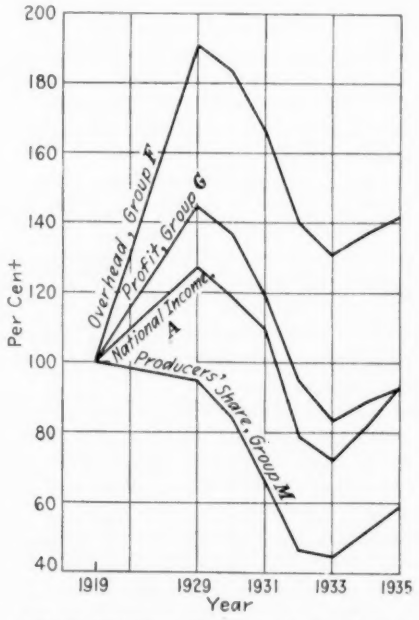

Fig. 1 Chart Showing Percentage of National and Group Incomes Based on the Year 1919
(Data taken from Table 1 of the paper.)

Now it is perfectly obvious that the additional profit spent in this way used up goods that the producers were not able to take, and therefore, there was a fictitious sense of prosperity and good times, accompanied by a side effect of rising prices on the New York Stock Exchange. When the debacle came in 1929, there was no place in which these surplus goods could be sold, and unemployment commenced.

It would seem that it is perfectly obvious that the three lines—profit, national income, and producers' share of the national income—should follow practically the same course. Overhead might increase, although perhaps a great deal of the increase

[1] Published as paper MAN-60-1, by Walter Rautenstrauch, in the April, 1938, issue of the A.S.M.E. Transactions.

[2] Consulting Engineer, E. G. Budd Mfg. Co., Philadelphia, Pa. Mem. A.S.M.E.

[3] Chief Engineer in charge of fire-protection engineering, Grinnell Co., Inc., Providence, R. I. Mem. A.S.M.E.

shown in Fig. 1 was unjustified. In other words, those engaged in trade probably got more than their share in the years 1919 to 1929. Certainly the other three lines must be held close to one another if any reasonable degree of security and employment is to be attained for the great mass of the people.

W. D. ENNIS.[4] With much of the author's paper it is possible to agree. The paper does real service in stressing the fact that national income equals national production. Disagreements will start with two questions of fact:

1 *Is the National Overhead Increasing?* The paper treats as productive, only the salaries and wages of workers in six of the fourteen groups contributing to national income, plus total incomes of farm owners. All else is overhead—for example, public-health service, education, merchandising, policing, and government road building. The paper shows, as between 1919 and the period from 1929 to 1935, a startling increase in the ratio of overhead (so called) to production.

Whatever this ratio is, it is not overhead. The implication is that the purchase of services is something to be limited, while the purchase of labor for producing commodities is something to be promoted.

Fig. 2 of this discussion reflects the results of a similar study, continuously from 1919 to 1935, according to the uniform technique of the National Bureau of Economic Research. The author's figures indicated are from two different sources, and in both cases are based on unrevised data. Here groups 1 to 4 correspond to the author's commodity-producing groups; not merely the labor included therein, but the whole of the national income credited thereto.

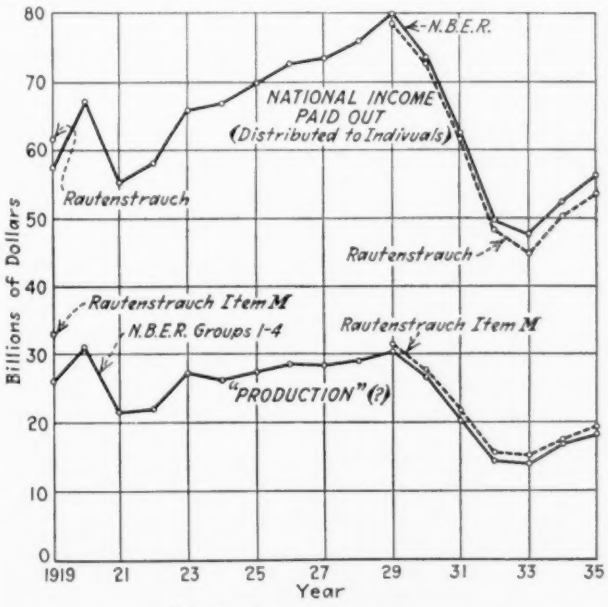

FIG. 2 COMPARISON OF DATA

(Solid lines represent data from National Bureau of Economic Research Publication 32, p. 18.)

The author's groups 5 to 7 are not included therein and not shown on the diagram. They, with group 8 (trade), bear a fairly constant ratio (0.219 to 0.249, lowest in 1935) to total income distributed to all groups, and may therefore be eliminated from the discussion.

[4] Humphreys Professor, Stevens Institute of Technology. Mem. A.S.M.E.

These curves, like the figures of the paper, spell a falling ratio of production to total income paid out, and hence a rising proportion of "overhead" (groups 9–14) to "production" (groups 1–8). The ratio of total overhead to commodity production (groups 1–4) rose from 120 per cent to 206 per cent. But, the reference[5] tentatively concludes, this increase was due "exclusively to the decline in the prices of commodities, which was greater than (that) in the prices of services." This point is ignored in the paper. The reference quoted in Fig. 2 makes the ratio referred to, when price fluctuations are eliminated, 148 per cent in 1919 and 138 per cent in 1933. The average for the first 8 years of the period was 158 per cent, and for the second 8 years it was 154 per cent. Here is no increase whatever.

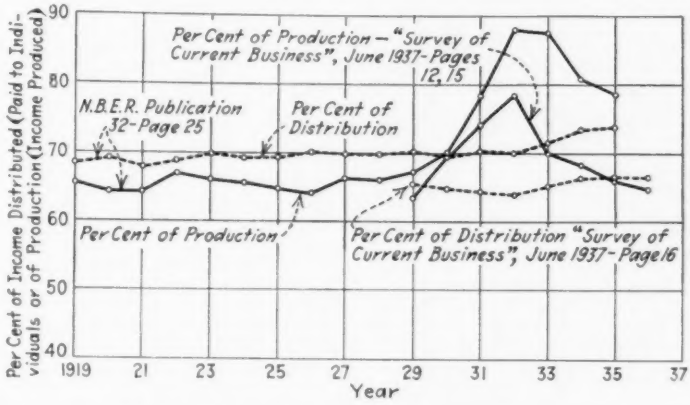

FIG. 3 LABOR'S SHARE IN THE NATIONAL ECONOMY

2 *Is Labor's Share Decreasing?* The paper stresses a decline in the percentage of total income paid as compensation to employees, although admitting that the amount paid employees has increased. Global figures were available, and are presented in Fig. 3. Labor's proportion in the total economy, on either basis referenced, has not decreased, it has increased. The share of labor in production, as here contrasted with the share in total distribution, is particularly noteworthy.

The paper shows declining shares to labor in manufacturing, mining, contract construction, and other activities. These are activities of increasing mechanization. Now mechanization has to be paid for, in interest and dividends. Thus, in such industries, labor's share tends to decline (not necessarily labor's amount). Relief is afforded by employment in service activities—which the paper labels unfavorably as overhead.

To sum up, the paper proposes a purely arbitrary definition of overhead. It exaggerates the increase in what it defines as overhead. There has, however, been some increase in the proportion of total income (actual dollars) paid out to the service activities. That this is disadvantageous has not been demonstrated. It is chiefly and perhaps wholly due to irregular price variations.

Dollar payments for labor have increased slightly faster than total national income. In hard times, they hold up better than national production. The percentage of income paid directly for labor may decline in particular industries, especially where labor is costly, and must do so where mechanization is involved. But in total, labor's share has not decreased. On the contrary, it is one of the most stable figures in our economy.

RALPH E. FLANDERS.[6] It is an original idea to analyze the operations of the national economy as a whole in much the same

[5] National Bureau of Economic Research, Publication 32, p. 22.

[6] President, Jones and Lamson Machine Company, Springfield, Vt. Past-President A.S.M.E.

way as would be done in analyzing the operations of an individual business. The paper is very much worth-while on this account. The writer's criticisms for the most part relate to factors which would be taken into account in the individual business, but whose counterparts in the national economy do not seem to have been recognized by the author.

If the analogy of private business is to be followed, it is not surprising to find the national overhead and, in general, the percentage of indirect expenses growing. That is the case as more and more efficient methods of production are applied to the individual business. Less of the expenditure goes to direct labor, and more to indirect labor and to capital expenditure, particularly in the recovery of capital costs through depreciation. It may be said roughly that the greater the efficiency of a business, the higher are indirect costs in relation to direct. The net cost, however, is lower, and all the indirect expenses serve as a means of distributing income for the purchase of the output.

These points are of particular importance in the treatment on page 215, in which it seems not to have been realized that capital costs are in a large measure distributed and become available as purchasing power of the product produced; and similarly on page 218, the process of distribution seems to have been assumed to be in some way separate from production and not a part of the process of putting finished goods in the consumers' hands. This seems to be fallacious. Distribution is part of the overhead in the total process and serves as one of the means for the distribution of the purchasing power for obtaining possession of the goods as they reach the market. In general, the author seems to have looked at the economic process too narrowly, as though some few workers most directly concerned with production were the only ones whose work contributed to the total result and whose wages constituted the necessary purchasing power.

In making comparisons with private business operations, it is not at all surprising to find that social overhead increases in a depression; it does in private business as well.

Another point that seems to need clearing up is whether the rendering of all services belongs in the overhead. It would seem that this is not the case. The great mass of people engaged in rendering personal services, whether in beauty parlors or kitchens, and those of higher grade, furnishing concert music and operating libraries, are as much a part of the process of making goods and services available as are the men in an automobile factory, for instance. Sometimes one wants to take an automobile ride, and sometimes one wants to read a book from the library. The whole nexus of organization which permits the one or the other to be done, stands very nearly on the same footing, except that the one is related to goods and the other to services.

A useful line of inquiry, it seems to the writer, would be to make some estimate of the proper proportion of the returns from industry that should go into capital expenditure and the proportion that should go into consumption goods. There is, of course, an optimum division of activity between capital and consumer goods which could theoretically be determined, although practically it would be difficult to do.

Capital-goods production must be great enough to replace worn-out equipment and finance an expanding population, as well as finance an increasing standard of living. It must also be great enough to replace uneconomic equipment with new and better equipment where economic conditions justify it. It must be great enough, furthermore, to finance the shorter working week and also single-shift operation in noncontinuous industries, unless two- and three-shift operation is considered to be a part of the "more abundant life." In addition, the proportion which goes into capital expenditures must be great enough to finance experimentation, research, and development work, much of which will be thrown away, as well as leaving a share for making good on the other types of losses inherent in a free economy.

To the writer the diagrams are the most interesting part of the paper. To appraise their significance, however, it would be necessary to have them carried over a greater span of years so that it could be seen whether the tendencies noted are cyclical, secular, or catastrophic.

RUSSELL SPRAGUE.[7] In connection with the matter of the overhead on the total national production, the writer has recently completed an analysis corresponding to that of the author for the whole period from 1910 to 1929. The picture presented in the paper seems somewhat distorted. The author compares the abnormal period from 1929 to 1935 with the single abnormal year, 1919. A truer picture is obtained when the periods immediately before and after 1919 are also studied.

Table 1 of the paper shows a "par" ratio $(F + G)/M$ of 85.4 per cent in 1919 and a large increase thereafter. But this ratio varied from 99 per cent in 1918 to 133 per cent in 1910, averaging 128 per cent for the whole period from 1910 to 1916.[8]

The author deplores the fact that while in 1919 the overhead group received only 46 per cent of the national income, this had increased to 68 per cent in 1932. But his Fig. 1 also shows that in 1909 the overhead group received 54 or 55 per cent of the national income.

Data exist for the period following 1919,[9] and also revised figures from King for 1919. The ratio varies from a minimum of 94.4 per cent in 1920 to a maximum 149 per cent in 1929. The maximum of 149 per cent compares with 148 per cent in the paper, but the figure for 1919 is 103 per cent, not 85.4 per cent as stated in the paper. For the whole period from 1921 to 1929, the ratio is 137 per cent, which is not significantly above the figure of 128 per cent for the period from 1910 to 1916.

G. L. TUVE.[10] The paper is an excellent example of engineering analysis applied to economics, and the author is to be commended for such a compact and unbiased presentation.

When he suggests that the facts are obscured "to those who think in terms of money instead of in terms of goods," he has certainly pointed out one of our basic troubles. Engineers should do their share to bring the attention back from the "counters" to the goods themselves, or better still, to the human effort necessary to produce the goods.

The author states (p. 218) that "the issuance of claims to goods (money) not associated with the processes of production always constitutes a hazard to the national economy when the issuance of such claims tends to increase at a rate greater than the rate of production." As an example he cites "government expenditures for relief which are not balanced by the production of goods." Is it not possible that if economic difficulties are being produced by an insufficient number of claims for consumer goods (low consumer purchasing power), the increasing of such claims may improve the condition of the national economy? According to Figs. 3 to 7, inclusive, the "claims to consumption of goods in excess of current personal needs," in other words savings, have been accumulating faster than they could be used in the capital-goods industries. If some of these claims to consumer goods are transferred by taxation to immediate consumers (i.e., families on relief), who will at once exchange them for consumers goods, will not the stoppage and unemployment in the consumers-goods industries be partially relieved at the same time that human need

is being met? Granted that better ways should be found to relieve the stoppage, nevertheless the taxation method should improve matters in an emergency, because it is actually a reversing of the trends shown in Figs. 3 to 7.

Readers of this paper should not miss the analysis made by another A.S.M.E. member, Dr. H. C. Dickinson, in his book "The Mechanics of Prosperity."

Author's Closure

Professor Ennis attempts to refute the argument that the overhead on the national plant has increased materially during the last 17 years, by using an entirely different grouping of income disbursement from that used in the paper. It is the author's belief that his own groupings are both rational and important and that the ratios shown in the paper have important significance in our economy.

However, their meaning should be more fully explained. This Professor Ennis fails to do. What the author had hoped would ensue from this discussion was more light on the economic and social significance of the ratios shown.

The Fig. 2 drawn by Professor Ennis does not "reflect the results of a similar study," but of a wholly different study. The study he refers to is found in chapter 3 of "National Income and Capital Formation," entitled "Distribution According to Industrial Origin;" the author's study related to "Income Payments to Individuals." In the study to which Professor Ennis refers, incomes by industries, a comparison is made between commodity-producing industries, not individuals, and "other industries." The complete reference, of which Professor Ennis quotes only a part, is, "If the estimates underlying Table 5 are to be trusted, the apparent decline over the period in the relative share of the commodity-producing industries in the economic system *as measured by the industrial distribution of the national product*, was due exclusively to the decline in the prices of commodities, which was greater than the price of services."

This reference also continues: "But in view of the slender basis upon which the difference and adjustment of price changes rest, it is perhaps best to leave this conclusion as a tentative suggestion deserving further explanation." In view of these considerations, Professor Ennis' criticism cannot be taken seriously.

Under the heading, "Is labor's share decreasing?" Professor Ennis cites the percentage which employees' compensation, both productive and overhead, is of the total national income. He does not address himself to the issues raised in the paper, but uses ratios which, as stated in the paper, do not set forth the important relationships. Under the same heading, Professor Ennis states, "New mechanization has to be paid for in interest and dividends." Many of us are not so sure of the "has to be," particularly as to the amounts involved. The paper raises the questions of the workableness of the relative shares of capital and labor to the goods produced. That is the engineering question involved. The concluding remarks of Professor Ennis are so obviously outside the scope of the author's thesis that a reply is not called for.

The comments by Professor Adams and Mr. Coleman throw additional light on the important problems of the relationships with which the paper deals.

Mr. Flanders suggests that because private business is increasing its ratio of indirect to direct expenses, it is not surprising to find the overhead on the national plant increasing. Quite true, but both the national plant and private businesses are now in a rather bad way. Mr. Flanders seems to have failed to grasp the main points in the paper, i.e., that it is the relationships between labor's claims and capital's claims to the goods produced which cause the first disturbance; and the relationships between the trend in employment and wages in creating form utility, and the trend in employment, wages, and income in creating other utilities, which cause the second disturbance. This is apparent in his statements, "All the indirect expenses serve as a means of distributing income for the purchases of the output" and "capital costs. . . . . become available as purchasing power of the product produced." Such statements are too general to have any value in a critical analysis. Furthermore, capital costs have not been expressing themselves in purchasing power, as Mr. Flanders well knows, and that is one of the causes of unemployment.

Mr. Sprague presents a more critical analysis and quite properly calls attention, as did the writer in his oral presentation, to the fact that 1919 was a "low" year for the producers. But to state that the period from 1929 to 1935 and the year 1919 were all abnormal, implies that Mr. Sprague knows what the normal is. The author does not. Certainly the data for the period including the war years cannot be regarded as relating to a normal period. The author does not understand how Mr. Sprague arrives at a ratio of overhead to production of 103 per cent in 1919. The data of Table 2, which are believed to be correct, show a total national income of 61,628 millions of dollars, of which the producers received 33,224 millions and the overhead was 28,404 millions. This gives a ratio of 85.4 per cent of overhead to production.

Professor Tuve suggests that taxation of savings and the use of the resulting funds in purchasing power through unemployment relief may improve the conditions of the national economy. It will, temporarily, but as a permanent measure it is, in the author's opinion, unsound. The very fact that this measure must be resorted to demonstrates that our present methods of distributing claims to goods are not workable.

Effect of Temperature Variation on the Creep Strength of Steels[1]

J. J. Kanter.[2] A much needed clarification of the effect of temperature variations on the creep strength of steels is afforded by the author's skillful and instructive treatment of the subject. Both the metallurgist who seeks to smooth his creep curves and the engineer who must incorporate creep data in the design of machines and structure, will find these correction formulas and methods helpful.

In discussing this paper it is the aim to suggest a somewhat different basis for the functional relationships between secondary creep rate, stress, and temperature, which in no way reflects upon the practical aspect of the author's analysis in so far as the end results are concerned. It is the writer's thought that a choice of such functions as lead to physical interpretations of the creep phenomena itself might ultimately provide a sounder basis for analysis than the purely empirical choice of functions and constants which are made in the paper. The advantages of generalizing the creep-strength equations in a manner that leads to fundamental constants which bear relations to other properties of the material should be obvious.

In a recent paper[3] the writer attempted a representation of the relationship between secondary creep rate, stress, and temperature, based upon certain concepts borrowed from thermodynamics and statistical mechanics. Consider a series of secondary creep rates obtained at a single stress over a range of temperature containing no critical points. If these are plotted with the logarithm of rate versus the reciprocal of the absolute temperature, a

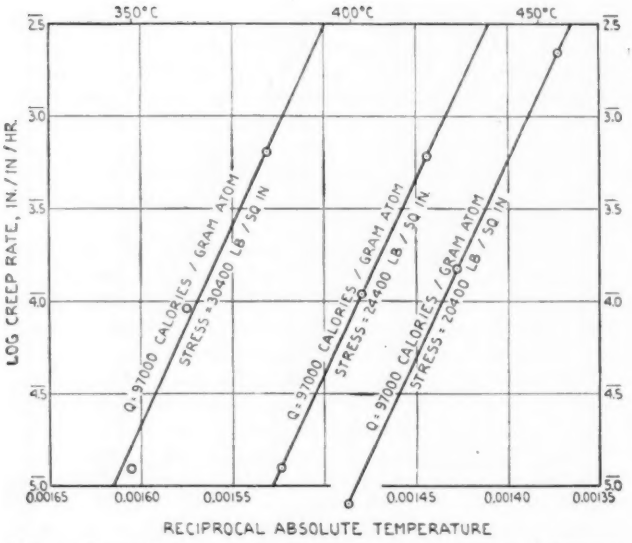

FIG. 1 CREEP RATE OF ARMCO IRON AS A FUNCTION OF ABSOLUTE TEMPERATURE[4]

straight line is determined as illustrated in Figs. 1 and 2. The slopes of lines so determined can be interpreted in terms of the energy involved in the process leading to creep strain over that range of temperature. It is noteworthy that the slope upon such diagrams, regardless of the stress involved is a constant value within the temperature range. If the logarithm of the creep rate divided by stress be plotted versus a suitable stress function the isotherms upon this diagram are linear and parallel, and the ratio of values also leads to a definite slope when plotted against the reciprocal of the absolute temperature, as illustrated in Fig. 3. These findings are mathematically expressed in the following equation, applying within the specified range of temperature

$$\ln\left(\frac{v}{\varphi_0 \sigma}\right) = f(\sigma) - \frac{Q}{RT} \quad \ldots\ldots\ldots\ldots [1]$$

where ln = natural logarithm; v = constant tensile creep rate, in. per in. per hr; σ = tensile stress, lb per sq in.; φ_0 = flowability constant; $f(\sigma)$ = stress function relating creep rate; Q = quantity of energy, cal per g mol; R = gas constant, 1.987 cal per deg mol; and T = absolute temperature, k. This analysis gives a kinetic picture of creep in which metal atoms, having an average energy proportional to the absolute temperature, must chance to

attain great enough activation to surmount a barrier energy Q, before participation in creep strain. The fact that similar values of Q are found over large ranges of stress suggests that strain energy has but little effect upon the necessary activation, but rather influences the probability that metal atoms will attain the necessary activation.

Suppose it is desired to apply Equation [1] to the problem of effect of temperature variation on the creep strength of steels with which the author is dealing—the variable is then defined as a constant, v_0, and $v_0/\varphi_0 = \sigma_0$. Furthermore, since a range of stress above zero is to be considered, a stress function compatible with Equation [1] of the paper can be chosen by letting

$$f(\sigma) = (n - 1) \ln (\sigma/\sigma_0) \quad [2]$$

where n is the same slope of a log-log plot as used by the author and σ_0 is the stress constant.

Substituting these values, Equation [1] becomes

$$\ln (\sigma/\sigma_0)^n = \frac{Q}{RT} \quad [3]$$

or, written as an explicit function of stress

$$\sigma = \sigma_0 e^{\frac{Q}{nRT}} \quad [4]$$

where e is the base of natural logarithms. Defining σ_T as the nominal creep strength at absolute temperature T, and σ_{T_0} as

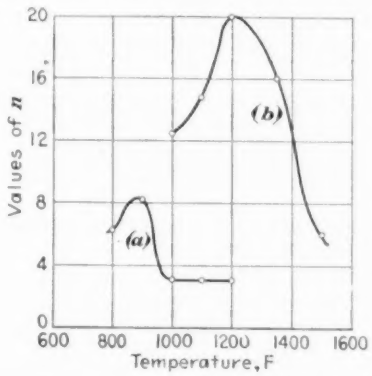

FIG. 4 VALUES OF n VERSUS TEMPERATURE

(n = slope of plot of log-log creep rate versus stress. Curve (a), 0.15 per cent carbon steel, Fig. 3 of the paper. Curve (b), austenitic steel, Fig. 6 of the paper.)

the nominal strength at any other absolute temperature, T_0, within the range where the data are represented by the log-log type of diagram

$$\frac{\sigma_T}{\sigma_{T_0}} = e^{\left(\frac{Q}{nR}\right)\left(\frac{\Delta T}{TT_0}\right)} \quad [5]$$

in which ΔT is the spread in temperature ($T - T_0$).

Equation [5] is then similar to case 1 of the paper. The value Q serves as a strength index as does the author's k. When considering steels and iron, Q is usually found to have values in the vicinity of 90,000 cal per g mol and merits being considered a physical constant of iron and steel. The author's k can be shown to be a function of Q and the temperature range by comparing his Equation [2] with the writer's Equation [5,] from which it is readily deduced that

$$nk = \frac{Q}{RTT_0} \quad [6]$$

Thus the various cases of temperature variation for which the

(Austenitic steel, Fig. 6 of the paper.)

author has derived formulas may be conveniently related to the creep of any metal for which Q and n can be evaluated, merely by making use of Equation [6].

The power n from the log-log plot assumes an interesting significance in connection with Equation [4]. As pointed out in the paper, experimental values of n vary from unity to as high as 20, depending upon the material, the temperature, and even the portion of stress range considered. Data upon the creep of lead at small stresses show the value approaching unity, in which case the rate of creep is directly proportional to the applied stress. Creep under this circumstance obeys the law of pure viscous flow, for which in general there is but little partition of energy, and motions or displacements of molecules are free to take place essentially as do the molecules of liquids or gases. The average energy of such relatively unrestrained molecules, as for instance those composed of grain-boundary atoms, is approximated by RT. The greater the restraints upon the atoms, however, the greater becomes their partition of energy, with the result that the effective average energy appears to become some value nRT. In general, as temperature increases and the molecular or lattice restraints of metals grow weaker, it is found from creep data that the values of n diminish and tend to approach unity as a limit. The decrease, as will be shown, however, does not always proceed uniformly, presumably due to phase changes which may occur.

Examining the references to the original data for Figs. 5 and 6 of the paper, one finds considerable variation in the slopes of the plots of log-log creep rate versus stress between various temperatures. Thus, the value of n cannot be considered a constant independent of the temperature, except over limited ranges. For the 0.15 per cent carbon steel tested by Clark and White, for which the author uses $n = 3$ at temperatures between 900 and 1200 F, the writer deduces the values shown in Table 1.

While $n = 3$ may be a fair value to use between 1000 and 1200 F, too large a change takes place between 900 and 1000 F to warrant its use as far down the scale as 900 F. Again, in the case of Norton's data for austenitic steel from Fig. 6 of the paper for which the author uses $n = 15$ for temperatures between 1000 and 1400 F, the following array of n values has been deduced by the writer from the published log-log plots.

While $n = 15$ represents a fair average of these values between 1000 and 1400 F, it is the writer's belief that the spread between $n = 12.5$ and $n = 20$ is too large to be discharged as error incident to experiment, but rather that it bears a definite physical significance. It is interesting to note that for both ferritic and austenitic steels the n values reach maxima at temperatures corresponding to the point of most intense temper embrittlement for the respective steels. See Fig. 4, herewith. These are also the temperatures usually associated with strain-hardening relief and equicohesion. All these facts are suggestive of the thought that transitions are in progress at these temperatures, which may well lead to anomalies in the observed values of n. If, as suggested, n is an index of energy partition, it is not surprising to find it rising to a maximum in the vicinity of a critical temperature.

Equation [4] suggests a diagram where the logarithm of the creep stress is plotted versus the reciprocal of the absolute temperature as illustrated by Figs. 5 and 6. As shown in Fig. 4, the power n is a function of temperature reaching a maximum value over the temperature ranges considered. It follows then that the creep-stress curve has an inflection point at the temperature corresponding to the maximum of the curve representing the index n. It then follows that the slopes of the tangents to the creep-stress curves in Figs. 5 and 6 determine the partition energies Q/n, involved in creep strain at the particular rate represented. The energy Q, then, is proportional to the product of the slope and the value of n for the corresponding temperature. Expressed analytically, this statement is equivalent to the equation

$$n \frac{\Delta\sigma}{\Delta T} = -\left(\frac{Q}{RT}\right)\left(\frac{\sigma}{T}\right) \quad \ldots\ldots\ldots\ldots [7]$$

This gives a method for testing the self-consistency of several creep stresses for a metal determined over a range of temperature. According to Equation [7] a temperature curve passed through the creep-stress points should have tangent slopes which, when multiplied by n for the corresponding temperature, are equivalent to the right-hand expression. Graphical tests upon the data of Tables 1 and 2 are illustrated in Figs. 5 and 6. If a Q value of 90,500 cal per g mol is taken for the 0.15 per cent carbon steel, tangents are determined which pass a smooth curve through the stress points, with an inflection point at about 870 F. In the case of the austenitic steel, a value for Q of 268,000 cal per g mol is deduced by this method, giving the curve an inflection point at about 1200 F.

While the writer holds no fixed brief for the validity of the physical conceptions herein expressed, he does believe that the mathematical methods used give a more precise representation of the actual data than is afforded by the corresponding devices proposed in the paper. The formulas for various cases of temperature variation, which the author has so ingeniously developed, will reflect actual data more accurately, if the index nk is computed according to the requirements of the writer's Equation [6].

Author's Closure

The author is greatly indebted to Mr. Kanter for his discussion of fundamental metallurgical questions. The paper as published was intended to represent the application or utilitarian viewpoint. The author's formulas are based on two experimentally determined coefficients or indexes which are usually subject to rather limited variation over the range of conditions required for the analysis of high-temperature machines and equipment. Thus they may be considered as constants except for great temperature differences. These limitations were discussed in the paper.

It is of interest to note in Mr. Kanter's Equations [6] and [7] that as T approaches T_0 the expression

$$-\frac{1}{\sigma}\frac{\Delta\sigma}{\Delta T} = \frac{-\frac{\Delta\sigma}{\sigma}}{\Delta T} \text{ approaches } k$$

thus establishing the essential identity of Equations [6] and [7]. (Mr. Kanter expresses k as a ratio instead of a percentage as used by the author.)

These expressions lead to the conclusion that the product kn, the increase of rate per degree, varies inversely as the square of the absolute temperature so that materials are likely to increase in rate somewhat less rapidly at higher temperatures than according to the author's formulas. Certainly this is a welcome conclusion.

Equations [6] and [7] enable the computation of the product, kn, from a thermodynamic constant of the material Q or vice versa. It is, of course, highly desirable to be able to do this when the constant Q is known for the material in question, especially if extensive creep data are not available. However, when good creep data are available, it may well be that they will serve to determine the value of Q. In any event the results computed from both sources should agree, and there is no reason why they should not. This whole process is a step toward rational interpretation of test results.

Mr. Kanter gives values of n for various temperatures in Tables 1 and 2. Tables 3 and 4 give, in addition, values of k, the product kn, and the values of Mr. Kanter's constant Q computed from the existing creep data by the use of his Equations [6] and

[7]. It is not the intention of the author to discuss the significance of Q. It is recorded here simply because the data are available to determine it at the various temperatures of the tests.

1350	16.0	0.541	8.7	314,000
1500	6.1	0.870	5.3	224,000

Fig. 7 has been drawn to illustrate how the original data correspond with the rules proposed by Mr. Kanter and those used by the author. The scales are logarithmic and the temperature scale has been doubled so that a 45-deg line has the required two-to-one slope for a line of constant Q; whereas horizontal lines represent constant kn.

The test points are connected by straight lines. The broken lines represent the values of Q suggested by Mr. Kanter while the shorter dot-and-dash lines represent the values chosen by the author for use over a limited range of temperatures. The carbon steel between 1000 and 1200 F appears to follow the author's rule more closely than Mr. Kanter's while the austenitic material, especially in the middle range of the data, appears to follow Mr. Kanter's equation.

The question arises as to how the results computed in the paper as published would be affected if the original creep-test data had been plotted against the reciprocal of the absolute temperature (as required by Mr. Kanter's theory), instead of the temperature itself, with a straight line on semilog paper being used to represent the results in each case. The difference is easily computed for a bar all too hot or cold, or for a bar hot half the time and cold half the time, but for the important case of uniform variation from cold to hot, the algebra does not seem easily integrated. However, graphic methods may be used. Figs. 8*A* and 8*B* duplicate Figs. 4*A* and 4*B* of the paper and show the altered results in fine lines. Looking at the left, the relations proposed by Mr. Kanter indicate just slightly less excess creep than the formulas published by the author. Similarly at the right, the proposed relations show slightly less deficiency of strength. In other words, the author's formulas are just slightly "on the safe side," as the engineer says, although for variations of ±30 F the difference is less than the width of the lines in the diagram.

Decomposition of Sodium-Sulphite Solutions at Elevated Temperatures[1]

R. M. HITCHENS[2] AND J. W. PURSSELL.[3] While the authors have been studying the behavior of sodium-sulphite solutions at high temperatures in laboratory bombs, the writers have been making a similar study on high-pressure boilers in which the temperatures are comparable but the concentration of sulphite is far less than that used in the bombs.

Tests have included examinations of boiler water and steam in boilers of 675 and 1400 lb pressure for traces of sulphide and sulphite. The purpose of the work was to investigate the possibility of hydrolysis of the sulphite to liberate sulphur dioxide, or autoxidation and reduction to sulphide and sulphite.

It was found possible to detect colorimetrically with lead plumbite as little as 0.02 ppm sulphide in a colorless boiler water, and 0.4 ppm in a colored water by distillation of the hydrogen sulphide into ammoniacal cadmium chloride.

By collecting condensed-steam samples in an inert atmosphere, reducing with aluminum and alkali, acidifying, and collecting the sulphide produced on a lead-acetate strip, it was found

[1] Published as paper RP-60-6, by W. O. Taff, H. E. Johnstone, and F. G. Straub, in the April, 1938, issue of the A.S.M.E. Transactions

[2] Monsanto Chemical Co.

[3] Boston Edison Co.

possible to detect 0.01 ppm sulphur and to estimate the amounts. Sulphide could be detected with the same sensitivity and technique by omitting the reduction step, or could be detected to 0.02 ppm colorimetrically.

These tests were applied to the boilers of the Monsanto Chemical Co. of St. Louis, Mo., which operate at 675 lb pressure, saturated-steam temperature of 497 F, and superheater outlet temperature of 730 F. The boiler water was dosed with 130 ppm of sodium sulphite. No sulphide whatever could be detected in the water. Likewise no sulphide or sulphite (less than 0.01 ppm S) could be found in steam condensed from the superheater inlet or outlet. The boiler-water sample was taken from the continuous blowdown line and cooled under pressure in a small steel-tube condenser. The steam samples from the superheater inlet and outlet were taken from connections welded into the tops of the two horizontal headers. From these connections, the steam passed through a short length of $^1/_2$-in. steel tubing to a stainless-steel-tube condenser in which it was condensed under pressure.

The absence of sulphite in the steam is to be expected since the boilers are equipped with steam washers which reduce the carry-over to a minimum. Failure to find sulphite likewise demonstrates the absence of hydrolysis of sodium sulphite.

The experiments at the Boston Edison Co. were carried out on boiler no. 7, Edgar Station, at 1400 lb pressure, saturated-steam temperature of 577 F, and superheated-steam temperature of 725 F.

With 100 ppm of sodium sulphite in the boiler water no sulphide whatever (less than 0.02 ppm S) could be found in the water by the sodium-plumbite method. This indicates the absence of autodecomposition to soluble sodium sulphide and sulphate. As mentioned before, this does not preclude the possibility of the reaction proceeding directly to a solid ferrous sulphide and sodium sulphate. The possible extent of this reaction will be discussed later.

Extensive tests were made of the sulphite and sulphide content of the saturated and superheated steam. The results of tests with the boiler on full load are tabulated in Table 1, which shows the sodium-sulphite content of the boiler water, the sulphite-plus-sulphide content of the steam, and the sulphide content of the steam.

[a] These tests run at a later time. See text

Even with no sodium sulphite in the boiler water, i.e., after the boiler had been drained, refilled, and run three days without sulphite addition, there was a trace of sulphite in the steam. This amount rose to 0.03 ppm S with 9 ppm sodium sulphite in the water and to 0.2 ppm with 175 ppm sulphite in the water. The tests for sulphide are conflicting. In the first series of tests sulphide was found in traces, increasing in amount with the sulphite content of the water. In a second series of tests run several months later, no sulphide whatever was found, even with 175 ppm sulphite in the water. See[a] Table 1. The latter tests were run on a boiler which had been drained, refilled with fresh water, and operated for three days without sulphite treatment. It is possible that any sulphide formed reacted with oxides produced on the metal surfaces during operation without sulphite.

There is in these tests evidence that if water containing sulphite goes over into the steam it can undergo autodecomposition, both while passing to and while passing through the superheater.

That the sulphite found in the steam is the result of carry-over is indicated by the reduction in the sulphite content of the steam which occurs with decreasing the load, as shown in Table 2.

TABLE 2

		Saturated steam		Superheated steam	
Load, lb steam per hr	Sodium sulphite in boiler water, ppm Na_2SO_3	Sulphite + sulphide, ppm S	Sulphide only, ppm S	Sulphite + sulphide, ppm S	Sulphide only, ppm S
120000	20	0.02	Neg	0.04	Neg
50000	20	..	..	Neg	Neg
30000	20	..	..	Neg	Neg
20000	20	Neg	Neg	Neg	Neg
200000	130–175	0.23	Neg	0.20	Neg
50000	130–175	0.05	Neg	0.07	Neg

If hydrolysis were occurring, its extent would be dependent only upon the concentration of sulphite in the water, the pH value, and the temperature, and would be independent of the load. Thus, the partial pressure of sulphur dioxide in the steam should be constant and the amount of sulphite would not vary.

Now a comparison of the reactions in the boiler water will again be considered. At 579 F, essentially the 577 F in the Edgar Station boiler water, the authors observed that a sodium-sulphite solution underwent autodecomposition to sodium sulphide and sulphate, the reaction rate conformed to a differential equation of the first order, and progressed half way in 90 min. If the same thing happened in the boiler, it would be necessary to feed an enormous amount of sodium sulphite to the water to maintain any appreciable residual. Likewise, dose feeding would show a high initial concentration which would drop to one half in 90 min, to one quarter in 3 hr, and so on. This, however, was not the case. Addition of sulphite was often omitted for a week, and the water still contained sulphite at the end of the period.

During a certain 44-hr period the sulphite concentration fell from 130 to 30 ppm sodium sulphite. Of this, a loss of 72 ppm was accounted for by carry-over. The remaining 28 ppm not accounted for, 35 per cent of the average amount in the boiler during the period, amounted to only 0.20 lb per million lb of steam, sufficient to react with only 0.025 ppm oxygen. Assuming no oxygen whatever, 35 per cent in 44 hr is the maximum loss of sulphite by autoxidation and reduction. The authors found this much in 40 min. Further, there was no evidence of any such decomposition.

A similar condition existed in a 1790-lb boiler recently visited. The sodium-sulphite concentration of this boiler was maintained continuously at 30 ppm, which required the addition of 2.5 lb per day.

Extrapolation of the reaction rate found in the bombs to 613 F the temperature of this boiler water, would indicate a consumption of 50 lb per day, which is far in excess of the total amount fed.

Conclusions

1 Hydrolysis of sodium sulphite does not occur in 675-lb and 1400-lb boilers with as much as 170 ppm sodium sulphite in the water and with pH values of about 11.5. The steam is free from sulphur dioxide (less than 0.01 ppm S).

2 Similarly the waters in these boilers are free from soluble sulphides (less than 0.02 ppm S).

3 Steam from the 675-lb plant is free from sulphite and sulphide (less than 0.01 ppm S).

4 Steam from the 1400-lb plant contains traces of sulphite as carry-over. It likewise contains traces of sulphide in some

tests, but not in others, showing that decomposition of the sulphite carried over can occur under some conditions.

5 There cannot be accounted for more than 35 per cent autodecomposition of sulphite to sulphide and sulphate in the boiler water at 1400 lb pressure and 577 F in 44 hr; further, there is no evidence that any occurs. The authors found 35 per cent autodecomposition in 40 min, 50 per cent in 90 min, and 75 per cent in about 3 hr at this temperature. In view of the variance between these findings, it is evident that there is a wide difference in the behavior of concentrated and dilute solutions and that the reaction is really only pseudo first order.

6 Operating conditions in a 1790-lb plant indicate the same situation as described in the preceding paragraph.

7 In view of these results, there seems to be no objection to the use of sodium sulphite for oxygen removal in high-pressure boilers. Continuous feeding to maintain 10 to 20 ppm of sodium sulphite in the boiler water is indicated.

This is not offered as a final report, because the results were obtained on a limited number of boilers. The details of the methods of test are available and will be furnished gladly to those interested upon request. Suggestions and criticisms are solicited

Authors' Closure

It is important to note that there is no essential disagreement between the results reported by Hitchens and Purssell and those of the authors. The tests made by the latter were run at concentrations of about 4000 ppm of sodium sulphite. Under these conditions decomposition was found in every case at temperatures of 545 F and higher. These tests have been extended to lower concentrations in some experiments made by Professor Straub in bombs equipped with a steel reflux condenser. His results are shown in Table 3 herewith.

TABLE 3 DECOMPOSITION OF SODIUM-SULPHITE SOLUTIONS IN STEAMING BOMBS

Test	Temp, F	Time, hr	Sodium sulphite, ppm At start of test[a]	Sodium sulphite, ppm At end of test	Per cent original sulphur present in solution
1	420	48	500	220	92
2	420	28	500	175	...
3	580	44	500	30	78
4	580	45	500	30	68

[a] Before bomb was closed; oxidation by dissolved oxygen is expected.

They show that there is an abnormal decrease in the sulphite and in the total sulphur in the water at 580 F when the initial concentration of sulphite is from 200 to 500 ppm. While soluble sulphide was not found in the residual solution, evidence that it was present in the steam was indicated by the copper-sulphide scale identified from the condenser.

There were two reasons for choosing the high initial concentration for the first tests: (1) To explain the disappearance of sodium sulphite from a high-pressure boiler in which localized concentration was believed to exist; and (2) to permit following the reaction without using complicated semimicroanalytical methods. At the high concentrations the rate of decomposition is proportional to the concentration of residual sulphite, a relationship which is generally said to indicate a first-order reaction. In all of the tests made over a 36-hr period, however, the percentage of sulphite remaining was between 2.4 and 4.1 per cent of the original amount, corresponding to from 96 to 160 ppm. Since this concentration would have been reached in a much shorter time (from 6 to 23 hr at from 600 to 550 F), if the initial rate of decomposition had prevailed, it is evident that the reaction either reached equilibrium, or slowed down appreciably at low concentrations. The small concentrations of sulphide found in high-pressure boilers by Hitchens and Purssell using sensitive methods of analysis, show that the latter alternative is probably true. The results of the two investigations, therefore, are not at variance and may be considered as actually confirmatory.

The fact that the decomposition is "pseudo first order" rather than of true first order is only of academic interest. The practical engineer is primarily interested in knowing the answer to the question, "Does sodium sulphite decompose in actual operation?" On the evidence obtained so far it appears that at concentrations not exceeding 30 ppm in a boiler in which no abnormal concentrations are likely to occur, the salt does not decompose at a rate of practical importance. At concentrations between 30 and 200 ppm and above 545 F, some decomposition does occur and this becomes rapid in still more concentrated solutions.

Even when decomposition does occur little is known about the nature of the products and whether their presence would be considered detrimental to boiler operation. It would be expected that the hydrolysis of alkali sulphides to give hydrogen sulphide in the steam would take place as readily as that of carbonates to give carbon dioxide. There is indeed some evidence that this hydrolysis does take place. First, in the laboratory tests under steaming conditions the total sulphur content decreases when the vapors come in contact with copper or clean iron surfaces. Second, in the tests reported by Hitchens and Purssell on the high-pressure boilers, in Table 1 of their discussion, no sulphide was found in the boiler water but in several cases corresponding analyses by their sensitive methods showed sulphide in the saturated steam entering the superheater, before concentration of carry-over could have taken place. Thirdly, in the production of hydrogen sulphide by the reaction of sulphur with caustic, it is reported that the sulphide is completely removed from the solution when boiled at 90 lb steam pressure.

It is obvious that the chemical investigation of this subject is not complete. In view of the complexity of the reactions of sulphur compounds as shown by the extensive work of Foerster on decomposition of sulphurous acid and its salts, further investigation would seem to be justified as a precautionary measure.

Combustion of Pulverized Coal[1]

E. Kilburn Scott.[2] Naturally, there is much said in this paper about oxygen. The writer notes especially the remark on page 294: ". . . .the large particles must complete their combustion in the end of the furnace where the concentration of oxygen is low and where there is only limited turbulence," and again on page 296: "In a boiler furnace the concentration varies from 21 to about 2 per cent, and the average concentration in which the large particles burn probably does not exceed 6 per cent."

May the writer suggest the installation of an oxygen-making plant, as an adjunct to superpower plants, which could furnish an intermittent or continuous supply of oxygen at points where there is still some fuel and the oxygen has fallen below, say, 5 per cent.

As a means of stopping smoke nuisance, this extra oxygen supply could be used to good advantage, especially since almost any expenditure would be justified to stop excessive smoke in populated areas. Modern power stations are not supposed to create smoke, but there are times, as when bringing a new boiler onto load, when it is almost impossible to prevent smoke entirely; therefore, the additional apparatus the writer suggests seems justified. The oxygen supply could be made automatic through a connection with the invisible-ray apparatus used for smoke-density detection.

[2] London, N. 1, England.

At places where there would be danger of burning the oxygen-jet nozzles, and where there is impinging due to change in direction of hot gases, powdered magnesite might be tried. That which the writer has in mind would be shrunk entirely in an electric furnace, then ground to a powder, mixed with a binder and brushed or sprayed on nozzles, etc. As long ago as 1902 the writer suggested such a use for some Indian magnesite which he had shrunk electrically in a furnace at Meraker, Norway. It was used for the protection of nozzles of water-gas burners at a plant in Hunslet, Leeds, where corrugated flues were being made for marine boilers; it was rather too expensive a proposition for those days, but that consideration would not apply today.

F. K. Ovitz.[3] The combustion reactions in a boiler furnace are practically completed within the flame boundary, and it appears that temperature in the flame rather than the temperature of the surrounding furnace gases would exert the major influence on the reactions.

The burning of fuel oil is more complex than the burning particle of coal. It is generally considered that the atomized oil entering the furnace is vaporized into gaseous form and raised to the ignition temperature before burning. The hydrocarbons from the vaporized oil combine with oxygen to produce primary oxidation products which react with a further supply of oxygen and finally are burned to carbon dioxide and water. Some of the hydrocarbons decompose thermally at the temperature of the flame to produce carbon, hydrogen, and lighter hydrocarbons which react also. Oxidation and thermal decomposition (cracking) occur simultaneously. The vaporization and cracking absorb heat which must be provided by the flame and furnace walls. Rapid vaporization and early ignition aid combustion as shown by experiments in a small furnace burning oil. These showed that higher CO_2 with the same degree of cleanness of combustion was obtained in a combustion chamber constructed of insulating firebrick than in one constructed of standard firebrick. The same burner and oil rate were used in each case. The difference is attributed to the higher level of temperature.

The writer's experience confirms the statement of the author that mixing is the controlling factor in combustion. Many examples have been encountered where the mixing characteristics of oil burners change significantly when the capacity at which they are operated is changed. Better control of mixing will solve many combustion difficulties.

W. C. Rudd.[4] Although this paper, with its many ramifications, is of utmost interest to those in charge of the design, construction, and operation of coal-burning power plants, there are many phases of pulverized-coal burning which merit further consideration. With this in mind, the writer submits the following questions and discussion:

How does pulverized-coal burning compare with stoker-fired plants? How does the investment in equipment of the two types of plants compare? What are the relative efficiencies of the two types? What are the costs of steam production in both types of plants over a long period of time? What grade and cost of coal can be used in a pulverized-coal plant as compared with a stoker-fired plant? Then too, there are other related operating problems, such as the explosion hazards in a pulverized-coal plant and the need for minimizing them. Probably one of the most important problems in a plant burning pulverized coal is the disposal of ash refuse, especially the elimination of the fly-ash nuisance.

[4] Engineer of Water System Construction, Water Department, Detroit, Mich. Mem. A.S.M.E.

There is another field for the burning of pulverized coal, that is, its use in conjunction with burning sewage sludge for the development of power in sewage-treatment plants. Incinerators for burning sewage sludge can be constructed so as to have steam boilers, thereby generating steam from by-products; a plant of this type is now being built for the Sanitary District of Chicago. Sewage sludge, depending upon the process of treatment, has a heating value of from 5400 to 6500 Btu per lb on a dry basis, and normally contains from 60 to 80 per cent moisture. As long as the moisture is below 75 per cent, the sludge has a definite heating value and can be used for steam generation.

When the new Detroit sewage-treatment plant was designed, nonheat-recovery and heat-recovery sewage incinerators were considered, but the former was chosen because the engineers in charge believed that the heat-recovery incinerator for steam generation was still in the experimental stage.

The new Detroit sewage treatment plant, now under construction, is expected to have a load of raw sludge of 280 tons daily (dry). This includes screenings and grit and the net heating value is about 1.7 billion Btu per day; the heat for evaporating moisture in the sludge has been deducted in arriving at this value. This heat used in a steam-generating plant burning both pulverized coal and sewage sludge would produce about 90,410 kwhr of electric power daily (33,000,000 kwhr per yr), or 80 per cent of the total requirement. The writer believes that there are great possibilities for the development of the sewage-treatment plant for steam generation, wherein the sewage-sludge incinerator for heat recovery and the burning of pulverized coal can be combined.

John Blizard.[5] The author has given an interesting description of the combustion of pulverized fuel and has dealt at some length with the rate of combustion in furnaces the walls of which are cooled. He was one of the first to advocate cooling the furnace and his early predictions that this cooling would not increase the combustible loss have been proved correct by tests on many boilers equipped with waterwalls. If, today, the combustible loss is unduly high, very few endeavor to reduce it by reducing the cooling surface in the furnace, but instead one looks to the fineness of the coal and the manner of providing it with air as a means of reducing this loss.

The commonly accepted idea that raising the temperature of reacting substances increases the velocity of the reaction very rapidly arose from experience with gaseous reactions. This increase of velocity is explained by assuming that it is necessary for a molecule to possess a minimum of energy E before it can react. The kinetic theory of gases tells us that the proportion of all the molecules at the absolute temperature T deg F abs, which possess kinetic energy in excess of E, is given by $e^{-E/RT}$, where R is the gas constant. If we assume E to have the value, for example, of 50,000 Btu per lb mol, we find that the number of molecules possessing energy in excess of E is twelve times as great at 2500 F abs as it is at 2000 F abs, and it is 47 per cent greater at 2600 F abs than at 2500 F abs.

However, when burning pulverized fuel we have a heterogeneous reaction, and the author suggests that the temperature of the oxygen is of little importance provided the temperature of the fuel is above the ignition temperature. He further suggests that when a particle of fuel at a suitably high temperature is in the presence of air, the rate at which the particle burns is governed largely by the rate at which oxygen molecules will impinge upon a surface, regarding presumably the diffusion of the oxygen and products of combustion to and from the particle as a negligible part of the process. He uses these suggestions as a means of ex-

[5] Consulting Engineer, Foster Wheeler Corp., New York, N. Y. Mem. A.S.M.E.

plaining the reduction of the time of combustion of a particle of fuel in an atmosphere of air when the temperature of the furnace is decreased. This does not appear to be a valid explanation of the U. S. Bureau of Mines experiments as may be seen from the following considerations.

Let us assume that a cube of fuel, each side of which has a length of d inches, is subjected to the impingement of oxygen at the rate of M lb per sq ft sec and that each molecule impinging on the surface combines with the fuel. Then, if S is the pounds of oxygen required to burn one pound of fuel, the density of which is w lb per cu ft, the total amount of oxygen required to burn the cube of fuel is $Sw(d/12)^3$. The average surface on which the oxygen impinges during the course of the complete combustion of the cube is equal to one third of the original surface or $(6/3)(d/12)^2$, and the total amount of oxygen impinging on the particle during the time t sec required for the completion of combustion is given by

$$2Mt(d/12)^2 = Sw(d/12)^3$$

from which the time for complete combustion is given by

$$t = wdS/(24M)$$

and for charcoal with $w = 30$ and $S = 2.7$, the time of combustion is given by $3.4\ d/M$.

The rate of impingement of oxygen under a pressure of 0.21 atm is given by

$$M = 145(1/T)^{1/2}$$

where T is the temperature of the oxygen, F abs; which, for a temperature of 1651 F ($T = 2111$ F abs) gives a value of 3.1 lb per sq ft sec for the rate of impingement. Using this value of M for the combustion of charcoal would mean that a cube of charcoal of 1 cu in. volume would burn in a little over 1 sec with air at this temperature, and a particle which is a cube 0.01 in. on a side would burn in something over 0.01 sec. These times of combustion are only a small fraction of the actual times and the impingement of molecules on a surface calculated from the kinetic theory of gases appears to have little bearing on the rate of combustion unless used in combination with principles of diffusion and some theory of molecular activation.

If the writer interprets the Bureau of Mines experiments correctly, they show the time during which a particle glows when dropped into a furnace which is held at various temperatures. While these times should represent fairly well the time taken to burn the particles, it must be remembered that they contain no record of the time taken to heat the particle up to a temperature at which it glows, and during this period the particle has oxidized to some extent. It seems reasonable to suppose that the particle begins to glow at the same temperature regardless of the temperature of the furnace, and since more heat will penetrate into the particle, when it is heated slowly in the cooler furnace than it will when heated more rapidly in the hotter furnace, the particle in the cooler furnace will actually be hotter as a whole on reaching the temperature at which it glows than will the particle in the hotter furnace. It appears to the writer that this higher internal temperature at the moment when glowing commences, coupled with the greater intensity of the convection currents of air caused by the greater difference between the temperature of the products of combustion and surrounding air in the cooler furnace, is a more likely explanation of the phenomenon, though it can only partially explain the large differences in the times of combustion with the temperature.

Messrs. Tu, Davis, and Hottel[6] give a good account of the theory of the rate of combustion of carbon and apply it to their experiments on the rate of combustion under forced convection. They found that at the highest surface temperatures and lower velocities there was little difference in the rate of combustion, so that it appears probable that, when as in a powdered-fuel furnace the relative velocity of the air and size of the particle are both smaller than that obtaining in these experiments, there will be little difference in the rate of combustion with a change of temperature of the particle of coal once the particle has reached a high temperature.

While it seems probable that a particle of coal will burn somewhat more rapidly in a furnace which is not cooled than in one which is cooled, it must be remembered that this does not mean necessarily that the particle will be burned more nearly completely in the hotter furnace. In fact, since the density of the gases in the hotter furnace is less than the density of the gases in the cooler furnace it will take the particle longer to pass through the cooler furnace, give it more time to burn, and so may render the combustible loss less in the cooler furnace than it is in the hotter furnace.

The theory of combustion of coal in suspension involves so many complicated aerodynamic, thermodynamic, and chemical processes that it is unlikely that any satisfactory equation will be established which will give a true picture of the rate of combustion. Certainly one would make a rash and ill-considered statement, were one to state that theory shows that combustion will be less complete in a furnace that is cooled than in one that is not cooled.

RALPH BRISCOE.[7] The author has apparently taken into consideration the basic principles of combustion of pulverized coal in connection with the most modern design of boiler and furnace. He stated that water-cooled furnaces absorbed a large quantity of heat, thereby lowering the temperature of the furnace gas and of the fly ash carried by the gas. As a result these entrained ash particles do not stick to the boiler tubes and the superheater elements.

The writer believes that the application of pulverized coal antedated the development of the water-cooled furnace as we now know it by a good many years. There were, though, very few installations made burning pulverized fuel that did not have some water cooling of the furnace even if it were only a hearth screen. The operation of these furnaces was very interesting from the standpoint of attempting to maintain low and constant furnace temperature over a wide range of rating and maintain these conditions over long periods of operation of the boiler.

In this connection furnaces were designed of relatively large size to keep down the heat liberation per unit of volume. Also, knowledge of the time element necessary for complete combustion of pulverized coal in suspension was perhaps very limited. The writer wonders if the latter were not more the reason than the former. Pulverized-coal furnaces were designed for a heat liberation not much in excess of the stoker, and the stoker installations had been tolerated without water-cooled furnaces because we did not know any different. With the stoker, apart from the high furnace-maintenance cost, most of the trouble due to clinker and slag was in the stoker itself. With pulverized coal burning in suspension, the ash would be in suspension and might stick or adhere to the walls with results only too well known. And stick it did in the early installations, not only on the walls, but also on the hearth where in some cases it was removed with chisel bars and sledges.

The use of pulverized coal was here to stay, because the expected increase in efficiency, greater flexibility, and adaptability

[6] "Combustion Rate of Carbon," by C. M. Tu, H. Davis, and H. C. Hottel, *Industrial and Engineering Chemistry*, vol. 26, July, 1934, pp. 749–757, and August, 1934, pp. 889–892.

[7] Plant Engineer, Trenton Channel Power House, The Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

to larger installations looked very desirable to the power-plant designer in comparison with the then stoker. However, something had to be done with the furnace. The early installations demonstrated that the solid refractory wall was far from being suitable, and, in fact, would be the retarding factor in the application of pulverized coal. But at this time, the air-cooled wall was developed. This generally consisted of a 9-in. refractory wall held back to another outer wall by rows of headers with an air space between the two. A part of the air for combustion was admitted with the coal and the balance circulated between the two walls.

The thought that prompted this was that the inner wall would be kept sufficiently cool with the circulating air so as to help keep the furnace temperature down somewhat and keep the refractory from melting and the ash from sticking to it, but, more particularly, the writer believes it was expected to reduce the thermal stresses that would be set up in a thick heavy wall.

Space will not permit of a review of all the interesting experiences obtained in the operation of large furnaces 25,000 cu ft in volume and over 60 ft high, built with the so-called air-cooled wall. As in most cases we condemn the materials of which the whole is made, this case was no exception to the rule. But experience gained in the operation of these furnaces over the last ten years has demonstrated that there are a large number of details which go to make up the design, and which had just as much effect on the life of the wall as did the kind of brick used.

On these refractory walls, there was a tendency to accumulate, even if it were fragile, a layer of slag over parts of the refractory surface which shaded some of the heat-absorbing surfaces, and, which, in turn, resulted in softening this slag, perhaps forming a ledge and then a concentration of flame on this part of the furnace with detrimental results. There would be some coating of the front bank of tubes and what little extra cooling medium was employed, with slag or ash in different forms, necessitating periodic cleaning and scraping to bring the furnace temperature back somewhere near that desirable and tolerable.

The writer has always thought of the change in furnace temperature with this change in furnace conditions as "furnace sensitivity," all brought about by the ash sticking to the side walls, the front bank of tubes, and the hearth screen. The writer wonders how much or what would be the furnace sensitivity of a completely water-cooled furnace burning pulverized coal of low ash-fusing temperature, operating at a comparatively high rating. Can the furnace temperature be maintained sufficiently low so that the ash when projected at high velocity against the tubes will not be so molten as to stick to the tubes, not necessarily in the form of heavy slag but as a thin layer of hard material sufficiently thick to reduce heat absorption and driven with such force against the tubes as to need exerted mechanical effort to remove?

The author has pointed out that almost any kind of fuel that can be pulverized can be burned. He also pointed out that temperatures above that necessary for combustion are not necessary, and, in the writer's opinion, are very undesirable, for, if we are to burn coals with low-fusing-temperature ash, the furnace temperature should be kept as low as possible. This is desirable because at high ratings we are apt to have high velocities of the gases entering the first bank of tubes and the superheater. If these gases carry the very fine ash in a molten condition at high velocity, it will be projected against the tubes, and, although the tubes might be staggered to prevent bridging of the ash, there will be an accumulation on the outside of the tube that is extremely hard to remove which results in a change in furnace temperature and an aggravated condition, completely undesirable.

Can a water-cooled furnace be designed with a very low sensitivity rating? Can the designer, within reason, predict in advance what the furnace sensitivity will be when burning a certain grade of coal? With the boiler proper reaching a greater perfection in design from a mechanical standpoint and with a furnace of low sensitivity and refractory maintenance costs practically eliminated, is the cleaning of the furnace and cleaning off of the tubes and the water-cooling surface to be the cause of the major outage factor as is now the case in some refractory installations?

It is not expected that combustion efficiency will increase much with the most modern design over the best designs of the last ten years. But the great output per unit now possible, and with an increase in the reliability factor, it would tend to reduce the necessity for so much reserve.

There is another very important factor not to be lost sight of in connection with furnace sensitivity. That is the superheater design. It has been recognized for some time that a nearly straight line of temperature for the superheated steam is desirable. It seems that outside methods—that is, methods used outside the boiler setting—to obtain straight line superheat have given way to the control of the distribution of the gases over the water and steam heat-absorbing surfaces. With low furnace sensitivity, the designer's problem is much easier. Although the design of superheaters and the control and distribution of the gases through the boiler passes and over the superheater might be outside the scope of this paper, it is unfortunate that the author was not asked to review this subject in connection with this paper. His knowledge of the subject in connection with large installations would have made it very interesting.

Naturally, it was desirable, and the writer presumes it is with the latest designs today, to admit the air so that the whole of the combustion space would be used, rather than have large heat liberation in local spots with resultant high temperature. It was surprising the effects on flame length, the furnace temperature, and the heat absorbed by what little furnace cooling was employed by the change in the air distribution into the furnace.

The author states that the impingement of flame against the side of the furnace does not damage the water-cooled wall. It is the writer's belief that the author had in mind the wall would not be eroded away or melted down or slagged over, as would be the case with refractory furnaces. Impingement of flame against water tubes is undesirable unless circulation is exceptionally good.

The author has also stated that the stability of fire is largely a matter of burner design. In the early designs of water-cooled furnaces, the question of fire stability and excess carbon in the ash, at low ratings was a topic. Has not the use of preheated air played a great part in the stability of fire, reduction of carbon in the ash, and high rates of combustion? Is there an upper limit in air temperature from the combustion standpoint above which it is not desirable to go? A discussion of this question would be of interest.

With the older style of furnace, when only a small portion of the air for combustion was admitted with the coal, it was an interesting experiment, mostly cut and try, to determine where and in what portions should the balance of the air be admitted at each place. Contrary to some opinions combustion should not be completed close to the burner, but should envelop the whole of the furnace and be complete before entering the boiler tubes.

The changes which have taken place in the last 15 years in the application of pulverized coal, the development of the equipment to produce it in proper form, and the development of the water-cooled furnace have been so great that only those who have had experience with an installation of recent design are in a position to discuss it with authority. From the bin-and-feeder system of 15 years ago to the present unit system with its improved burner, improved mill and classifier, and the all-water-cooled furnace is a very great step. Again it is unfortunate that the author was not asked to discuss, if only in a limited way, the part the mill

with its complement of auxiliaries plays in connection with success of any pulverized-coal installation. Coal in all its different forms is a very complex mixture and to reduce a larger share of its different forms in one piece of apparatus to usable material in pulverized form is an achievement

E. A. SITTER.[8] The author has stated many advantages of using water-cooled furnaces and has covered them very thoroughly with the exception of the one pertaining to feedwater treatment. Before heat-absorbing surfaces surrounded our furnaces the question of feedwater treatment was not of such vital importance as it is today. The installation of the water-cooled furnace has made it necessary to treat the feedwater to the extent of keeping the heating surfaces entirely free from scale and dirt and to maintain them so continuously. Not only has this practice effected a saving in maintenance costs but it has also contributed largely to higher boiler and furnace efficiencies.

Pulverized fuel fired in water-cooled furnaces makes a very flexible arrangement. Changes in steaming rate of the boiler can easily be followed; however, it also sets up a problem of water-level control in the boiler. A sudden change in steaming rate will tend to change the level of the water because of the difference in density of water in circulation through the wall tubes. Has the author had any trouble maintaining water level in pulverized-fuel-fired boilers where there were wide fluctuations in steaming rate?

Pulverized fuel is not difficult to ignite in the case of starting a fire because the furnace is water-cooled. The difficulty lies in the fact that the air which carries the fuel from the pulverizer to the furnace and that supplied for combustion is at a temperature below that at which pulverized fuel will readily ignite. The temperature of the air and the coal must be raised to and maintained above the igniting temperature by lighting torches of ample capacity until such time as preheated air at reasonably high temperatures is available. A question arises regarding the fuel that should be used for the torches: What are the advantages and disadvantages of fuel oil versus natural gas?

Pulverized-fuel-fired furnaces lend themselves very easily to maintenance of fuel-air ratios, and thus maintain a low excess-air value in combustion at all times; however, the design must be such that an interruption in coal feed from one pulverizer will not seriously reduce the steaming rate of the boiler, and the combustion control regulators must be easily and quickly adjusted to establish a new correct fuel-air ratio, otherwise the furnace efficiency will be considerably lower and there is danger of losing ignition. What precautions should be taken when taking one pulverizer out of service where two are supplying fuel to one boiler? Where in the conventionally designed tangential burner will the greatest heat release occur?

The writer would like to ask a few questions regarding the burning of various types of coal: Is it possible to obtain bituminous coal so low in volatile matter that ignition cannot be maintained? What changes in distribution of air entering the furnace should be made for coals of high volatile content as compared with coals of low volatile matter? Where a plant has a load which varies from high rating to low rating on boilers, is it advisable to select a fuel with high volatile content rather than low volatile content to support ignition at low rating loads? In our plant we have always admitted the major volume of air around the coal nozzles, believing this method will stimulate turbulence. Is this method preferred to the one that admits secondary air through the regular air passages and retards the flow of air around the coal nozzles? Is it not a fact that considerable savings can be made with a pulverized-fuel plant versus a stoker-fired plant where operation is on a five-day-week basis because of the fact that no banking is required?

We have had some interesting experiences in burning wet coal. Recently we pulverized $^3/_8$-in. Pittsburgh no. 8 screenings containing 10.6 per cent moisture. No difficulty was experienced anywhere along the coal path from the bunker to the Richardson scales, to the feeders located 15 ft above the pulverizers, in the pulverizers, or in the coal pipes to the burners with one exception, that was in the coal pipes between the feeders and the pulverizers. The design of these pipes is such that the coal fell about 12 ft and then turned an angle of 25 deg to the pulverizer. It was at this turn that stoppage occurred. The design of the pipe was altered to eliminate this angle as much as possible by dividing it between two angles of approximately 11 deg and 14 deg, respectively. While this alteration improved conditions materially it did not produce a satisfactory solution, some stoppage still occurred. It was then decided to admit sufficient preheated air to the feeder pipe to maintain the air temperature within the pipe at 140 F; this was done with satisfactory results, no stoppage has occurred since these changes were made. It appears as though preheated air could be used in the mill feeder pipes advantageously as standard practice. What has been the experiences of other operators of pulverized-fuel plants in this respect?

C. SHOWERS.[9] While it is true that the most important source of heat for ignition lies in the propagation of flame along the fuel stream, or along eddy currents of that stream, and that a well-designed burner will maintain ignition in the open air, it is also true that for boilers generating up to 1500 boiler hp, where one direct-firing mill and one burner is used and continuity of operation is important, it is safer to have some uncooled refractory in the furnace wall in which the burner is located so that in case of a slight interruption in the fuel supply to the burner due to mill feeder stoppage, caused by wet coal or foreign material, the heat from the refractory will ignite the coal stream immediately when it again issues from the burner.

It might be well to point out that regardless of the fact that combustion of fuel progresses more rapidly at lower temperatures, it is also true that the rate of heat absorption by waterwalls drops much faster than the furnace temperature. For instance, 1 sq ft of projected tube area will develop 2.4 boiler hp at a furnace temperature of 2350 F, whereas the same area will only develop 1.2 boiler hp or one half as much at 1900 F, so that on a basis of first cost it is possibly more economical to design for the highest furnace temperature possible with respect to the fusion temperature of the ash and try to design the burner so that the coal particles pass through the furnace by such a tortuous path that they have sufficient time to burn before entering the tube bank.

J. R. JAMES.[10] Although pulverized-coal firing has its advantages, it also has the disadvantage of collection and disposal of fly ash in those localities where public policy demands it.

In speaking only of dry-bottom furnaces there are two methods which are successful in the cleaning of the flue gases. One is the scrubbing of the gas by water spray and the other the use of electrostatic devices. However, as more uses for fly ash develop it is reasonable to believe that the collection of the ash in a dry state will predominate, for in that condition it is in a more salable state. Large sums of money have been spent in research by various agencies endeavoring to discover uses for fly ash. The

[8] Chief Engineer of Power Plants, Chevrolet-Forge Division of General Motors, Detroit, Mich.

[10] Senior Engineer, Engineering Division, The Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

present situation, however, is that there is no well-known generally accepted use for this by-product.

Fly ash as collected by electroprecipitators has been used as follows: (1) Due to its puzzolanic properties it has been used as an admixture to Portland cement; (2) it has displaced clay as a raw product in the manufacture of Portland cement; (3) it has been used as a filler in the asphalt and rubber industry; and (4) it has been used in the manufacture of lightweight concrete, building block, and insulation.

The Detroit Edison Company has developed a lightweight concrete (100 lb per cu ft) composed of fly ash, prepared cinders, and cement. A mixture of five parts cinders, two parts fly ash, and one part of cement by volume gave a compressive strength of 3000 lb per sq in. at the end of 28 days. This same proportion by weight, using damp cinders and fly ash, is 1500 lb of cinders, 650 lb of fly ash, and 500 lb of cement.

This company has also developed a building block similar in shape to ordinary cement or cinder block. This block, which is 18 in. long instead of the usual 16 in., is of a slate color due in part to carbon in the ash and for an 8-in. block weighs about 28 lb in contrast to 40 lb for a concrete or cinder product. Due to its being formed in the steel mold box of a tamping machine it is always of an exact size with sharp edges. Its most valuable characteristic is its smooth surface, which lends itself to painting or enameling, and with proper construction can be mistaken for a plastered surface. It has ample strength in compression but has to be handled carefully during construction as its sharp edges are readily chipped. A bare 8-in. wall as tested at the University of Minnesota gave a heat-conductivity test of 0.318 Btu per sq ft per hr per deg of temperature difference. After its hollow cells were filled with rock wool it gave a coefficient of 0.16. The rock wool was removed and the spaces refilled with ordinary dry fly ash. The coefficient was 0.18.

The process for making this building block is similar to that of a sand-lime products plant. A mixture of 100 per cent ash, 10 per cent hydrated lime, 0.6 per cent rosin with about 20 per cent water is mixed in a wet pan for about 8 min. A tamping machine receives this material and forms about 360 blocks (8 in.) per hour. Loaded on cars the blocks are placed in a steam kiln at about 120-lb pressure where they remain for about 7 hr and are then taken to stock piles.

To date, about ten homes, ranging in value from $3000 up to $10,000, two churches, and several breweries have been constructed. At the present time, The Detroit Edison Company is constructing a six-story service building, all the floors of which are formed of fly-ash cinder concrete, about 3500 cu yd. In this building more than 100,000 blocks will be used.

The process used in the manufacture of the building block is controlled by the Rostone Company of Lafayette, Ind. The three uses of fly ash as developed commercially by this company, namely, fly-ash cinder concrete, building block, and insulation in connection with the block, appear to have an encouraging future, especially so in that private capital has recently shown its willingness to take over the manufacture and sale of these products.

T. W. Jeffords.[11] The author has called attention to certain rumors regarding the supposed difficulties experienced in maintaining combustion in water-cooled furnaces. An interesting experiment was run at our Mistersky Power Station, which throws a further sidelight on this question. In 1932 the City of Detroit faced a situation of having no place to dispose of its garbage due to certain financial circumstances encountered by the local reduction company. The Common Council instructed the Public Lighting Commission to experiment with the disposal of the city's garbage by dehydrating and burning it in the powdered-coal furnaces at the Mistersky Power Station. These furnaces are of the usual vertical firing design, being approximately 19 ft square at the base and 30 ft high. In carrying out these experiments an inclined hearth was constructed on top of the water screen at the bottom and rear of the furnace. This hearth was composed of cast-iron blocks, attached to the water screen, extending the full width of the furnace end to within about 5 ft of the front wall.

The garbage was fed in on top of this hearth through openings at the rear of the furnace. The powdered coal was fed into the furnace vertically through the arch at the top of the front wall. The powdered-coal flames were allowed to follow the usual U-shaped path encountered in vertically fired storage systems, except that the flame was shortened so that it turned just above the garbage on the hearth. The radiant heat from the powdered-coal flame drove off the moisture from the garbage as it was pushed down the hearth. Actual burning of the garbage took place, after it had become sufficiently dried, at the lower end of the hearth.

This bed of garbage at the bottom of the furnace formed a black heat-absorbing surface producing an effect similar to that of a waterwall. In addition, however, volumes of water vapor were driven off from this bed of garbage, thus producing a still further cooling effect upon the powdered-coal flames. It was found possible to burn approximately 9 tons of dehydrated garbage per hour. The moisture content of this garbage averaged between 50 and 60 per cent, which means that it was necessary for the powdered-coal flames to evaporate between 4 and 5 tons of water per hour, which passed off with the gases. At no time was any difficulty experienced in keeping the powdered-coal flames burning or in carrying low ratings on the boiler. The only change which was found necessary in the operation of the furnace was to carry a higher percentage of excess air. Normally the CO_2 at the boiler outlet on coal alone averages approximately 15 per cent. It was necessary to reduce this to approximately 13 per cent while burning garbage.

We are pleased to submit these comments on our garbage-burning experiments as further evidence of proof of Dr. Kreisinger's contention that water-cooled surfaces have no detrimental effects upon the stability of powdered-coal firing. We believe that these garbage-burning experiments have again proved that the powdered method of firing coal is quite flexible in that it can not only be burned in conjunction with blast-furnace gas and oil, but also with waste products such as rubbish and garbage.

W. D. Drysdale.[12] The author brings out the fact that a water-cooled furnace absorbs a large quantity of heat, thereby lowering the temperature of the furnace gas and of the fly ash carried by the gas. What provision has been made when burning coal of low-fusion-temperature ash, to maintain the temperature of the superheated steam at a steam load output between 50 to 75 per cent of boiler rating? As higher steam pressures and superheater temperatures are coming into use, the cooling of the gases to a point of preventing the fly ash sticking on boiler and superheater tubes becomes a major problem in maintaining the desired superheater outlet temperature.

Also, as a boiler operator and thinking of "safety-first" operations when lighting a burner using pulverized coal, oil, or gas, the safe thing to do is to open the boiler outlet damper so as to purge the furnace before applying the torch and feeding pulverized coal, oil, or gas to the torch. This reduces the hazard of a puff blowing back on the operator when applying the torch to the burner.

[12] Assistant Engineer of Power Plants, The Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

H. W. STRONG.[13] The author states: "Almost any kind of coal can be reduced to powdered form and burned like gas." It is generally acknowledged that the pulverized, fuel furnace has proved to be a very flexible, dependable, and economical means of producing steam. It has lived up to expectations. We are convinced from experience that this furnace will burn, more or less successfully, many grades of rather poor-quality coals which are abundant.

A rather new problem in coal utilization is now receiving the attention of the coal industry, that is, the advent of the small domestic stoker. This appliance is rapidly becoming recognized as a very useful labor-saving device and will, if given proper combustion-engineering guidance, become a user of a substantial tonnage of low-quality coals.

There are now on the market several small stokers, designed, engineered, and built by reliable companies, which, when provided with suitable grades of coal, do an excellent job of providing safe, dependable, automatic heat with a minimum of attention at a cost which is substantially below that of natural gas or fuel oil.

The present small-stoker design favors low-quality, small-size ($^3/_8$- to $1^1/_4$-in.), low-fusion, medium-ash, and highly volatile coals, without excessive fines. The fines are very objectionable in home basements. The pulverized-fuel furnace, on the other hand, also favors such low-quality coals but the fines are not objectionable. Therefore, a proper correlation between these two outlets would be of mutual benefit to both consumers and coal producers.

A. C. PASINI.[14] The writer agrees with the author regarding the use of pulverized fuel and the use of water-cooled walls. However, the advent of pulverized fuel and the use of water-cooled walls also stimulated the development of stoker-fired furnaces. The use of waterwalls in the Conners Creek Plant stoker-fired furnaces has produced a tremendous change in the design. In the old stoker-fired furnaces the refractory walls had always been a source of trouble because of their inherent weakness. The use of refractories also required carrying higher total air values in the furnace. With continued high ratings, the replacement costs for refractory walls were much too high. Water-cooled walls have completely changed the picture in so far as stoker-fired furnaces are concerned.

In the fall of 1934 the first new high-pressure boiler went into service at the Conners Creek Plant. This boiler is stoker-fired with automatic metered-air control and 100 per cent waterwalls. It has a furnace volume of 11,000 cu ft as compared to a furnace volume of 25,000 cu ft in the pulverized-fuel furnaces at Trenton Channel. The maximum heat release in the Conners Creek furnace of 50,000 Btu per cu ft per hr is comparable to some pulverized-fuel installations and greater than most pulverized-fuel-fired furnaces. This heat release has been maintained for as long as 12 hr without any trouble. At this rate the dust loading in the stack was approximately 1.3 lb of cinders per 1000 lb dry gas. The carbon content at this loading was approximately 55 per cent. The sieve analysis at normal rating showed 30 per cent passing through a 325 mesh, 13 per cent through a 200 mesh, 28 per cent through a 100 mesh, 28 per cent through a 50 mesh, and only 1.2 per cent retained on a 16 mesh.

Waterwalls, while an aid in cooling the gases and fly ash in large furnaces, do not tend to prevent fly-ash adherence on the boiler tubes where the furnace volume is small and heat release high. In the Conners Creek furnaces the tubes must be sprayed with water approximately every two days, despite the fact the flame travel is very small on the stokers.

No trouble has been experienced in lighting fires or in steaming at small ratings with stokers and waterwalls.

With metered-air-control equipment on the stokers, no secondary combustion has been noticed. We are able to maintain 16.5 per cent CO_2 with no CO at the superheater outlet. The semiradiant superheaters are located in the first pass and the convection superheater in the second pass.

As to stoker maintenance from November, 1934, to January, 1937, the cost of all iron replacement was 50 per cent less in the new stokers using metered-air-control equipment as compared to the old stoker-fired furnaces. This low cost was maintained even though the new stokers operated with 360 to 400 F preheated-air temperatures.

The author did not mention ash disposal. We are able to dispose of all our ash at a profit—no small item when you consider that the Conners Creek plant consumes approximately 1500 tons of coal per day.

T. C. TAYLER.[15] The best proof of a theory is to carry it to extremes. A boiler furnace with its demands for a short flame constitutes one extreme, while a rotary lime-kiln furnace demanding a long flame is the opposite extreme. Ideal conditions in the company with which the writer is associated call for a flame 50 ft long in a horizontal furnace 4 ft 6 in. inside diameter by 100 ft long. The cooling surfaces consist of the insulated fire-brick walls and partly and completely calcined lime varying in temperature from about 2000 F at 50 ft from the burner up to 2300 F about 25 ft from the burner and continuing at this temperature as it moves to the burner. Our conditions demand that we maintain flame temperature at 2500 F from the burner tip to a distance of 50 ft. To hold the flame temperature down to 2500 F at all points, the walls and lime must absorb heat as generated. There will be little absorption in the first 10 ft from burner and almost constant absorption in each foot from 10 to 50 ft from the burner tip. We require quick ignition at the burner tip, slow rate of combustion in first 10 ft, then a faster but almost constant rate for 40 feet.

Our problem of combustion is complicated by the facts that first we burn petroleum coke which is about 85 per cent fixed carbon and 14 per cent volatile, and second because our entire volume of combustion air is preheated to 1000 F. Moisture in fuel and cold air admitted to fuel pulverizer reduce primary air only enough to eliminate preignition.

The author names three factors as necessary for quick ignition: (1) Small amount of primary air, (2) fine pulverization, and (3) turbulence. It is not difficult to obtain all three. We need quick ignition, but having obtained it find ourselves facing the opposite problem of preventing almost complete combustion close to the burner. If the three factors give quick ignition and short flame, conversely, the opposites should give long flame. Hence, we might expect to find it necessary in our case to supply simultaneously both small and large amounts of primary air, both fine and coarse pulverizing, and have both great and little turbulence. These combined conditions may not be quite as impossible as might at first appear. We can have a burner that supplies a rich mixture at low velocity around the rim while it supplies a lean mixture at high velocity in the center; we can have both fine and coarse fuel simultaneously; and we can have great turbulence at one point and less at another.

We burn with an exceptionally small amount of excess air and, with high preheat, have no difficulty in getting quick ignition; our difficulty is to get sufficient heat into the space 35 to 50 ft

[13] Associate Mechanical Engineer, Public Lighting Commission, Detroit, Mich.

[14] Technical Engineer, Conners Creek Power House, The Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

[15] Vice-President, Belle Isle Lime Company, Detroit, Mich.

from the burner without having too much in the space 20 to 30 ft from the burner.

The author seems to eliminate fuel sizing as a factor in control of our flame temperatures. We have evidence that the larger particles failed to burn.

On the strength of the facts presented by the author, it seems that we will have to go further with burner design to get rich mixture at low velocity around the rim and lean mixture at high velocity in the center, and also go further in our attempts to increase turbulence without effect upon the streams from the burner. Design may take the form of means to create a slight whirl to the secondary air, the burner being in the vortex but having no whirl of its own unless perhaps in the opposite direction.

It is interesting to note that instead of water-cooled walls, we use lime-cooled walls, the rotating furnace carrying the heated walls under the bed of lime to give up some heat during a part of each revolution. We seek controlled rates of combustion rather than high rates. We seek retarded mixing, which is difficult in a rotary kiln where all fuel and air must enter through the end wall within 2 ft of the burner. We seek to avoid cooling lime close to burner by putting a blanket of 1000 F air between the flame and lime. It would be ideal if we could rotate that blanket of air between the part of the flame having excessive temperature and lime subject to overburning without actually creating at that point such turbulent mixing as to actually make matters worse. The author states that excessive furnace temperatures are not desirable He tries with water-cooled walls to extract heat as it is produced; we also try to extract heat as produced but for a different reason, namely, temperatures above 2500 F cause overburning of lime, tending to flux acid brick with basic lime.

It is interesting that our experience under conditions which represent the opposite extreme from boiler-furnace combustion are in harmony with the author's experiences, and as a result of his paper we are forced to rule out fuel sizing as a factor in our plans to control flame. We hope through concentrating our efforts on the burner velocities and turbulence in combustion space to approximate eventually ideal combustion conditions.

A. W. Thorson.[16] The data on furnace temperature versus time for combustion are very interesting, and seem to agree with subsequent work at Carnegie Institute of Technology on coal carbonization. It has been found that when coal is heated, the amount and composition of distilled products depend upon the rate of heating. As this rate is increased, due to higher furnace temperature, more products of heavier molecular weight are distilled off which require more oxygen for combustion. In addition, a less reactive residue coke remains as the carbonizing temperature is increased. Both tend to increase the time required for combustion.

The statement that temperature in excess of that for ignition retards combustion is further borne out in a more practical way. Recent furnace designs for traveling-grate-stoker firing show a replacement of the conventional long ignition arch by a very short one, supplemented by a long rear arch. Such a change prevents excessive temperature in the ignition zone and assists in burning out fixed carbon at the rear of the stoker. Results with such installations show reduced solid-carbon loss and increased burning rates.

There are three questions the writer would like to ask:

(1) Replacement of mill fan blades is one of the larger items of maintenance in a pulverizer plant. There has been a recent tendency to locate the mill fan on the clean-air side of the pulverizer. How much does this reduce fan maintenance, as compared to that of a fan handling both air and coal?

[16] Junior Engineer, Production Department, The Detroit Edison Company, Detroit, Mich. Jun. A.S.M.E.

(2) There has been some discussion on the relative ability of underfeed stokers and pulverized fuel to pick up load. Some engineers find it faster with the bin-and-feeder system than with the stokers, whereas some with direct pulverizer firing find that slower than with stokers operating on the same coal, presumably due to lack of storage in mills, and to boiler lag. The latter is reported to be a factor in the case of slag-tap furnaces where slag gives up heat when dropping load and absorbs it when increasing load, thereby contributing to boiler lag. The writer would like to have the author discuss this point.

(3) A recent compilation showed that of all new capacity under construction, or recently placed in service, over 80 per cent was pulverized coal. Is this the result of a tendency toward a wider latitude in fuel selection? Will the author please explain this trend?

F. J. Linsenmeyer.[17] In this short discussion of the paper the writer's views may be considered in the nature of support for pulverized-fuel applications. The writer believes that the use of pulverized fuel has brought a great many benefits and improvements to industrial and central-station plants, and that it opened up opportunities to the designer for some real ingenuity in the selection of water and steam circulation. The older form of Stirling boiler with vertical or horizontal tubes, gives way to circuits which permit steaming in any or all banks of tubes. The direct result is that the stoker furnaces have also adopted new circuits. The writer has always wondered why boiler designers resisted any attempt at steaming in the waterwalls. Certainly the pulverizer designers led the way here. These same water and steam circuits may have been the incentive for high-pressure plants such as the Loeffler, Schmidt, and Benson Boilers. While all Americans may not agree with such unconventional designs, they are adopting some of the fringes of these designs.

It may be true that pulverized fuel uses larger furnace volumes per unit output, but that is the very nature of the burning, stokers being a concentrated-heat application. As stated, pulverized fuel is more like liquid or gaseous combustion. A heat release of 33,000 Btu per cu ft of furnace is not as high, perhaps, as may be obtained with stokers, but the ease in control with slow-speed burning is evident. It seems then that the very nature of the pulverized fuel approaching the suspended-particle condition is in its favor as having greater potentiality for a complete combustion with minimum excess air.

Pulverized fuel is so finely divided that it may be compared with a Diesel spray wherein the small charge is broken up into particles of even smaller size than the coal and can be projected to any desired position in the combustion chamber to suit maximum control of the flame propagation. This analogy is a rather typical one for an instructor to use and has its limitations, but our knowledge of fluid flow is increasing so rapidly that the application seems an excellent subject for further speculation.

Fly ash is an ever-present nuisance and the closer the preparation of the fuel is to a real suspended solid, the more serious this fly ash becomes. The writer has been thinking of the possibility of still better preparation of the fuel until the fly ash will be so fine as to be suspended further in the atmosphere and carried away by the wind.

The draft characteristics of the pulverized system, where all the pressure drop is in fluid friction and not through a fuel-bed restriction, is commendable. This same effect is attained by vertical jet furnaces.

The burning of pulverized coal in a boiler furnace is a slower but more continuous process of combustion than the burning of pulverized coal in an internal-combustion engine. By proper

[17] Professor of Mechanical Engineering, University of Detroit, Detroit, Mich. Mem. A.S.M.E.

mixing at ignition temperatures, one can get an explosion of pulverized solids. The problem may then very well be one of holding down the flame propagation to reasonable limits until combustion is complete. The writer believes that the author has made an excellent point in discussing the control of ignition temperatures; in liquid fuels at high flame rates this is called thermo-equilibrium and while still in a formative state, seems to follow the same idea proposed by the author.

The writer believes that the particle size of pulverized coal may be a little small; 1/1,000,000 in. is 1/25,000 micron. This comes well below the scale of "smokes" as indicated in the A.S.H.andV.E. scale of air-borne solids. If we say none would go through a 1000-mesh screen (if such a screen were available), we may use this figure for comparison. Assume the particle is 10 microns. With a surface area of 0.0003 sq mm, a volume of particle of 0.0000005 cu mm, a volume per pound of 30,000 cu mm, a total number of 600,000,000,000 particles per lb, and an area of 180,000,000 sq mm area per lb, then the pulverized coal, compared with a single piece of 1 lb, has 600,000,000,000 times as many particles with 8000 times the surface. It would seem that if the particles could be kept from fusing together, fly ash would be one tenth as small or at least one tenth the density (if as large).

The writer does not quite understand the time allowed for combustion. It would seem that the maximum would be 1 sec instead of 2 sec or more. Would the author give more detailed information on the final stage of combustion, that is, that of the burning of fixed carbon. Assuming 10,000 lb of coal produces 5,000,000,000 cu ft of combustion gases per hr in a 900-sq-ft furnace, then the velocity would be 150 fps, and the time therefore less than 1 sec.

W. D. Canan.[18] The author's paper deals largely with theory and design, but there are several matters in connection with the operation of pulverized-fuel equipment which are worthy of some consideration, and the writer would therefore ask that he give more information in connection therewith.

(1) What is the power consumption of the equipment for coal preparing and firing, i.e., of auxiliaries such as the pulverizers, primary-air fans, and coal feeders? Is the power used by this equipment a considerable proportion of the total energy output of the boiler? When it is taken into account is the resulting over-all boiler efficiency equal to or better than a stoker-fired job?

(2) Is the emission of fly ash from the stack a serious problem, and what if anything is being done to solve it? The writer has been quoted figures ranging from 20 to 80 per cent of the total ash produced as being the amount which would pass up the stack. It would therefore appear that, especially in locations where there are a large number of manufacturing plants and residences, considerable objection would be raised to the emission of any such quantity of ash. Some users object to using pulverized coal on account of contamination of the product which they manufacture.

In addition to the fly-ash nuisance there is also the matter of the disposal of the ash taken from the boiler. This ash is not desirable for fill, nor can it be dumped into rivers. Some other method must, therefore, be suggested for its disposal if neither of the above methods of disposal are available. Some years ago several wet gas-washing systems were given prominence as a means of collecting and disposing of the fly ash, but experience with this type of system has led the writer to believe that it will not satisfactorily solve the problem.

(3) Can a pulverized-fuel installation be made entirely safe from an operating standpoint? Are explosions in the boiler furnace itself due to incorrect design, or is it entirely a matter of operation? If it is a matter of operation, what, if any, safeguard can be incorporated in the design of the equipment to guard against explosions?

(4) The author has stressed the advantages of water-cooled furnaces, and their desirable features have not been overstated. Almost every boiler installation that goes in today has more or less of this type of construction. There is a tendency to cut down boiler heating surface and add waterwalls, and the writer is wondering how long it will be until the boiler heating surface as such disappears entirely. In this connection it might be interesting to know what proportion of the total heat absorption of a boiler of modern design takes place in the waterwalls.

[18] Rust Engineering Company, Pittsburgh, Pa. Mem. A.S.M.E.

Author's Closure

Mr. Briscoe refers to the change in furnace temperatures caused by a slag or ash deposit on the water-cooled furnace walls and the first row of boiler tubes as "furnace sensitivity." Such slag or ash deposit reduces the heat absorption by these surfaces, thereby raising the temperature of the products of combustion when they enter the boiler and superheater. This higher gas temperature raises the superheat and may also result in slag or ash deposit in the superheater and boiler.

With most designs of water-cooled furnaces the slag or ash accumulates to a certain degree and then begins to drop off as fast as it is deposited. The temperature then remains nearly constant. This nearly constant condition of slag deposit and temperature depends a great deal on the adjustment of burners, air supply, and the fineness of coal. The slag deposit is less when the coal is fine and when the burners and the air supply are so adjusted that the combustion is nearly complete when the gases reach the boiler. Delayed combustion is the greatest factor in the deposition of slag on heating surfaces. The air supply should be adjusted according to excess air or CO_2 content in the gases leaving the furnace, and not at the exit from the boiler, economizer, or air heater, where the gases may be greatly diluted by air leakage. Careful operation and good maintenance of the mills, furnace, and setting are as important for good results as good design.

Low temperature of gases entering the boiler or superheater eliminates much of the slag trouble, but there is a limit to the amount which this temperature can be reduced, particularly in an installation with high superheat temperature. The gases must be hot enough when they enter the superheater to contain enough heat at sufficiently high temperature to produce the desired superheat. If the temperature difference between the hot gases and the steam is too small, a large and expensive superheater is required.

Large cross section of the gas passage at the entrance into the boiler results in lower gas velocity and greatly reduces the slagging of the boiler and superheater. Careful operation contributes much toward the elimination of slagging. However, with coals having low-fusion-temperature ash, some slag deposits must be periodically removed. Therefore, it is desirable that facilities for cleaning during operation should be provided when the steam-generating equipment is designed. There are many installations which are kept in operation for many months at a time. If any cleaning of slag is necessary it is done without any interference with operation.

The temperature of superheated steam rises with boiler rating. The following methods are used to keep the superheat nearly constant over a desired range in steaming rate.

(*a*) The superheat is kept nearly constant by a damper-controlled gas by-pass which permits a varying volume of the hot gases to by-pass the superheater. The superheater is designed for the lowest steaming rate at which the full superheat is desired. As the steaming rate rises above this point, part of the

volume of hot gases is made to by-pass the superheater. Thus, the rising temperature of the hot gases entering the superheater is compensated by their decreasing volume. This method of control requires a larger and more costly superheater, an idle gas pass around the superheater, and a damper to regulate the volume of gases flowing through the by-pass. The regulation of the by-pass damper can be done manually or by an automatic control.

A modification of this method is used in a double boiler with a large superheater on one side and a smaller one on the other side. Varying quantities of gases are passed through the two sides. Superheat is controlled by regulating the flow of gases through the two sides of the unit.

(*b*) The superheat can be controlled by the manipulation of the fires. In this method burners are placed at different heights in the furnace. At low rating the burners located in the upper part of the furnace are put in operation and the fires are brought closer to the superheater. At high rates of steaming the lower burners are used. For superheat control over a wide range of rating this method can be used in combination with the by-pass-damper method.

(*c*) Superheat is maintained nearly constant by the combination of radiant with convection superheater. The radiant superheater is placed in the furnace as a part of the wall cooling surface, or, part of the superheating surface is placed between widely spaced boiler tubes in the first bank of the boiler. The surface in such locations is exposed to radiation from the furnace and absorbs a greater proportion of heat at low rating. The main part of the superheater is located in the usual place back of the first bank of boiler tubes and absorbs heat by convection. The steam flows first through the radiant section and then through the convection superheater. This method of superheat control is largely a matter of proportioning the amount of surface in the two parts of the superheater. It may be combined with the methods outlined under (*a*) and (*b*).

(*d*) The superheat can be controlled by a separately fired superheater. In this method the superheater is set over a separate furnace and the superheat is controlled by the amount of fuel burned. This method has the widest steaming range with constant superheat. It is also the most expensive and is now seldom used.

(*e*) The superheat can be controlled by partial desuperheating at the high rates of steaming. In this method the superheater is designed to give full superheat at the desired low rating. At higher ratings the steam is partly desuperheated after it has gone about half way through the superheating process, and the extent of the desuperheating is controlled by the final temperature. The superheater is installed in two parts with the desuperheating apparatus between them. This method of superheater control is rather complicated and is seldom used in this country.

Direct impingement of concentrated flame against water-cooled walls is not desirable, but flame sweeping or brushing over the walls is not objectionable. By direct impingement is understood the condition in which the flame strikes the wall nearly at right angles a short distance from the burner. A flame is sweeping over a water-cooled wall when the flame moves nearly parallel to the wall a considerable distance from the burner. In tangential firing the flame may sweep over the walls after it has traveled nearly diagonally across the furnace.

Preheated air helps the ignition because less heat is required to bring the incoming mixture of coal and air to ignition temperature. The ignition is quicker and closer to the burner. There are practical limits to the temperature to which air can be preheated. This limit is usually set by the efficiency of the steam-generating unit. If high efficiency is desired the temperature of gases entering the air heater should not exceed about 650 F. It is not economical to bring the temperature of preheated air closer than about 100 F to the temperature of gases entering the heater because the air heater would become too large and expensive. The weight of gases is always greater than the weight of air to be heated. The specific heat of the gases is also higher than that of the air. Therefore, the temperature rise of the air is greater than the temperature drop of the gases. The weight of gases is equal to the weight of air going through the air heater plus the air leaking into the setting plus the weight of the ash-free fuel. The specific heat of the products of combustion, particularly with coals of high hydrogen and high moisture content, is from 10 to 15 per cent higher than the specific heat of air. Usually for every 300 F of the temperature rise of the air there is only about 200 F drop of the temperature of the gases. Thus, if the temperature of the gases is to be reduced from 650 to 350 F the temperature of air would rise from 100 to 550 F. If the temperature of gases entering the air heater were 900 F, it would require a large air heater to bring the temperature of air to 800 F. The air temperature rise would be 700 F and the gas-temperature drop would be about two thirds of 700, that is, about 466 F. The resulting temperature of gases would then be 434 F. The over-all efficiency of the steam-generating unit would then be about 2 per cent lower than with the gases leaving the air heater at 350 F.

A further disadvantage of the highly heated air would be the oxidation of the air heater and air ducts, more expensive expansion joints, and insulation covering. To reduce the oxidation of the air heater and the ducts they would have to be made of heat-resisting steel alloy. There is no limitation to the temperature of preheated air from the standpoint of combustion.

During the last few years efforts have been made to develop a mill which would pulverize coal to more uniform fineness with lower power consumption and lower maintenance. By more uniform fineness is meant the reduction of the percentage of oversize and the superfine coal.

Mr. Sitter brought up the question of the necessity of feedwater treatment with water-cooled furnaces. The water-cooled furnace walls absorb heat at a high rate and must be kept clean internally to prevent their overheating. With internally clean tubes the temperature of the metal seldom rises over 50 F above the temperature of the water inside of the tube. To keep the surfaces internally clean the feedwater should be properly treated to prevent scale formation. All make-up water should be treated in a separate feed water-treatment plant. This primary treatment should be followed by a secondary treatment with phosphate which is supplied directly to the boiler through a separate line. The methods of feedwater-treatment have been sufficiently developed so that there is no excuse for the formation of scale inside of the boiler.

Widely fluctuating loads require large steam drums to take care of the variation in water level and at the same time leave sufficient space in the drum to separate the water from the steam. It is much easier to obtain clean steam with a steady rating than with widely fluctuating load.

Oil torches are more stable and are preferable to gas torches for lighting pulverized-coal fires. The oil torch has a hot and luminous flame and if the torch is blown out the furnace is not filled with explosive gas as may be the case with gas lighting torches. Oil leaks are more easily detected than gas leaks particularly leaks due to incompletely closed valves.

To take one mill out when two mills are supplying the fuel to one boiler the output of the mill to be taken out should be reduced in about three equal steps to the minimum output at which it will operate satisfactorily. At the same time the output of the mill to remain in operation sould be increased by similar steps. The air supply should also be shifted to maintain the stability

of flame. When the operator has assured himself that the flame remains stable, the mill to be taken out is shut down and the load fully taken by the other mill.

There are coals which are classed as bituminous coal with the percentage of volatile matter as low as 14 per cent. When the volatile matter drops below 20 per cent a delay in the ignition becomes quite noticeable. For burning coals so low in volatile matter, provision must be made for the reduction of primary air. This is at times difficult to do in direct firing because the mill must have a definite minimum quantity of air to operate satisfactorily. This minimum air for the mill may be too much air with the coal to produce good ignition. When coal low in volatile matter is burned in a tangentially fired furnace the air supply around the coal nozzle should be cut off and the secondary air should be supplied through the air port above the upper burner. With highly volatile coal the air around the coal nozzle should be reduced to bring the ignition to the burner without allowing the flame to back into it. The air ports above and below the burner should be kept fully open, and the air supply should be controlled by the air pressure at the burner, by regulating the speed of the pressure fan or the damper in the air supply line. Such air regulation supplies the greatest amount of energy to the furnace for mixing. The greatest heat release will occur in the center of the furnace in the plane of the burners where the streams of coal and air meet and where the mixing is most intensive. Any mixing that is done at the burners should be done to quicken the ignition. Mixing for rapid combustion is done in the center of the furnace away from the burner where the secondary air does not interfere with the ignition.

Highly volatile coal is better suited for a widely fluctuating load particularly with direct firing. The ignition is more stable because the volatile matter makes a rich mixture which ignites readily even with wide fluctuation in the air supply.

Irregular flow of coal to the pulverizer due to moisture and an excessive proportion of fines is one of the drawbacks of direct firing. If the hanging of the coal is between the feeder and the pulverizer, hot air supplied to the pipe connecting the two may prevent the hanging, but this increases the flow of air through the mill which at times may not be desirable for good ignition. If the hanging occurs before the feeder it is difficult to remedy.

Mr. Showers points out the advantage of some refractory surface in a pulverized-coal furnace. Such surface when hot reignites the fires after a short interruption in the fuel supply to the furnace. In many of the pulverized-coal installations with horizontal firing such surface is on the front, or the burner wall. This wall is made of refractory for structural and economic reasons; it is easier to make the front wall of refractory than of water-cooled surface, because the water-cooled tubes have to be bent around the burners and cannot be made to cover the burner wall completely. Slag may stick to such refractory surface and accumulate and may have to be removed by hand tools. In other cases the refractory may wash out and the wall require frequent patching. The reignition of the fuel after a short interruption may not occur promptly. It may be delayed until the furnace is filled with coal mixture and then ignite with a violent puff which causes leakage into the setting. If feeding of coal to the furnace is unreliable a small oil burner is a better security against a loss of fire.

The temperature of a pulverized-coal flame even in a completely water-cooled furnace is considerably above 2000 F. At lower rating the flame may be reduced to a smaller volume but the temperature of the flame is practically as high as it is at high ratings. A match can be burned in a completely water-cooled furnace with an average rate of heat liberation of a fraction of a Btu per cubic foot of the furnace volume. The flame will occupy a volume less than a cubic foot and have a temperature of about 2000 F. Furnaces are made completely water-cooled to avoid refractories in the furnace, the sticking of slag to them, and also to get away from the maintenance of such refractories.

It is largely the extent of the surface of the flame that determines the amount of heat radiated to the water-cooled walls. At low rating the surface is small because the volume of the flame is small, and the amount of heat radiated to the walls is small because of the small flame surface. At high ratings the flame fills the furnace almost completely. The surface is large and a large amount of heat is radiated to the furnace walls.

Mr. James presents interesting and complete information on the use of pulverized-coal ash. His discussion is a valuable addition to our knowledge about the use of pulverized coal.

Mr. Drysdale brings up an interesting point in connection with maintaining nearly constant superheat with varying steam output. This problem is more difficult to deal with in the design of units for high steam pressure and temperature. The gases entering the superheater must be hot enough to give the desired superheat and they should not be hot enough to cause slagging of the boiler and superheater. The designer has to work between two serious limitations. The methods for obtaining nearly constant superheat have been described in connection with Mr. Briscoe's discussion. The method outlined under the manipulation of fires promises a satisfactory solution. This method strives to maintain the temperature of gases entering the superheater nearly constant regardless of their volume.

Mr. Thorson asked three questions which can be answered as follows:

The maintenance of mill fans averages about 0.5 cent per ton of coal pulverized. If other maintenance remains the same, placing the mill fan ahead of the mill would reduce the over-all mill maintenance by 0.5 cent. There are some objections to such a mill-fan location. The mill is put under pressure and there may be leakage of coal dust from the mill and particularly from the coal feeder. Coal dust may be forced into bearings and increase their maintenance.

It does not seem likely that a stoker installation would have a quicker pickup than a direct-fired pulverized-coal installation. It takes time to build up a good stoker fire that will carry heavy load over extended periods. Banked stoker fires or low-rating fires are not usually in good condition for heavy load.

There is a decided trend toward pulverized-coal firing which is probably due to wider latitude in fuel selection. "Change of coals upsets the operation of a pulverized-coal plant to a much smaller degree than a stoker-fired plant."

Explosions in pulverized-coal furnaces are usually caused by faulty operation. The explosions are generally less disastrous than explosions in oil- or gas-fired furnaces. Coal is pulverized to make it more inflammable or combustible. The greater inflammability makes it more explosive. The greatest asset of safety is a good operator who does not take risks.

Originally the boiler was made to evaporate water. In modern high-pressure steam-generating units the boiler performs mostly a structural service. The boiler supplies rigid water-cooled walls, water-cooled supports for the superheater, water-cooled frame for partitions for gas passages through or around the superheater, and a water-cooled chamber for the economizer. The water-evaporating duties have taken secondary place. However, a boiler will always be necessary to perform the structural service.

A water-cooled furnace makes from 25 to 50 per cent of the steam made by the steam-generating unit.

Professor Linsenmeyer asks about the time required for combustion. This time depends on the size of the particles; the finest particles burn instantaneously, the large ones require more than two seconds because they contain many times more com-

bustible than the small ones, and because their combustion must be completed after the concentration of free oxygen in the furnace gases has been greatly reduced. In the last part of the path of gases in the furnace the oxygen concentration is 2 or 3 per cent. In fact some of the large particles never burn completely.

Mr. Canan's questions may be answered as follows:

The power consumption of the equipment for coal preparation and burning in a pulverized-coal plant is greater than it is in a stoker-fired plant. In general the difference probably does not exceed 2 per cent of the energy represented by the boiler output, and is offset by a higher over-all operating efficiency. The application of pulverized coal is about fifteen years old and has ceased to be a novelty. There must be a tangible reason for the preference for pulverized coal. There are undoubtedly some cases where stokers have an advantage over pulverized coal.

The emission of fly ash is greatly reduced by various dust-collecting devices. Some of the mechanical devices can be installed at low cost. They collect most of the coarser dust which would settle near the plant if allowed to go out of the stack. The emission of stoker cinders has also become objectionable and in some cases provision must be made for collecting them. If dust collectors must be used with either firing, engineers apparently prefer to use pulverized coal.

The disposal of the collected dust is a problem that seems to lack a good general solution. There are apparently many special solutions: Mr. James presented one of them.

Mr. Scott proposes supplying pure oxygen to the furnace near the end of the combustion process to raise the concentration of free oxygen and thereby obtain more complete combustion of the large coal particles. Pure oxygen for the combustion of fuel in boiler furnaces has been proposed before but the cost of supplying all the oxygen seemed prohibitive. Besides, the extremely high temperatures at the beginning of the combustion process, due to all pure oxygen, might damage the furnace. Supplying only a small quantity of oxygen near the end of the combustion process looks more practical because it would increase the oxygen concentration without high losses due to a great excess of air. In the Velox boiler air for combustion is compressed to obtain more oxygen per cubic foot of combustion space. Supplying pure oxygen near the end of the combustion process may give the same amount of free oxygen per cubic foot without the necessity of compressing a large quantity of inert nitrogen.

Mr. Rudd submits several questions referring to comparisons of pulverized-coal firing with stoker-fired plants. To answer such questions completely would require a thorough study of a number of representative plants using the two methods of firing. Some of the questions have been partly answered in connection with the discussions by Mr. Thorson and Mr. Canan. Although a majority of the new boilers now being installed are designed for pulverized-coal firing there are many new installations with stoker firing. These later installations undoubtedly have good economic reasons for the use of stokers.

Part of Mr. Blizard's discussion is devoted to mathematical analysis of the author's attempt, given on page 296 under (*a*), (*b*), and (*c*), to account for the slower combustion at higher furnace temperatures as shown by the results of the laboratory experiments made by the Bureau of Mines. The first two factors considered under (*a*) and (*b*) when combined agree with Mr. Blizard's equation for the rate of molecular impingement $M = 145(1/T)^{1/2}$.

However, the diffusion or rather the factor which removes the products of combustion from the surfaces of the coal particle and brings free oxygen within the range of impingement, must be given full consideration. The effect of temperature on this factor has been considered under (*c*). In the case of the laboratory experiments, the factor was the combination of natural diffusion and the movement, caused by the force of gravity, of the coal particles through the furnace atmosphere. The author is of the opinion that if the particle of coal were moved through the furnace atmosphere at sufficient speed to maintain the partial pressure of free oxygen within the range of impingement at 0.21 atmosphere, the time of combustion of the coal particle would be close to the value indicated by Mr. Blizard's calculation. It is certain that under the conditions of the experiments the partial pressure of free oxygen within the range of impingement was much smaller than 0.21 atm, because the products of combustion could not be moved out of the range of impingement and free oxygen brought into the range fast enough to maintain the oxygen pressure. With the time of combustion indicated by the experiments the same mathematical method gives the partial oxygen pressure to be of the order of 0.005 atm. This partial oxygen pressure within the impingement zone depends largely on the speed with which the burning particle of coal is moved out of one place where all oxygen has been consumed to another place where free oxygen is available. In all cases where rapid combustion is obtained it is produced by intensive mixing.

Mr. Blizard's explanation, that the particle as a whole is hotter when it begins to glow in a lower furnace temperature, may hold with particles of charcoal or coke. In the case of coal the first part of the heat absorbed by the particle is used to drive off the volatile matter, and this volatile matter bursts into flame long before the particle is brought to glowing temperature. Fig. 9 shows that combustion begins abruptly and ends gradually. During the first part of the process of combustion the coal particle moves downward out of the rising envelope of flame, and in doing so continually moves into new locations with high concentration of free oxygen. On the other hand, during the last part of combustion the burning particle rises with the rising products of combustion, and remains in an atmosphere with low free-oxygen concentration or low partial pressure.

Locomotive Axle Testing[1]

HUBER O. CROFT.[2] The writer would like to have the authors answer the following three questions: (1) What method is used to discover fatigue cracks when they form initially? (2) What stress effects are developed at the hub by the temperature increase due to the braking action of brake shoes? (3) What is the effect on fatigue stresses of the impact of the wheel when passing over crossings at high speed?

P. W. KIEFER.[3] It should be pointed out that the application of roller bearings has changed considerably the functional characteristics of the different axles and has made necessary the development of additional information on axle designs and materials in order to obtain a reasonable expectation of service life. In addition, it has become necessary to increase the power output of new locomotives to meet the requirements of improved schedules, but at the same time to avoid the higher unit costs for the more complicated driving-wheel and running-gear arrangements when the number of driving wheels is increased. Similarly, the weights of existing passenger equipment cars operating on faster

[1] Published as paper RR-60-2, by T. V. Buckwalter, O. J. Horger, and W. C. Sanders, in the May, 1938, issue of the A.S.M.E. Transactions, p. 335.

[3] Chief Engineer of Motive Power and Rolling Stock, New York Central System, New York, N. Y.

schedules are being materially increased because of air-conditioning installations and other improvements. All of these factors impose more exacting demands on the equipment axles.

Although the paper under discussion is confined to the subject of locomotive-axle testing, it is of interest to state that a series of tests on passenger-car axles now in progress on one of the Timken machines is being conducted under the direction of W. I. Cantley, mechanical engineer of the mechanical division of the A.A.R., through the cooperative activities of a joint subcommittee consisting of representatives from the directly interested main committees, including the A.A.R. mechanical division committee on car construction. Encouraging progress is being currently reported on these tests. To the best of the writer's knowledge, this method of testing represents a pioneer effort, but it is too early to attempt reaching conclusions from the data thus far collected.

In a few months from now much additional information will be available to the railroads and related industries from which it is believed many of the problems involved in the successful operation of axles under modern railroad equipment, either with or without roller bearings, may be answered, and the performance of such axles greatly improved.

Authors' Closure

Professor Croft raises three questions which may be answered as follows:

1 The only certain method known by which fatigue cracks can be detected in the wheel fit of the axle requires pressing the wheel off the axle. Magnaflux examination of the axle is then made to detect any minute cracks which are not evident to the eye. In some tests the wheel center has been cut into halves so that there would be no question about the influence of pressing the wheel off the axle as a contributing factor in causing the fatigue cracks to develop. It is believed, however, that the pressing-off operation does not develop such fatigue cracks.

2 Little knowledge is available concerning the stress effects at the hub due to temperature increase resulting from braking action. The feeling exists that, with the rim of the wheel in a heated condition, it would tend to expand and relieve the press-fit stresses at the hub. Available information from tests indicates that the press-fit pressure required to prevent a wheel from loosening on an axle is of such magnitude that any considerable increase or decrease in such press-fit pressure would cause little, if any, change in the fatigue strength of the axle. For this reason it is considered that brake-shoe action has small, if any, influence on the axle, fatigue-failure problem, although this is a subject which may deserve further consideration.

3 The case of stresses set up in an axle due to impact conditions which may occur when a wheel passes over crossings at high speed is a subject which is not investigated in this paper. Such stresses have actually been measured in service and it is known that peak stresses occur under such operating conditions. If such peak stresses are of sufficient magnitude and quantity, early axle failure will develop.

Mr. Kiefer suggests that the axle life may be considerably extended by the use of roller bearings except as it is limited by the development of fatigue cracks as explained in this paper. It is the ultimate object of the reported tests as well as those mentioned by Mr. Kiefer now being conducted for A.A.R. in this same laboratory to obtain an axle design specification which will result in a life much longer than is now being obtained. Based on information available now, the influence of roller bearings on the fatigue failure of axles has little or no effect on the fatigue strength of the axle at the wheel seat.

Quantitative Analysis of Process Lags[1]

J. C. Peters.[2] While the terms "lag" and "time lag" have been widely used for a number of years in describing the characteristics of industrial processes, the meaning of these terms has, in general, been somewhat vague and indefinite. The author suggested[3] in 1933 that the general effects be referred to as process lags and that these be classified as capacity lags, transfer lags, and velocity-distance lags. Such a breakdown is valuable in that it concentrates attention on certain fundamental factors involved. A process designed with these factors in mind is likely to be easier to control than would otherwise be the case, and the operation of existing processes can sometimes be improved by following similar considerations.

When temperature is the controlled variable, few processes lend themselves to exact mathematical analysis. In general, the equations contain variable parameters not too definitely known and are of such complication as to defy solution. In these cases, simplifying assumptions are required which often make the results useful only on a qualitative basis. Nevertheless, the writer feels that such solutions may be very valuable and should be encouraged.

The solution for the author's single-capacity process represented by Figs. 1 and 2 of the paper is one that is directly useful. When set up on percentage basis, the equations for it can be readily applied without the use of curves. An equivalent of the author's Equation [8] is

$$(T_a - T_{a0}) = (T_p - T_{a0})[1 - \epsilon^{-(ft/B)}] \quad \ldots\ldots [1]$$

where T_a = temperature of the liquid in the tank at time t; T_{a0} = initial value of T_a; T_p = final value of $T_a = (Q_s/cf) + T_0$; T_0 = temperature of entering liquid; Q_s = rate of electric heat supply, expressed in heat units; f = rate of liquid flow, mass per unit time; B = mass of liquid in the tank; c = specific heat of the liquid; and $\epsilon = 2.718$. When written in this way, the equation is equally useful whether a sudden change is made in the rate of electric heating, the rate of liquid flow, or the temperature of the incoming fluid.

On the left-hand side of Equation [1] of this discussion we have the amount by which the temperature in the tank has increased in time t. The ultimate change is $(T_p - T_{a0})$. Dividing both sides of the equation by this quantity and multiplying by 100, we obtain that percentage of the total change P that takes place in time t, or

$$P = 100[1 - \epsilon^{-(ft/B)}] \quad \ldots\ldots [2]$$

It is evident immediately that when $t = B/f$, $P = 100[1 - (1/\epsilon)] = 63$, approximately. The change is therefore 63 per cent complete in the time equal to that quantity referred to in physics and electrical engineering as the time constant.

Solving Equation [2] of this discussion for t gives

$$t = \frac{B}{f}\left[\log_\epsilon\left(\frac{100}{100 - P}\right)\right] \quad \ldots\ldots [3]$$

This is a very convenient equation for practical use. With the aid of a curve or table giving the value of the factor in brackets as a function of P, solutions are obtainable by simple slide-rule

[1] Published as paper PRO-60-1, by C. E. Mason, in the May, 1938, issue of the A.S.M.E. Transactions, p. 327.

calculation. The curve of Fig. 1 of this discussion gives the required relation for values of P between zero and 99 per cent.

When a knowledge of the actual magnitude of the ultimate change is desired, it may be obtained from

$$(T_p - T_{a0}) = \frac{Q_s}{cf} + T_0 - T_{a0} \quad [4]$$

Other equations of considerable interest and value are those giving the per cent change per unit time, obtained by differentiating Equation [2] of this discussion. These are

$$\frac{dP}{dt} = 100\,\frac{f}{B}\,\epsilon^{-ft/B} \quad [5]$$

and for the initial rate when $t = 0$

$$\frac{dP}{dt} = 100\,\frac{f}{B} \quad [6]$$

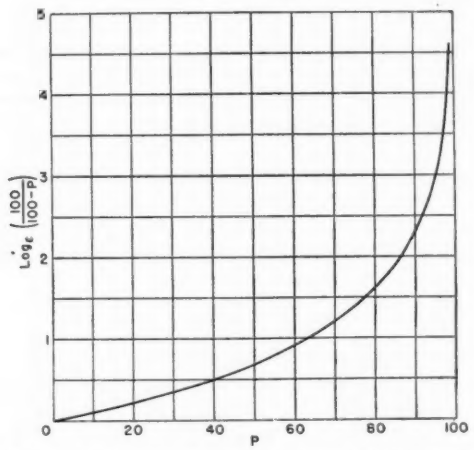

FIG. 1 VALUES OF P BETWEEN 0 AND 99 PER CENT

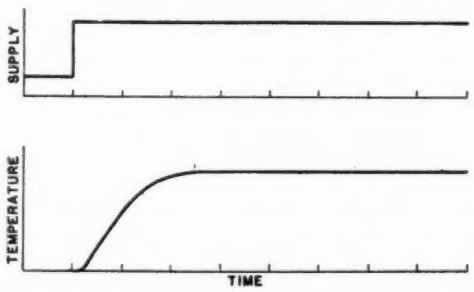

FIG. 2 TYPICAL RESPONSE CURVES AS OBTAINED WHEN HEAT TRANSFER TAKES PLACE THROUGH A MEDIUM INVOLVING BOTH THERMAL RESISTANCE AND THERMAL CAPACITY

With regard to hydraulic analogies, it appears that these can be of only limited service in connection with temperature-control problems, even when rate of fluid flow is assumed to vary directly with head. Considering the author's Fig. 4, capacities A_a and A_b are assumed to be separated by a simple thermal resistance. Most of the more difficult temperature-control problems involve resistance associated with capacity. With such a partition separating simple capacities A_a and A_b, response of the temperature in A_b to a sudden change in Q_0 would be of the type shown in Fig. 2 of this discussion. This curve is an experimental one taken from Fig. 6 of the paper by Bristol and Peters.[4] The temperature change is insignificant for a more or less definite time following a change in supply, after which it becomes similar to that for a single-capacity system. To give a practical example, we observe this effect when we heat a long iron rod at one end and continually observe the temperature at a distance from the point of application of heat. The theoretical solution of a corresponding ideal case is found in books on the theory of heat, where an infinitely long rod, perfectly insulated except at the ends and initially at uniform temperature throughout, is suddenly subjected to some higher temperature at one end. The temperature at any distance x from the heated end, expressed as that percentage P of the total change complete in time t, is

$$P = \frac{2}{\sqrt{\pi}} \int_0^{x/2\sqrt{(\kappa t)}} \epsilon^{-y^2}\,dy \quad [7]$$

For wrought iron, the diffusivity κ, expressed in cgs units, is 0.173. Curves a and b of Fig. 3 of this discussion apply to this material and are for distances from the heated end of 5 and 10 cm, respectively. At 10-cm distance, the change is 1 per cent complete in 0.72 min, and 63 per cent complete in 20.7 min; the ratio of the latter to the former time is 28.6. This ratio for the experimental curve of Fig. 2 of this discussion is approximately 5.

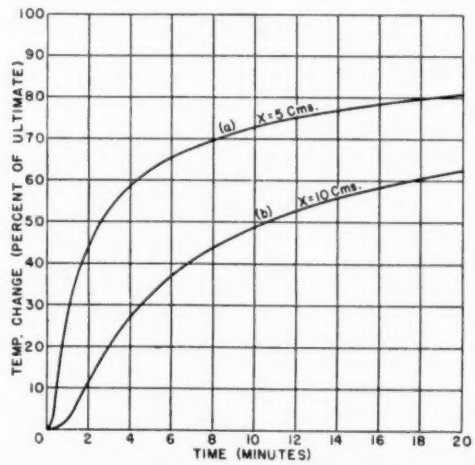

FIG. 3 RISE OF TEMPERATURE AT POINTS ON AN INFINITELY LONG IRON ROD FOLLOWING A SUDDEN CHANGE IN TEMPERATURE AT THE END

Experimentally obtained response curves of the type shown in Fig. 2 are of considerable interest to those working on the theory of automatic control. It would be very helpful to them if those in a position to make such tests on industrial processes would do so, submitting their results to the secretary of the A.S.M.E. Committee on Industrial Instruments and Regulators.

ED S. SMITH, JR.[5] This paper[1] is a creditable example of the type which the A.S.M.E. Committee on Industrial Instruments and Regulators was formed to consider and use. It is restricted to a single phase of the large subject of automatic regulation or control, and represents a worth-while attempt to provide a generalized and graphical treatment, following methods used occasionally on individual problems by others in this field. The generalized treatment promises to become a widely used tool as facility in the technique is attained by those working in this field, especially since the mathematics involved is only undergraduate calculus with simple solutions. The paper creates confidence in the use of the hydraulic analogy and technique; the value of the

[4] "Some Fundamental Considerations in the Application of Automatic Control to Continuous Processes," by E. S. Bristol and J. C. Peters, presented at the Annual Meeting of the A.S.M.E., held in New York, N. Y., December 6–10, 1937.

[5] Mechanical Engineer in charge of Patents, C. J. Tagliabue Manufacturing Company, Brooklyn, N. Y. Mem. A.S.M.E.

paper is unquestionable and not lessened by the fact that the methods per se (e.g., the use of the hydraulic analogy for temperature relations) are not original as presented by the author, but old.[6]

The hydraulic analogy breaks down into one more use of model testing, which method is of value in so many different fields. It is not necessary, of course, to stop with the tanks and resistances, since an automatic regulator may be added and the performance of the whole determined. It is old, especially in the hydraulic field, to test regulators on models of the proper sort to simulate working conditions fairly. In other words, the technique of the paper may be used with far more confidence than the unnecessarily conservative approach of the paper would indicate.

As to terms,"transportation lag" seems preferable to the hyphened "distance-velocity" lag. Also, the use of "interval" seems better than the use of "lag" for capacity and transfer lags, where the retardation, rather than seconds lag, for the transportation lag is meant.

However, there is another and valid approach. The lag may be expressed for the case of a gradual instead of an instantaneous change, in the former case the lag is expressed in seconds. There is a corresponding number of seconds for the interval required, following the sudden change, for the effect to approach its final value within 10 per cent of the total change. Further, where the process is complex and multiple time constants are involved, these may have corresponding multiple lags and multiple intervals in seconds. In most practical recorder-controller applications, it appears that the initial rate of change of the effect per unit change of the variable is more important than either the lag or interval, but such rate of change may be readily determined from the interval.[7] The writer favors the decimal interval because, in his experience, its use with semilog paper has proved to be most convenient.

The unnecessary difficulty in following the present paper would be largely obviated if the closure were to include a table which would present at a glance the corresponding types of lags, figures, cases, plots, formulas, and whether the example is thermal or hydraulic.

The low price of usual industrial controllers, or regulators, leaves an inadequate margin for the research which is required to put the subject of automatic regulation on the most useful basis. Consequently, cooperation among all those concerned is needed to distribute the common burden so that the best results will be obtained. Mr. Mason and the Foxboro Company, which made possible such use of his time, are thanked for their generous cooperation.

Model testing and dimensional analysis are inseparable. Instead of a formidable mathematical structure, the writer hopes to see in the future a simple graphical analysis with the performance of the several types of regulators and processes falling within generally recognized zones when plotted against the appropriate operator, a dimensionless ratio derived by dimensional analysis from the pertinent variables.

For example, the zones of hunting and nonhunting performance of a simple throttling regulator for various sensitivities and lags should be correlatable with a dimensionless ratio involving the product of terms involving the sensitivity (which is taken by Fairchild as a dimensionless ratio, i.e., effect/cause in the same units) and the ratio of metering to process lags. From the standpoint of common sense or common experience, an increase in sensitivity tends to cause increased hunting, as does an increase of metering lag, while capacity lag generally acts as a stabilizing balance wheel. Thus, without resorting to a blind use of the formal π theorem of Buckingham, the operator would reasonably appear simply as s/i, where s is the sensitivity and i is ratio of the capacity lag to the metering lag, expressed in the same units. Considering limits, unless metering lag were present, hunting would be impossible. Similarly, with zero capacity lag, hunting would result from the least actual metering lag. These considerations check the direction but not the powers of the terms of the operator. Using s/i as the abscissa, the exponent factor k would be used as the ordinate; the expected critical value of s/i would be of the order of unity. A single line would appear on the graph for the simple throttling regulator under these simple conditions; however, a surface would appear if an additional dimensionless ratio for another contour line, for more complex conditions, were used. For example, a surface would be obtained in the case of adding reset to such a regulator, or for a fixed-speed motor-operated valve and a fixed-speed reset; a logical operator for the contours would be the ratio of the reset speed to the valve speed. The writer regrets that he is unable under present conditions to take the time to confirm or expand these tentative operators but submits them as of related interest and of possible use in helping others attain the expressed aim of the paper of better attacking the general problem.

[7] For a further treatment of these interrelated terms see comments made by author on Behar's discussion in the closure of the paper "Industrial Instruments, Their Theory and Application," by Ed S. Smith, Jr., and C. O. Fairchild, Trans. A.S.M.E., vol. 60, October, 1938, p. 595.

Author's Closure

It is of course true, as mentioned in the discussion submitted by Mr. Peters, that exact solutions for complex thermal problems are often so intricate as to be prohibitive. It was precisely this intricacy which originally suggested investigation of the possibilities of the many schemes of hydraulic analogy in order to determine a procedure which would be reasonably practical and which would reduce to relatively simple analysis.

A careful study of fundamentals is essential for the development of a practical scheme of analogous representation, in order to avoid faulty premises in the construction. The scope of the paper permitted only the introduction of some of the simpler basic principles. The author's experience has shown that, when properly constructed, such analogs can be made to characterize the behavior of complex systems far more faithfully than might be expected. Most every discouraging result in the earlier work has been traceable to insufficient care in the representations.

Equations [1] to [6] of Mr. Peters' discussion, paraphrasing the author's development, are exceedingly welcome if they add to the clarity of the paper.

In these forms the equations are not general but apply only to single-capacity thermal processes in which heat is conducted by a medium. The author's presentation for this type of thermal process followed a general scheme which would be equally applicable for other types of single-capacity processes as well as for the more complex multiple-capacity processes.

Whether the integrated equations are written in terms of $T_a - T_{ao}$ or in terms of $T_a - T_p$ seems most a matter of choice. Mr. Peters' alternative forms are further welcome since they may better serve to correlate the author's development with that of other phases of engineering. Solutions in terms of $T_a - T_{ao}$ are probably most easily obtained by adding $T_p - T_{ao}$ to both sides of the integrated equations which are given in the paper.

Expressing the results in terms of $T_a - T_p$ gives a convenient form for plotting directly in semilogarithmic coordinates. However, the exponential function

$$C(1 - e^{kt})$$

does not give a straight line in semilogarithmic coordinates. This function could be represented by two straight lines in these

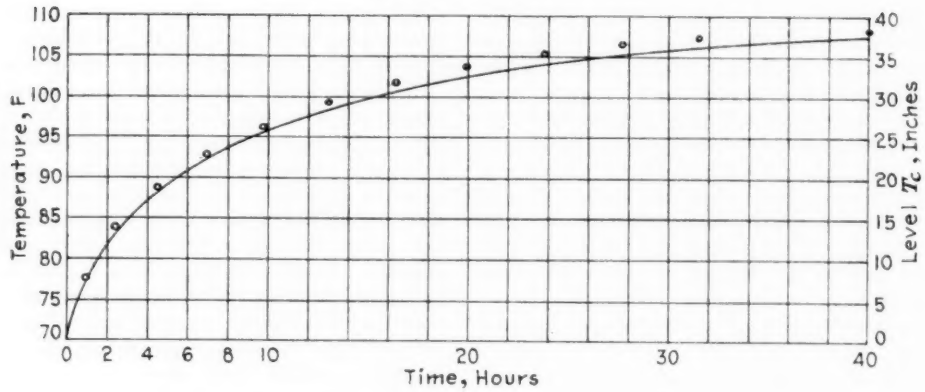

FIG. 4

coordinates. The possibility of confusion in using this function is more apparent when dealing with multiple-capacity processes. When the values of the fraction

$$\frac{T_a - T_{ao}}{T_p - T_{ao}}$$

are desired it seems more convenient to obtain them after the construction of the semilogarithmic plot.

In process analyses, and particularly in those which include an automatic controller, it seems we are more concerned with the deviation at any time from the eventual value for the present condition than with the deviation from some previous value which was the result of a previous condition.

When a process has been in static balance the value of T_{ao} for a new condition is the value of T_p for the previous condition. When changes are imposed on processes not in static balance the value of T_{ao} for a new condition does not have the same importance as a reference value.

Every actual thermal process will have capacity associated with resistance. It is possible, by proper construction of hydraulic analogs, to represent this condition with sufficient accuracy by means of a system of concentrated capacities and resistances more complex than those given in the paper. The inclusion of additional capacities results in differential equations of increased order. Many times the solutions of these more complex systems are not materially different from those of simpler systems involving fewer segregated capacities and resistances. It seems to the author that it would be a worthy purpose for the combined groups of the Committee on Industrial Instruments and Regulators to extend this field of investigation to determine the degree of complexity necessary for practical industrial use of the hydraulic analogy.

As a concrete example of the representation of a thermal process having distributed resistance and capacity by means of a hydraulic system, we have considered a problem given by Doherty and Keller in a recent text.[8] This problem concerns an insulated box which is constructed of cork and lined inside and out. The inside dimensions of the box are 5 × 5 × 4 ft, while the thickness is 4 in. The linings are of $^1/_{16}$-in. sheet steel. It is required to find the difference in temperature between the inner and outer walls as a function of time following the energizing of a 100-watt bulb within the box, the whole system being initially in equilibrium at an ambient temperature of 70 F. A careful solution is given by Doherty and Keller for this problem, using the methods of function theory. Their results are shown by the encircled points of Fig. 4

Fig. 5 shows an extremely simple hydraulic system to be considered as representing the above thermal process. The fundamental correspondences between the two systems are as follows:

Thermal process	Hydraulic analog
Btu of heat	Lb of liquid
Degrees F above 70 F	Inches of liquid level
Hours	Hours

The inflow of liquid corresponds to the heat generated by the bulb, while the outflow of liquid corresponds to the heat lost by the box to its surroundings. The liquid level T_b represents the temperature difference between the inner and outer walls of the box.

The constants of the hydraulic system, as shown in Fig. 5, have been evaluated as follows:

A_a = Total heat capacity of cork walls
= Volume × density × sp ht = 226 (Btu / deg F)

R_a = R_b = Half the thermal resistance of cork walls

$$= \frac{\text{thickness}}{2 \times (\text{mean area}) \times (\text{conductivity})} = 0.05665 \left(\text{deg F} \Big/ \frac{\text{Btu}}{\text{hour}} \right)$$

A_b = Total heat capacity of inner lining plus enclosed air
= 40 (Btu/deg F)

A solution by the usual methods as outlined in the paper, of the corresponding problem involving the hydraulic system, yields the following result

$$T_b = 39.1 - 13.026e^{-0.5328t} - 26.074e^{-0.06469t}$$

in which T_b is the level in inches (corresponding to the temperature of the inner wall in deg F above 70 F) while t is the time in hours following the application of heat. The solid curve of Fig. 4 is a plot of this equation.

Considering that the analog has been simplified by being restricted to a two-capacity system, the representation may be thought to be quite close. It is evident that a closer representation could have been obtained with a more complicated analog.

The theoretical solution for the ideal infinitely long rod cited by Mr. Peters, if considered as representative of a practical process, assumes all capacities and resistances of the process to be uniformly distributed, and permits the adjustment of only one parameter. It is difficult to imagine an industrial process which exhibits a resemblance to such a hypothetical case. It is the author's opinion that, by using hydraulic analogs, practicability may be attained with fewer simplifying assumptions due to the availability of any desired number of parameters.

The probability-integral, or error function

$$\frac{2}{\sqrt{\pi}} \int_0^z e^{-y^2}\, dy$$

[8] "Mathematics of Modern Engineering," by Doherty and Keller, John Wiley and Sons, 1936.

has found wide use for the solution of linear-heat-flow equations. Equation [7] of Mr. Peters' discussion, as written, would indicate a decrease in P as time increased. For the case of the semi-infinite rod, heated suddenly at the finite end at $t = 0$, the theoretical solution in per cent of ultimate change for any point at any time is given by

$$P = 100\left[1 - \frac{2}{\sqrt{\pi}}\int_0^{\left(\frac{x}{2}\sqrt{\frac{RC}{t}}\right)} e^{-y^2}\,dy\right]$$

where R and C are the distributed thermal resistance and thermal capacity, respectively, of the rod. The diffusivity κ, used by Mr. Peters, is the reciprocal of the product of the quantities R and C, and is a constant parameter.

The author wishes to acknowledge the new viewpoints contained in Mr. Smith's discussion but hastens to explain that there was no intention to imply any element of originality in the use of hydraulic analogies, but rather to extend their field of usefulness in connection with automatic-control analysis.

One of the most promising uses of the simplified mathematical representation of process characteristics lies in the analytical

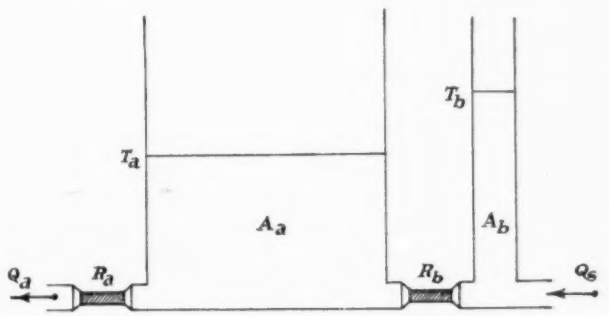

FIG. 5

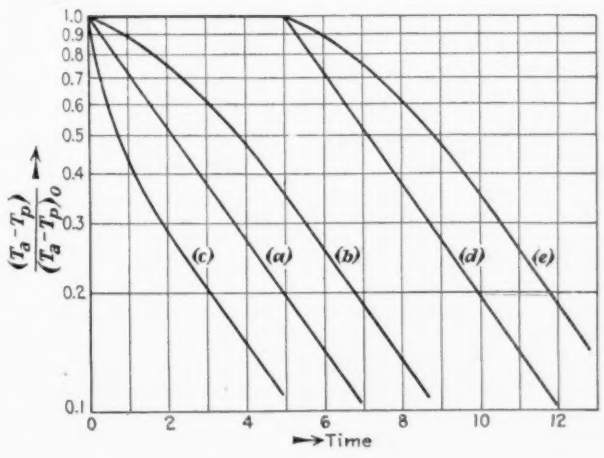

FIG. 6

study of the reactions of processes to the application of automatic control.

There has always been a great deal of confusion in the terminology with respect to process lags and the author would welcome any carefully considered standardization. The term "lag" has become almost useless due to a variety of ill-defined usages.

Many useful conclusions can be drawn from an analysis of single-capacity processes but only a limited number of these have any counterpart in the analysis of a two-capacity process. The author's experiences in the analysis of multiple-capacity processes has led him to despair of any interpretation of these processes in terms of the properties of simpler processes. The opposite development, in which simpler processes are considered as special cases of more complex processes, has permitted a greater degree of generality. The author hopes in future publications to extend his general development along the lines here indicated.

In view of the limited scope of the present paper, the author does not feel that the development has progressed sufficiently to substantiate any practical classification of processes. It is, however, within the scope of the present development to make a qualitative characterization of the three types of process lag as defined and discussed in the paper. Fig. 6 shows curves on semilogarithmic coordinates representing, in a purely qualitative way, the characteristics of these various process lags and of their possible combinations. These several curves represent: (*a*) Capacity lag alone; (*b*) transfer lag for which the initial rate of change is zero; (*c*) transfer lag for which the initial rate of change is finite; (*d*) distance-velocity lag associated with capacity lag alone; and (*e*) distance-velocity lag associated with type-(*b*) transfer lag.

There is no question but that dimensionless ratios and dimensional analysis will play an important part in the future development of theories governing automatic control; but dimensional analysis cannot be intelligently applied in any field until the nature of the phenomena involved is fully understood.

The portion of Mr. Smith's discussion relative to automatic controllers applied to processes has definitely gone beyond the development of process analysis as covered by the paper under discussion. It seems, however, that some of the conclusions concerning hunting and nonhunting charcteristics must be limited to these controls applied to single-capacity processes.

The order of the combined differential equation representing both the instrument and process can be increased either by the characteristics of the instrument or those of the process; thus any second-order process, combined with a simple proportional controller, may produce damped oscillations, if the sensitivity of the instrument affects the coefficients so as to give a pair of imaginary roots. Proportional control applied to third-order processes may produce continuous or increasing oscillations when the sensitivity is sufficiently high.

Many mathematical truths may be used to formulate theorems relating to automatic control but the author feels that a much more substantial progress can be had by following a gradual development and by the application of general theorems developed for the more complex processes and instruments, to the simpler processes considered as special cases of the more complex.

Design of Flanged Joints for Valve Bonnets[1]

E. C. PETRIE.[2] The subject of valve-bonnet-joint design is one which is of considerable interest to valve manufacturers and users. The high pressures which are now being used in many industries coupled with high temperatures have made flange-bonnet-joint design a problem which must be considered seriously. The authors have presented in the paper under discussion one of the first practical applications of the design

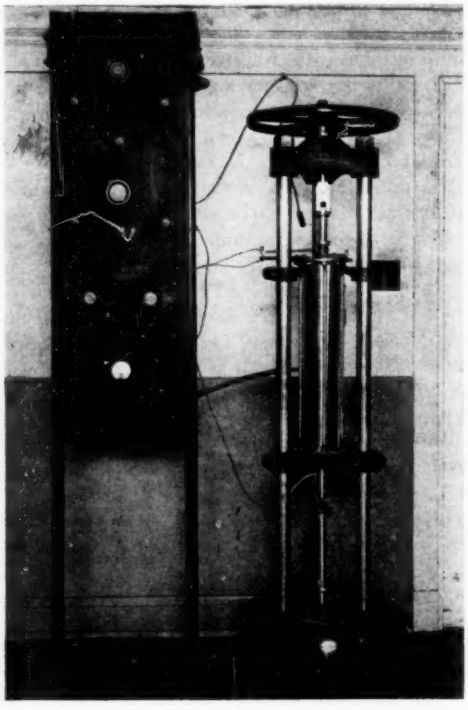

FIG. 1 RELAXATION-TEST UNIT

formula for flanges as developed by Waters, Wesstrom, Rossheim, and Williams.[3]

The authors have pointed out that for flanges smaller than 24 in. the calculation of the distributed moments should be based upon the mean diameter of the hub at the junction of the hub and flange. The writer believes that this same change from the original formula should be incorporated in the formula for X where the value of B should be changed to $(B + g_0)$. Similarly, the value of $h/\sqrt{(Bg_0)}$ should be changed to $h/\sqrt{[(B + g_0)g_0]}$.

In designing a flanged bonnet joint the authors correctly state that the starting point is to select a proper ratio of residual gasket contact pressure to line pressure. This ratio is one which must be based upon actual operating experiences and tests combined. The authors have eliminated the gasket material as a criterion by proportioning the width of the gasket face on the flange so that the compressive yield strength of the flange material will not be exceeded. This method for determining gasket dimensions may be suitable when the gasket material is strong enough to withstand the compressive loads applied.

There is another point which must be considered, that is, in most cases the bolt load applied to a flange joint is in excess of any load used in the theoretical calculations. For example, in the determination of the flange dimensions for a 6-in. 1500-lb bonnet joint the authors obtain a gasket width of 5/16 in. and a total gasket area of 9.94 sq in. The bolting used in this joint is sixteen 1 3/8-in. bolts. In sledging or pulling up these bolts in the shop or field, stresses of approximately 40,000 lb per sq in. are usually applied. A stress of this magnitude produces a total bolt load of 18.48 × 40,000 or 739,200 lb. This in turn develops a compressive stress of 739,200/9.94 or 74,400 lb per sq in. in the gasket or flange material. The writer believes that probable maximum stresses which may be applied when bolting a bonnet joint should be used in determining the proper gasket area.

In order to illustrate the probable magnitude of stresses which are applied in service, the writer has included Table 1 of this discussion which gives stresses based on a check up of bolt stresses in joints made up in the field and in the shop.

The American Standard steel end flange male and female facings give, as a general rule, low residual gasket pressures due to the wide gasket face. Experience has indicated that the gasket width should be decreased to approximately the width of the wide tongue-and-groove facing to insure a tight joint. Under this condition the average compression load applied by the bolts, when pulled up to stresses given in Table 1 of this discussion, is about 30,000 lb per sq in. as this compressive stress has produced satisfactory joints in the past, it seems to the writer that proper gasket proportions can be obtained by considering 30,000 lb per sq in. as the design gasket compression using bolt stresses as given in Table 1 of this discussion.

DESIGN OF HIGH-TEMPERATURE FLANGE JOINTS

When flange joints are designed for temperatures above 750 F, factors enter into the problem which do not have to be considered at the lower temperatures. At these high temperatures, the materials used for the bolts and flange are subjected to a plastic deformation which has been termed "creep." This plastic deformation causes residual gasket compression to decrease as increases occur in the time the joint is subjected to the temperature. If the decrease in gasket compression becomes great enough, the joint will leak.

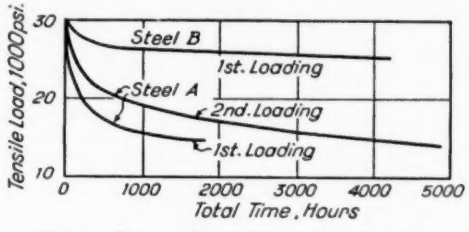

FIG. 2 TYPICAL RELAXATION-TEST CURVES

Tests conducted by the company with which the writer is affiliated, on a 10-in. 1500-lb flanged tee equipped with Sarlun-type joints, indicated that joint leakage occurred when the bolt stress dropped to approximately twice the total load exerted by the pressure on the area bounded by the outside diameter of the contact face.

In the last few years an attempt has been made by several laboratories to determine the amount of creep which occurs in steels used for manufacturing bolts, in order to develop design stresses for bolting materials. The first tests which were made

[3] "Formulas for Stresses in Bolted Flanged Connections," by E. O. Waters, D. B. Wesstrom, D. B. Rossheim, and F. S. G. Williams, Trans. A.S.M.E., vol. 59, April, 1937, paper FSP-59-4, pp. 161–169.

measured the creep at various temperatures under constant loading. This method of testing has now been supplanted by attempts to reproduce the same conditions which prevail in flange joints by testing under loads which become less as creep increases. This method of testing has been referred to as relaxation testing of bolting materials. A special machine for obtaining relaxation curves of steels under conditions similar to those occurring in a flange joint is shown in Fig. 1 of this discussion.

The test specimen under stress is held at a constant temperature in a special heater. The stress is measured by the strain in a calibrated external bar which is subjected to the same load as the test specimen. As creep progresses, the relaxation of load is measured on this external "weigh bar" and the values obtained are plotted against time in hours. Fig. 2 of this discussion shows the relaxation curves for several grades of alloy-steel bolting material.

It will be noted by referring to Fig. 2 of this discussion that the load-retention characteristics of steel *B* is superior to that of steel *A* due to its lower primary creep. It should be noted that the second loading of steel *A* indicates a greater load retention than the first loading. This leads to the conclusion that if bolts were retightened in a flange joint after the joint has been subjected to the operating temperature for a short period of time the joint will remain tight for a longer period of time than if the bolts were not retightened.

Another conclusion not apparent from Fig. 2 of this discussion is that if higher initial stresses be applied to the test specimen, the initial relaxation curve will be much steeper and the final stress after a period of time will be approximately the same or only slightly higher than that shown at, say, 4000 to 5000 hr.

Since the load-retention curve for bolting steels indicates the amount of stress which remains in a bolt after being subjected to temperature for a certain period of time, it is the writer's opinion that design bolt stresses can be obtained in this manner. If we again refer to Fig. 2 of this discussion it can be seen that the design stress for steel *B* at 850 F can be assumed as approximately 25,000 lb per sq in.

A.S.A. Flanges

The authors state in their conclusion: "In fairness to the A.S.A. flanges, it should be stated that they were purposely designed with excessive bolting." It must be remembered that these flanges are generally used with the raised face or male-and-female type of joint which comprises a gasket width and outside diameter of gasket much greater than the narrow tongue and groove illustrated by the authors. Under these conditions the residual gasket compression using A.S.A. bolting is much lower than that which has been used by the authors. With reference to the dimensions of the flanges, the writer does not believe that the differences shown are due to excessive bolting, but to the fact that loose flanges, such as the lap-and-screwed type, were used in determining the flange dimensions.

E. O. Waters.[4] Slightly over a year ago, the writer presented, along with three coworkers, the results of a very extensive study of flange stresses and deflections.[3] At that time, it was evident that there was some misapprehension on the part of designers and users that the authors were claiming a particular degree of potency for the three main formulas of their paper[3] (Fig. 1 of the present paper). Nothing could have been further from the truth; the formulas were no more nor less than the results of a formal stress analysis applied to specific locations of the flange structure at which it could reasonably be assumed that the stresses would have maximum values. Having accomplished this work, there still remained the problem of interpreting these results, determining suitable factors of safety which might, or might not, permit exceeding the elastic limit at certain points, and finding out how best to use the formulas, not only for checking but for assisting in the actual design of new sizes. The question of bolt stress and gasket pressure was also involved, and here again the paper[3] made no attempt to lay down any rules or even make suggestions.

It is extremely gratifying to find that others have been eager to carry on the work which the writer helped to initiate. Full-scale tests have been made,[5] while others it is hoped will be made public in the near future. The Taylor Forge and Pipe Works have developed one very practical design system, based on an orderly arrangement of calculations outlined in special work-sheets which they have constructed; however, in the present paper[1] we have a detailed account of another design procedure, independently arrived at, which shows clearly the difficulties that beset the flange designer, and gives an extremely interesting and effective means of overcoming them.

In the writer's opinion, the chief merit of the method outlined in this paper[1] lies in its elimination of many troublesome variables at the outset by the simple assumption that $f = 1$, $g_1/g_0 = 1.25$, and K is determined by the bolt circle that will carry the necessary bolting with the minimum practical clearance for the nuts. Nothing then remains but to find the flange thickness t in relation to one of the stresses, by means of the cubic or fifth-degree equation as indicated. Designers may differ when it comes to the auxiliary computations, such as that for gasket load and dimensions, bolt load and dimensions, and flange moments, but these are really nonessential to the method, and should be welcomed as adding to the body of information available on points that are still subject to differences of opinion. In particular, attention should be called to the choice of the value $f = 1$, since it not only contributes to the concise nature of the method, but eliminates at one stroke any argument as to the possibility of high stress at the small end of the hub or the critical nature of such a stress, if high. The analysis of the effect of hydrostatic pressure is worth noting, since it gives a good qualitative picture of the resultant variation in S_H, S_R, and S_T. The arbitrary 10 per cent reduction is of course a judgment factor and must be accepted as such in lieu of any more precise data on the effect of internal pressure.

In their concluding paragraphs, the authors make a comparison with A.S.A. flanges which, to say the least, is remarkable. There is no doubt that in many cases, flanges are subjected to heavy loads caused by dead weight and thermal expansion which are largely indeterminate, and here the A.S.A. standards offer the designer a set of proportions which experience has shown to be well within the limits of safety. When, however, the actual stress conditions are predictable with some degree of accuracy, it is interesting to note that the use of rational formulas, based upon an analysis of these conditions, makes possible a large saving in space and weight over what would result from the use of empirical data.

In their fourth paragraph, the authors mention an approximation that was made in the original development of the formulas for S_H, S_R, and S_T which has some bearing on their application to small-size flanges. It may be well to throw some further light on this matter by the following two considerations:

1 In deriving the equations, three simultaneous equations were set up in these three unknowns: Bending moment between flange and hub, shear between flange and hub, and rotation of

[4] Associate Professor in Mechanical Engineering, Yale University, New Haven, Conn. Mem. A.S.M.E.

[5] "Tests of Heat Exchanger Flanges," by D. B. Rossheim, E. H. Gebhardt, and H. G. Oliver, Trans. A.S.M.E., vol. 60, May, 1938, paper FSP-60–10, pp. 305–314.

flange and hub, all at the point of juncture. Now, as far as the flange is concerned, this point was taken at the inside diameter and middle surface, whereas for the hub it was taken at the large end and the mean diameter, for convenience in computation. These points are indicated approximately in Fig. 1 of the paper,[1] in the sectional view of the flange and hub, where the arrows representing S_R and S_H have zero length, and it is obvious that they are far from coincident.

The writer believes that the rotations at the two points are practically identical in the vast majority of cases, since, to a first approximation, the flange section acts as a rigid rectangle and rotates without curvature of the middle line. However, there may be an appreciable difference between the respective moments and shears, the importance of which cannot be determined without much additional computation. It is suggested that in any doubtful case, calculations be made on the basis of $K = A/B$, and then compared with those made on a basis of $K = A/(B+g_1)$; if the first assumption is possibly on the unsafe side, the second one certainly errs on the side of safety, since it neglects the material of the flange between the diameters $B + g_1$ and B.

2 In the analysis of the hub, which is based on the theory of a beam on an elastic foundation, it was assumed that the effective diameter of the hub is equivalent to the inside diameter, and two items of considerable importance for small-size flanges were completely ignored, namely: (*a*) The shear P on a plane normal to the axis of the hub is not uniformly distributed, since the hoop stress (proportional to the hoop strain) is greater at the inside diameter than at the outside diameter; (*b*) the unit slice of hub, which is considered equivalent to an elastically supported beam, is not rectangular in section, but trapezoidal, with a minimum width of 1 and a maximum width of $1 + (2g/B)$, so that the neutral axis and moment of inertia are subject to correction. For a hub of constant thickness, correction of these two items is equivalent to using an effective hub diameter of

$$B\left[\frac{2 + 4\frac{g}{B} + \frac{4}{3}\left(\frac{g}{B}\right)^2}{\left(\frac{B}{g} + 1\right)\log_e\left(1 + \frac{2g}{B}\right)}\right]^{1/2}$$

or approximately

$$B\left[1 + \left(2\frac{g}{B}\right) + \frac{1}{3}\left(\frac{g}{B}\right)^2\right]^{1/2}$$

for hubs of constant thickness.

This corrected diameter should be used in all the formulas and charts involving the ratio or product of B and g_0. For tapered hubs, the correction can be closely approximated by using the mean of g_0 and g_1 in the correction factor.

The calculation in Table 2 of this discussion shows the effect of these corrections in a deliberately chosen extreme case, and indicates the danger of a too carefree application of the formulas. As already stated, the change of K from 5 to 2.5 is overconservative; nevertheless, the true stresses probably lie somewhere between those in columns 2 and 3 of Table 2 of this discussion, which would make them quite different from the results of column 1

TABLE 2

Let A = 5 in., B = 1 in., $g_0 = g_1$ = 1 in., t = 1 in., $h = \infty$, and ν = 0.3. Then:

ARTHUR MCCUTCHAN.[6] This paper is a valuable complement to the paper by Waters, Rossheim, Wesstrom, and Williams.[3] The transition from purely theoretical flange analyses to specific application often is a difficult process and this detailed account[1] should serve a useful purpose. As pointed out by the authors, the requirements of a formula for checking existing designs do not necessarily coincide with the requirements of a formula for developing new designs. The authors' device of using a similarity of proportions to reduce some of the formula ratios to constants appears to have merit.

The comparison of the new series of bonnet flanges with fitting flanges of the American Steel Flange Standards having approximately the same bore helps tie in these recent analyses with the original Waters-Taylor formulas. The reduction in weight of the flange ring is noteworthy, but should be attributed in part to the greater number of smaller bolts and the type of flange facing employed. Incidentally, it would seem that even lighter flanges would have resulted if the tongue-and-groove facing had been located close to the bolt holes rather than near the bore of the flange.

The writer is inclined to question the statement that the bolting in the Steel Flange Standards is heavier than necessary for the raised-face type of joint for which the standard was designed. Considerable improvement in joint life was obtained in an experimental high-temperature installation with which the writer is familiar by reaming out the bolt holes of 600-lb flanges and installing $^1/_8$-in. oversize bolts. Had the flanges been the weaker part of the assembly, the use of larger and stronger bolting would have been less effective in increasing joint life.

In view of the urgent need for practical rules for the design of bolted flange connections which can be incorporated in the A.S.M.E. Boiler Construction Code, A.S.A. Code for Pressure Piping, and other codes, this paper giving a demonstration of the practicability of designing flanges by the recent formulas developed by Waters and his associates,[3] is particularly timely.

AUTHORS' CLOSURE

The discussion by Professor Waters discloses that certain corrections are required in the stress formulas given in "Stresses in Bolted Flanged Connections"[7] where such formulas are used for the design or analysis of flange connections having high K values ($K = A/B$; A = outside diameter, B = inside diameter of flange), such as occur with flange connections for valve bonnets.

In addition to the corrections, the discussion also suggests that an alternative set of calculations of flange stresses be made for such types of flanges by using a smaller value of K, namely, $K = A/(B + g_1)$, in the corrected formulas, instead of the true value, A/B.

The object in making this alternative set of calculations is to obtain another set of flange-stress values above which the true stresses will not go. "The true stresses," it is stated, "probably lie somewhere between" stresses figured for $K = A/B$ and for

[6] Engineer, The Detroit Edison Company, Detroit, Mich. Jun. A.S.M.E.

[7] By E. O. Waters, D. B. Wesstrom, D. B. Rossheim, and F. S. G. Williams, Trans. A.S.M.E., vol. 59, April, 1937, paper FSP-59-4, pp. 161–169.

$K = A/(B + g_1)$ in the corrected formulas. The reason stated for considering the use of the smaller values of K as giving, so to speak, an upper limit of stress values is, that the addition of the flange-hub thickness g_1 to B in the denominator is equivalent to neglecting the material of the flange between the diameters B and $(B + g_1)$ and consequently such calculation "errs on the side of safety."

A flange weakened by a cutout of this amount of material at this particular place, most certainly will show an upper limit of stress values, providing the formulas which are used for calculating the stresses apply to this weakened and odd form of flange. This proviso must be made, otherwise the stresses calculated lose their meaning.

To the authors, however, it seems more natural to interpret the smaller value of K as simply creating another flange with a smaller outside diameter. Such smaller diameter is then to be considered as equal to $[B/(B + g_1)]A$, for this value of it will give the suggested smaller value of K of $A/(B + g_1)$. However, if this interpretation is accepted as correct, then the authors do not any more see clearly why a reduction in the outside diameter should cause the flange stresses calculated accordingly always to become a logical upper limit for flange stresses in the original flange. The authors realize that such stresses will be higher than the original stresses but cannot agree always to consider them as limiting stresses. Further, there does not seem to be any need for the upper limit of the stresses. Tests have shown the formulas to give reliable and safe stress results and therefore the authors prefer to accept the originally calculated stresses as final.

The correction of the diameter B given in the second paragraph of the discussion is most helpful and the authors are grateful for this information. Of the two formulas therein given, the last or approximate formula appears to be the most practical one to use in calculating flanges, and this formula when converted to tapered-hub flanges will be

$$B_c = B\left[1 + \frac{g_1 + g_0}{B} + \frac{1}{12}\frac{(g_1 + g_0)^2}{B^2}\right]^{1/2}$$

This B_c, therefore, or the theoretically correct one, is to be used instead of B in all the formulas and charts involving the ratio or product of B and g_0. That means the charts for f, F, and V and the formulas for X and h.

In Mr. McCutchan's discussion it is suggested "that even lighter flanges would have resulted if the tongue-and-groove facing had been located close to the bolt holes." It is quite possible to believe that this would be so for the moment arms of the forces concerned appear to be shortened by moving the gasket toward the bolt holes. However, as the gasket is moved outward the forces acting on the gasket and on the annular surface between the gasket and the inside diameter will increase in amount. This increase in the forces requires more bolt area, therefore, larger bolts, and larger bolts in turn will increase the bolt-circle diameter, thereby causing an increase in the moment arms. To show this, a practical example has been worked out for a flange of 10 in. inside diameter with a constant hub thickness of 3 1/8 in. and for a pressure of 1500 lb per sq in. On this flange the gasket has been moved out progressively in four equal steps 1 in. apart, keeping the gasket width constant. The results are tabulated in Table 3.

TABLE 3

Gasket dimensions, ID, in.	Gasket dimensions, OD, in.	Moment, in-lb	Bolt load, lb	Bolts, No.	Bolts, Size, in.	Bolt stress lb per sq in.	Bolt-circle diam, in.	Flange OD, in.
11 1/8	11 13/16	1005000	275800	16	1 1/2	12300	19 3/8	22 1/2
13 1/8	13 13/16	1229000	355600	14	1 3/4	12800	19 13/16	23 3/8
15 1/8	15 13/16	1423000	445000	14	2	12000	20 1/4	24 1/4
17 1/8[a]	17 13/16	1660000	543600	14	2 1/8	12800	21	25 1/4

[a] Diameter at inside of bolt hole is 18 13/16 in., or gasket OD is 1/2 in. from bolt hole.

In the table the number of bolts has been kept practically the same in order to have a fair comparison. It is, however, perfectly possible to start out with a few large bolts and to increase the number of them as required by the increase in force, thereby keeping the bolt-circle diameter almost constant, but that would hardly constitute proper design practice and accordingly would not give a reasonable or fair comparison.

Attempts have been made by the authors to put the gasket location in a purely mathematical form with one variable, namely, the distance of the gasket from the inside diameter of the flange, but bolt sizes cannot be reduced to a continuous function, therefore, approximations and assumptions are necessary. These approximations complicate the formulas to an extent that makes it difficult, if not impossible, to interpret the result and obtain a universal answer. The actual example given is typical of the flanges which the authors have investigated, and for such flanges it is well to locate the gasket as near to the inside diameter as it is practical and possible.

The bolting for standard flanges referred to in the discussion is a matter of considerable scope. The authors meant with the term "excessive bolting," to express the facts that the bolting requirements for a line flange are higher than for a bonnet flange and that due to the several different flange facings for which the standard bolting is designed, such bolting for some facings, of necessity, will be excessive, while for others, not at all excessive. Overbolting and excessive bolting are terms needing a definition or qualification before they can be fully discussed or understood.

In the discussion by Mr. Petrie there are certain calculations pertaining to a gasket unit pressure calculated by giving the bonnet bolts an assumed unit stress of 40,000 lb per sq in., whereby the gasket unit pressure becomes excessive. The assumption of 40,000 lb per sq in. is rather unwarranted in view of the authors' expressed statement in the paper that the gasket was designed to prevent an overloading of it. From their statements it naturally follows that the bonnet bolts would not be stressed to 40,000 lb per sq in. or any other arbitrarily selected stress, but to a stress in full conformity with the design of the gasket.

A bonnet flange is quite different in one respect from a line flange in that a bonnet flange is made up in the shop where full control of the bolt stresses can be exercised, while a line flange is made up in the field where such control is not often present, if ever. This control is exercised by the company with which the authors are connected, and the bonnet bolts are all uniformly stressed to a predetermined stress, and so marked by tag. That stress is not over 40,000 lb per sq in., but depends upon the flange-material yield point and the hydrostatic test pressure, as explained in the paper.

The authors wish to call attention to an error which appears on page 299 of the paper in Eq [4]. This formula should read

$$T = \frac{3K^2\left(1 + 2\frac{1 + \nu}{1 - \nu} \times 2.3026 \log_{10} K\right) - 3}{\pi(K - 1)\left(1 + \frac{1 + \nu}{1 - \nu}K^2\right)} \quad \ldots [4]$$

Operation of Emergency Shutoff Valves in Pipe Lines[1]

ROBERT W. ANGUS.[2] In his paper the author called attention to the very important case of the bursting of a pipe line above

[1] Published as paper HYD-59-10, by F. Knapp, in the November, 1937, issue of the A.S.M.E. Transactions, vol. 59, p. 679.

Friction loss neglected, Fig. 2, dashed lines	4	5.23	6.46	7.70	7.88	7.60	5.3

[a] The methods referred to are shown in Figs. 1 and 2 of this discussion.

NOTE: This table shows the type of error that may result from neglecting friction head in this case. The results by the two methods of allowing for friction agree fairly well, but neglecting friction makes a great difference both in pressure and velocity.

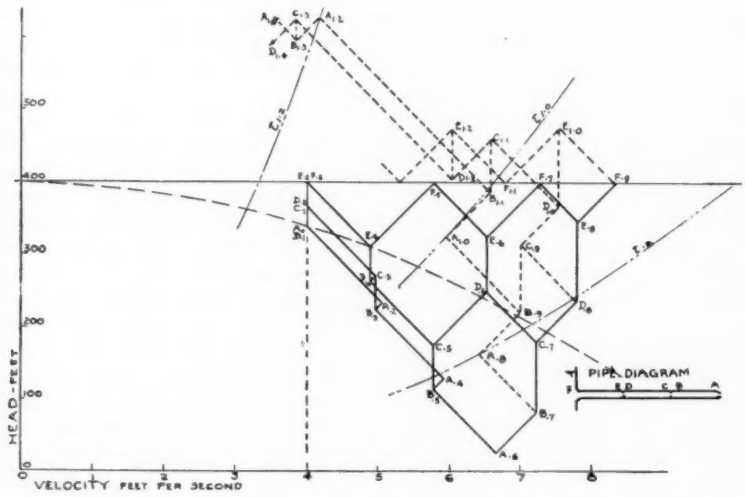

FIG. 1 EFFECT OF PIPE BURSTING JUST BELOW THE VALVE, WITH VALVE CLOSURE AS GIVEN BY τ AND ALLOWING FOR FRICTION

(H_0 = 400 ft, V_0 = 4 fps, a = 3216 fps, and L = 965 ft.)

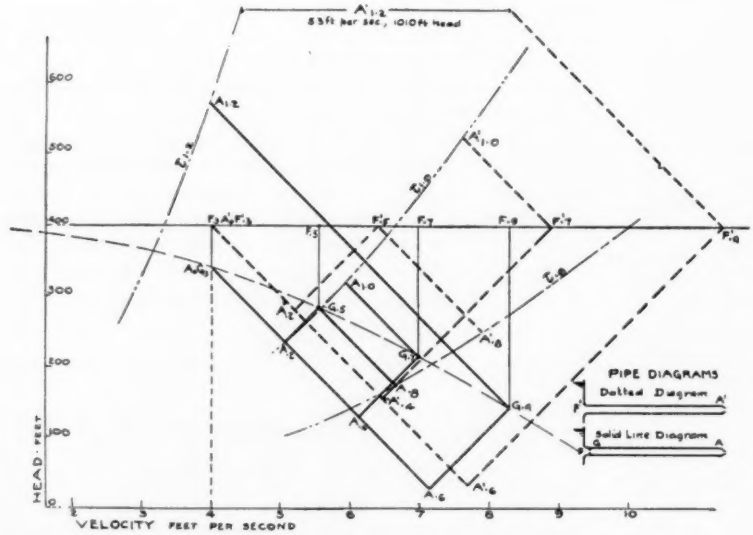

FIG. 2 EFFECT OF PIPE BURSTING JUST BELOW THE VALVE WITH FRICTION NEGLECTED (DASHED LINES) AND WITH FRICTION ALLOWED FOR BY SCHNYDER'S METHOD (SOLID LINES)

(H_0 = 400 ft, V_0 = 4 fps, a = 3216 fps, and L = 965 ft.)

or below a valve. Such a condition tests the value of the valve and its controls to the limit, particularly if the break were to occur just below the valve, because the pressure just above the valve would then become nearly atmospheric, exceeding the latter only by the pressure necessary to overcome the loss in the valve and jagged opening in the pipe. Accompanying this drop in pressure is a corresponding increase in discharge, and closure of the valve must be effected with great care to avoid further ruptures in the line, however, the operation must usually be rapid or serious damage may be done by the discharging water.

The author shows a shutoff valve with a self-acting by-pass valve, an arrangement of much value in larger pipes, because when the large valve becomes nearly closed it is difficult to control the areas in the way necessary to prevent water hammer, therefore, the smaller by-pass is most helpful. The writer discussed elsewhere[3] one such case, but if the by-pass connections are short and free from losses, the writer believes that the action of the by-pass differs in no way from a properly controlled large valve, assuming such control practicable.

In the case of the burst pipe, with large increase in velocity and great decrease in pressure, it does not appear to be possible to neglect friction loss and velocity head. In some experiments made by the writer on a $1^1/_4$-in. pipe about 160 ft long and discharging freely into the atmosphere, it was found that the calculation without considering friction gave answers far from those determined by measurements. This is to be expected, because while in normal operation on power plants and distribution piping the losses are usually much under 10 per cent, yet with a burst pipe the entire head available is lost in friction or converted into velocity head.

In order to observe the effect of friction, the writer solved the case shown in Figs. 1 and 2 of this discussion, allowing for losses by two different methods, and then he solved the same problem neglecting the losses. The data are not the same as those used by the author of the paper[1] under discussion, but the cases compared are all on exactly the same basis.

The problem solved by the writer is for a pipe with H_0 = 400 ft, V_0 = 4 fps, and a/g = 100 sec. The friction loss has been assumed as shown on the dashed line through A_0 and the point H_0 = 400 ft, V = O; in this case, in order to make a clear figure, the friction loss has been taken as 60 ft at a steady velocity of V_0 = 4 fps. Further, the selected value of L/a = 0.3 sec, and, when the pipe bursts, the pressure drop at the valve is assumed to vary uniformly with time, a statement which is not greatly in error, however, the exact relation is easily allowed for. It is further assumed that the minimum pressure at the gate is

[3] "Air Chambers and Valves in Relation to Water Hammer," by R. W. Angus, Trans. A.S.M.E., vol. 59, November, 1937, p. 667.

slightly different for all three cases, in view of the fact that the calculated velocities at this minimum pressure are not the same.

In Fig. 1 of this discussion, all of the losses are assumed concentrated at two points, as shown in the sketch of the piping. The broken lines have no significance beyond helping the reader to keep different parts of the diagram distinct.

In Fig. 2 of this discussion are two diagrams, one in solid lines and the other in broken lines. The one in solid lines shows one of Schnyder's constructions, which assumed the entire head loss concentrated near the reservoir end of the pipe. The diagram in broken lines shows the construction if friction were neglected. The principles used in constructing these diagrams are explained in the writer's papers.[3,4,5]

The same law of valve closure has been used throughout, and corresponds to the values of τ shown; it is assumed that there is no by-pass. The valve is assumed to have no effect until after 0.6 sec. Table 1 of this discussion compares the results obtained with the three constructions, that is, Fig. 1 of this discussion and the two constructions in Fig. 2 of this discussion.

Tests of Heat-Exchanger Flanges[1]

S. C. Hollister.[2] The writer believes that in the test vessel used by the authors the length of the upper section between the tapered hub and the dished-head knuckle radius is so short that the hub would not be free from effects of distortion arising from the performance of the head. The writer believes the minimum dimension should be 18 in. in order to prevent the possibility of affecting the flange region against the restraints offered by the head; and the writer is of the opinion that there is enough restraint to account for at least part of the discrepancies shown in Figs. 10 and 11 of the paper.

N. O. Smith-Petersen[3] and J. D. Mattimore.[4] A study of the authors' flange tests leads to the conclusion that the formulas developed by E. O. Waters and his associates, presented in another paper,[5] produce designs which are on the safe side by an appreciable margin. The test results are more conservative than the calculated results except in the case of the flange rotation due to bolt load for flange *C*-2 and for the hub stresses in flanges *C*-1*B* and *C*-1*C* in the higher ranges of bolt load where it would appear some yielding was taking place. In the case of flange *C*-2, the test points in Fig. 9 of the paper for flange rotation due to bolt load practically coincide with the calculated curve for the worst moment condition. In view of the complexity of the stresses involved and the difficulties of obtaining exact test data, the writers believe the correspondence of the theoretical figures with the test results is very good. The test is also of interest in several of its details.

Of interest is the banjo attachment of the Huggenberger tensometers to the hub. It is a clever solution of this problem and should prove very helpful to others contemplating similar tests.

The arrangement of ball bearings at both ends of flange studs is a refinement which assures a greater accuracy in stud-length measurement than obtained by flat surfaces on the studs.

The arrangement of two ball bearings on a few studs for measuring stud bending does not appear to have given conclusive results, for no data or comments concerning the usefulness of it are given. However, stud bending appears to be present in results recorded on the many charts. Upon them are shown calculated curves for the stud load acting through the center line of the studs and acting on the inside shank line of the studs. The actual measured results seem to change from one of these lines of action toward the other as the bolt load increases. The direction of the change is from the shank line toward the center line of the the stud. This direction is opposite to that expected to take place were the change due to flange deflection only, and therefore appears to be due to bending of the studs. A simple calculation will confirm this and will show that high stresses are produced in the studs when eccentrically loaded. In fact, when the stud load acts on the shank line of the stud the bending stress is exactly four times as great as the direct tensile stress caused by the load. Accordingly, for high stud stresses it seems likely that the stud reaction is more nearly through the center line of the stud than elsewhere.

Fig. 7 of the paper, showing the influence of the internal pressure upon the bolt load, is of considerable importance. Again it is shown by tests that an appreciable loss of bolt load is caused by the internal pressure, but the extent to which it is due to radial and to axial internal pressure is not stated. The gasket location may have much to do with the axial effect.

In the design of flanges for heat exchangers and similar vessels for comparatively low pressures and temperatures, it may be permissible, from an economic standpoint, to allow relatively high hub stresses. On the other hand, it is the writers' opinion that a flange designed for both high-pressure and high-temperature operation should have a much lower permissible hub stress. A high initial hub stress, under high-temperature conditions, might conceivably result in a readjustment of stress conditions within the structure which would defeat the designer's purpose. Actually there should be little, if any, economic hardship involved in this since conditions involving high pressure and high temperature usually bring about proportions producing low hub stresses without much effort on the designer's part.

The authors made an excellent selection of the types of flanges to be tested, since they constitute two extreme designs between which almost all other designs can find a classification.

T. McLean Jasper.[6] The authors have tested two sets of flanges made of ductile steel which have tapered hubs. In the use of ductile-steel flanges, the ductility acts as an extra insurance with reference to the operation of the flanges in service because at the point of maximum stress there is a certain amount of relief long before much deformation occurs. However, a test on a formula for design could best be carried out with something like cast iron, or some other brittle material, which does not adjust itself and for this reason will not tend to obscure the problem.

The tapered-hub flange does not in general represent a large quantity of flanges used in pressure vessels or in industrial work of all kinds. One important fact is brought out by Fig. 7 of the paper, which reaffirms the idea that the greatest bolt loads, and incidentally the greatest stresses, occur with the type of flange and gasket considered when the bolts are tightened and not when the pressure is exerted.

The question of the value of the tapered-hub flange is one which

[6] Director of Research, A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

can lead to very important discussions. The method of putting the gasket near the bolt hole in the test flanges increases the inside pressure area, and, incidentally, an increased requirement is experienced in the design for the pressure times the area on which the pressure acts. The taper of the hub increases the diameter of the bolt circle, and this increases the moment with a fixed gasket circle.

Has it been established that a tapered-hub flange is superior to a flange without a taper and with a reasonable fillet? May it not be asked that the Special Committee establish also values for hubbed flanges without taper. This is important where outlet necks are relatively thick for design reasons.

The writer would like to know whether the stresses shown in Figs. 12 to 15, inclusive, are actual stresses or strains multiplied by a factor. If the latter were true, then the real stress values would be something very different from those shown. In Figs. 14 and 15 are the hub stresses, due to pressure, negative? They are shown as increases, but Fig. 7 shows a decrease in bolt length and therefore in load, as the pressure is increased. How were these values obtained?

E. O. WATERS.[7] The writer is interested in the results secured by the authors of this paper[1] and regrets that lack of time has prevented him from undertaking an independent analysis of the data. As far as the effect of flange loading is concerned, whether by bolt pull or by hydrostatic end force, the theoretical formulas for flange rotation used as a standard of comparison by the authors show reasonable agreement with these tests. The same is true for hub stress. The fact that this agreement is improved by taking the effective bolt-circle diameter as *B.C.-d* instead of *B.C.* is beside the point; for after all, when the two major loads (gasket reaction and bolt pull) are applied at points which are only one third of the full flange width apart, and the moment which they produce is equated to a fictitious moment caused by forces at the extreme inside diameter and outside diameter of the flange, there is bound to be some discrepancy between calculated and test results, and a small change in the bolt-pull location makes a big change in the value of the equivalent moment. To state the matter from another viewpoint, tests such as those reported by the authors should be regarded not so much as a check on proposed design formulas, as a determination of empirical constants by which such formulas should be multiplied in order to fit designs of the type tested. In the present case, where B is large and K is close to unity, it appears that the empirical correction is obtained by using *B.C.-d* for the effective bolt-circle diameter. This does not mean that the bolt reaction is actually moved in to this circle; it is merely a way of correcting for the approximations involved in the highly artificial calculation of effective flange moment, the arbitrary location of bolt reaction, and other simplifying assumptions in the design formulas.

The foregoing statement is by no means intended as criticism, but simply as a warning not to extend the authors' conclusions to miscellaneous flanges of widely different proportions. On the other hand, the authors deserve the thanks of all individuals and organizations connected with the manufacture and use of flanges for their very carefully planned and thorough-going research. It is to be hoped that the work may be extended along the lines suggested, with a view to determining how much yielding it is safe to permit in the hub, especially at the small end. Possibly further light could be shed on other questions of a controversial nature, such as the relation of allowable bolt stress to allowable flange stress, and the actual location of the bolt reaction which may shift toward the flange center as the flange rotation increases.

In regard to the superimposed effect of pressure on flange rotation and hub stress, shown in Figs. 10*a*, 10*b*, 11, and 14*a* to 15*c*, inclusive, it is obvious that the calculated and test results are not in as good harmony as could be desired. However, these flange rotations are small in magnitude as compared with the basic rotations caused by flange loading, and it is frequently found that elastic measurements made under such conditions fail to check closely with theory. In the case of hub-stress increase, most of the disparity appears to be confined to two locations on the long-hub unit, which may be due to undiscovered causes of a local nature. At any rate, the agreement in general appears to be good enough to justify an effort to extend the design formulas for S_H, S_R, and S_T to include the effect of hydrostatic pressure, for certain specified values of the latter.

In conclusion, a brief comment would seem to be in order regarding the authors' doubts as to the accuracy of appendixes B and W of reference 6. As far as flat plate theory is concerned, there is no reason to expect a more or less fixed relationship between the flange rotations at the inside and outside radii. For all practical purposes, the two are equal for rings of the proportions tested, and any theoretical difference would probably be less than the range of experimental error to be expected in measuring the rotation at several points, either at the outside or inside radius. The theory itself indicates that the ratio of the two rotations may be either greater or less than unity. For a simple ring having K, B, and t as given in the authors' Appendix 3, sheet no. 1, and a loading equivalent to M according to the conventional method of flange load distribution, but no moment concentrated at the inner edge, calculation shows that the inner slope exceeds the outer slope by $0.9197\ M/E$. If the loading consists only of a moment $-0.147269\ M$ at the inner edge, the inner slope (now in the opposite direction) exceeds the outer slope by only $0.5808\ M/E$, which is not enough to compensate for the slope difference caused by the first loading. In other words, for the designs tested by the authors, the hubs were not stiff enough to make the flanges dish in the manner which the authors expected.

ARTHUR MCCUTCHAN.[8] The authors of this paper and the Heat Exchange Institute are to be commended for the realistic view they have taken of the problem of flange design. Testing such large heavy structures under conditions so nearly simulating actual use is reassuring as an indication that too great significance will not be attached to localized high hub stresses which have little if any relation to the problem of securing tight joints.

The choice by the authors of flange rotation as a measure of flange rigidity rather than flange deflection eliminated uncertainty as to the effect of crushing the gasket and contact faces which has attended many previous flange loading tests. The writer has particular reference to the tests described by Bailey[9] in which this direct compression had to be subtracted in attempting to correlate the results with derived formulas.

While the one-quarter-scale models of a flange with an 8-in. bore tested by Bailey are rather a far cry from the flanges of $30^3/_4$ in. outside diameter described in the paper under discussion the greater deflection found for drilled flanges over undrilled flanges in Bailey's tests suggests that this factor may need to be considered in analyzing the authors' test data. Apparently Bailey's findings on drilled and undrilled tensile specimens would indicate that the flange rotation for a given bolt loading might be expected to be about 15 per cent greater for a drilled flange than for an undrilled flange of the proportions given in Fig. 1 of the paper.[1] Tests reported by Solsnoes[10] on light flange rings ap-

[9] "Flanged Pipe Joints for High Pressures and Temperatures," by R. W. Bailey, *Engineering*, vol. 144, October 15, 1937, p. 419.

[10] Discussion by Leif Solsnoes of the paper "Flanged Pipe Joints for High Pressures and Temperatures," by R. W. Bailey, *Engineering*, vol. 145, April 22, 1938, p. 443.

proximately $13^3/_8$ in. outside diameter, $^5/_8$ in. thick, and $^{23}/_{32}$ in. wide with 0.351-in. holes showed the drilled ring to rotate approximately 30 per cent more than the undrilled ring. While this effect of bolt holes was stated to be less than deduced by Bailey[9] from tests on drilled and undrilled tensile specimens of similar proportions, it appears to be an important factor.

The shifting of the point of application of the bolt forces and gasket reaction as the bolt load is applied with its resulting reduction in moment arm has plagued the steps of all who have tried to apply flange formulas to actual flange design. The authors' tests throw some light on this question but in the opinion of the writer additional tests are needed to establish the effect of this reduction in moment arm on the relation between bolt loading and flange rotation.

The reason for providing the small nubbin at the center of the tongue facing as shown in Fig. 1 of the paper, is understandable since it tended to define the location of the gasket reaction. But, this simplification destroyed part of the value of the test since the customary shortening of the moment arm due to shifting of the

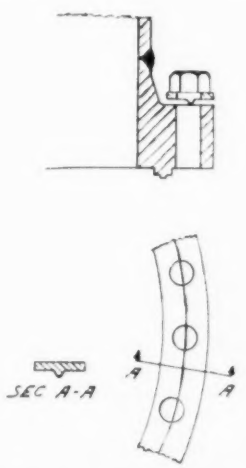

FIG. 1 CENTERING RING FOR PROPOSED CONSTANT-LEVER-ARM TEST

gasket reaction was prevented. If two additional tests were made, definite information could be obtained as to the effect of this reduction in moment arm due to shifting of the points of application of the bolt forces and of the gasket reaction. The following two tests are suggested:

1 Determine the bolt load versus the angular flange rotation for constant lever arm by providing an annular ring with centering rib, as shown in Fig. 1 of this discussion, to fit under the nuts and definitely locate the bolt forces on the bolt circle. The height of the nubbins on the gasket faces should be increased to give more positive location of the gasket reaction at the center of the tongue facing.

2 Determine the bolt load versus the angular flange rotation for variable lever arm by removing the nubbins from the gasket faces and applying bolting as in the present tests.[1]

The ratio of the bolt loads required to cause a given flange rotation determined from these tests should give a direct measure of the reduction in moment arm resulting from shifting of the points of application of the bolt forces and gasket reaction in an actual flange assembly.

The reduction in moment arm determined from such tests should give quantitative answers to one of the most intangible factors entering into the application of derived formulas to actual flange design.

It is hoped that these suggestions will be helpful and that the authors and the Heat Exchange Institute may find it possible to make these further tests.

AUTHORS' CLOSURE

It would be extremely helpful in a further study of the test results if Professor Hollister could make available any calculations which he has made on the effect of the hub length and dished head on deflections and stresses. It is admitted that a longer cylindrical section would more closely satisfy the assumption of an infinite hub. However, in line with the usual reasoning, hub lengths beyond (shell diameter $\times$ shell thickness) are considered to have little effect on the moment distribution and are usually neglected.

The authors are in agreement with Messrs. Smith-Petersen and Mattimore in their interpretations of the shift in the bolt reaction. The permanent loss in bolt load is attributed to relaxation of the gasket while the change in bolt load with internal pressure is probably a function of flange rotation. The opinion expressed that high hub stresses are not compatible with high-temperature conditions deserves further amplification, since it is not apparent why a readjustment of stresses or moments should prove harmful, although the proportions of such flanges are usually such that hub stresses do not control.

The authors agree with Mr. Jasper that the use of a brittle material would have afforded a better check on the initial hub stresses. However, it was not the object of this research to determine conditions at fracture, but rather to explore the readjustment of stresses between the flange and the hub due to yielding, and accordingly the use of a ductile material was prescribed. Tapered flanges are used on the shells of a large number of heat exchanger and pressure vessels as well as piping flanges, and are the rule rather than the exception, as stated by Mr. Jasper. While the taper does increase the bolt circle, it would appear obvious that the stress distribution is more favorable in a design with a reasonable taper than in a straight hub, which attracts a large part of the moment into the hub while offering no increase in resistance over that of a tapered hub of the same thickness at the root. It is generally found that a hub the thick end of which is twice the thickness of the small end gives the best conditions, combined with a taper length of approximately one half (shell diameter $\times$ shell thickness). While a location of the gasket close to the bolts produces an increase in the bolt load, the bolt moment which controls the flange design is reduced, in general, by such an arrangement.

Professor Waters' comments on the practical significance of referring the bolt moment to the bolt circle or the circle tangent to the inside shank of the bolts, are agreed with fully. This adjustment of the lever arm can be considered as an empirical correction of the formula which would take account of the stiffness of the flange.

Mr. McCutchan refers to Bailey's and Solsnoes' tests on the influence of the bolt holes. While some effect no doubt must be ascribed to holes in the flange, the authors know of no simple way of compensating for them, and believe that this effect together with the effect of gasket grooves and bolt spacing should be merged into the safety factor for the present. The additional tests proposed would no doubt be of great value in establishing the location of the bolt and gasket reaction, and when further tests are contemplated, will receive consideration. However, due to the wide variety of gaskets and facings in use, the results obtained would be valid only for the ideal conditions of loading used in such tests.

Trends in Fuel-Burning Equipment and Furnace Design as Shown by Recent Eastern-Seaboard Applications

By RALPH D. BOOTH,[1] BOSTON, MASS.

By reviewing the steam-generator installations made during the last five years in eastern-seaboard industrial plants, it is the purpose of the author in this paper to determine trends in the design of furnaces and fuel-burning equipment. The subject matter is divided into three general parts: (*a*) A brief summary of the apparent trends in kinds of fuel, fuel-burning equipment, and furnaces; (*b*) a more detailed examination of the characteristics of representative installations; and (*c*) a summary of comments and suggestions with respect to future design.

Résumé of General Characteristics

A CASUAL review of the characteristics of steam generators utilized for industrial purposes along the eastern seaboard during the last five years shows little that is unique to the industrial boiler in contrast with the boiler of central stations of comparable size and age, nor any marked difference in the trends in the East from those of the country at large. It is, of course, well known that practically all of the larger units are being equipped with waterwalls and that pulverized-coal firing has made tremendous advances in its general application and popularity. We have, during this period, increased markedly the use of bent-tube boilers in contrast with straight-tube types, in the sizes above approximately 30,000 lb per hr. Also during this period there has been developed as one of the bent-tube types the two-drum integral-furnace steam generator for general application in sizes of 20,000 to 30,000 lb per hr up to 150,000 lb per hr and more. These boilers have met with considerable popular acclaim because of the lower prices possible on the more or less standardized designs in which they are available. One manufacturer reports that during the last $2^1/_2$ years the integral-furnace type of boiler has constituted some 25 per cent of his total boiler sales and approximately 40 per cent of the sales of the waterwall type, and that currently it constitutes approximately 50 per cent of his sales of waterwall-type boilers.

From a review of the industrial plants in this area, it would be fair to say that the use of stokers on new boilers in excess of 100,000 lb per hr in contrast with the use of pulverized coal or oil, is the exception to the general rule.

Data given in Table 1, submitted by one manufacturer on 50 representative sales of larger boilers for industrial application, show the effects of these predominant trends.

It is impossible to generalize with respect to the fuel or firing equipment on boilers in the range of size from 40,000 to 100,000 lb. This size finds application in plants serving loads of markedly different load factors and often loads subject to appreciable variation. Also this is a size frequently used in replacement units which must be installed within the limitations and under the conditions surrounding the existing boilerhouse. These conditions create an ideal "no-man's land" where each individual application needs a careful study to determine upon the appropriate firing equipment.

We do find that on the eastern seaboard in general the fight is largely between pulverized-coal installations firing eastern bituminous coal, and multiple-retort stokers firing the same fuel. Only in the states of Pennsylvania, New Jersey, and New York do we find any appreciable number of the traveling-grate stokers firing anthracite coals. In the last five years there has been to the author's knowledge only one new anthracite-burning plant constructed in New England and there have been several anthracite-burning plants replaced with equipment for burning powdered coal and oil. In passing, it should be noted that within the last three years there have been two applications of pulverized-coal units burning anthracite culm with apparent success.

The most that can be said of boilers in this range of sizes is that a greater proportion of pulverized-coal or oil-fired boilers is finding recent application than those of the stoker-fired types. Also the industrial pulverized-coal furnaces in these sizes on the eastern seaboard are almost entirely of the dry-bottom type. Very probably the integral-furnace type boilers, which are particularly adapted for the use of pulverized coal and/or oil, and all of which with one exception are of the dry-bottom type, are playing an appreciable part in these trends.

In sizes below 40,000 lb per hr, stokers are still finding an appreciable field of application and, in this size of boiler, a relatively small percentage of waterwall furnaces is found.

One does not have to search long to find the cause of these trends. The development of waterwalls has so increased the availability factor of boilers and so decreased the furnace maintenance cost, particularly in conjunction with the application of pulverized coal that their wide acceptance in boilers to be operated on high load factor is readily understandable.

The development of the unit type of direct-firing pulverizer to its present degree of reliability, which is comparable to that of the boiler unit itself, has contributed largely to the present wide acceptance of pulverized-coal-fired boilers. This development has materially reduced the cost of pulverizing equipment. It has eliminated the coal-preparation building and storage bins for the pulverized coal and the space requirement of the equipment itself

TABLE 1 USE OF STOKERS COMPARED WITH PULVERIZED COAL OR OIL FIRING

Type	Capacity, M lb per hr 100–250	250–499	750 and over	Total
Bent-tube	39	5	2	46
Straight-tube	3	1	0	4
				50
Firing:				
Pulverized coal	27	5	2	34
Stokers	5	0	0	5
Oil or gas	10	1	0	11
				50

NOTE: Approximately 30 per cent of pulverized-coal burners are tangentially fired and the majority of the balance, horizontally fired.

[1] F and A.
S.T. = straight-tube boiler. B.T. = bent-tube boiler.

is little more than that required by stokers. To a large extent, it has also reduced the hazards formerly associated with the storage of large quantities of finely pulverized coal.

The use of pulverizing equipment in general permits the use of a wider range of coals than is permissible with the stoker-fired installation which usually requires the use of premium-quality fuels. Today in New England this advantage will vary from 20 to 30 cents per ton of coal. Also, the boilers designed for pulverized coal are suitable for oil or gas firing and can, in fact, fire either or both fuels at the same time.

In the light of the equipment development, the trends found appear logical and it is therefore to be presumed that they will continue. The two largest items entering into the cost of steam or power are the fuel costs and the investment charges. In the large plant operating at high load factor the fuel costs usually outweigh the fixed charges on the investment. The development of high-availability pulverizers at a lower investment cost, making the low-priced fuels available, would naturally throw these larger plants into the pulverized-fuel class.

In the smallest units of 40,000 lb per hr or less, where we usually find low load factors and a wide variation in loads to be carried, the investment costs constitute a much larger portion of the annual cost. The additional investment burden to apply pulverizers in this range is often disproportionately high, because of the limitations imposed by the range of loads to be carried, and often the use of waterwalls would be unjustified except with pulverizers. It is therefore not surprising, in those plants that have not gone to oil firing, to find stokers still holding the field.

Under today's price situation, intermediate-sized units, applied under widely different loads, load factors, and plant conditions should logically be unclassifiable as to type of firing equipment

Comparison and Discussion of Typical Furnaces

In Tables 2 and 3, are presented data on two groups of furnaces and firing equipment found in representative installations on the eastern seaboard. Table 2 presents the data on pulverized-coal-fired boiler installations ranging in size from 20,000 lb per hr to

approximately 300,000 lb per hr, which are equipped with water-wall furnaces of the dry-bottom type. As such, this group is representative of the greater portion of the furnaces which have been installed on the eastern seaboard in the last five years. All of these units are in service and, according to the author's understanding, meet the ratings. It should be noted in passing that the first three units in Table 2 are utility units, included to permit a comparison of furnace characteristics over a slightly wider range of installation.

Table 3 is a presentation of the characteristics of representative stoker-fired installations which in the main are of partial water-wall design. The comparative number of units on which data are presented was chosen to cover with some degree of completeness the range of unit sizes found, and is not intended to reflect the relative proportion of these two types of installation. Because of the space and time limitations, the detailed discussion will be confined to the pulverized-coal-fired units, which are representative of the majority of industrial installations made within the last five years on the eastern seaboard.

These data purposely include boilers of one manufacturer only in order to permit comparisons which might be invalid if the variable of different furnace-wall design, as introduced by the different manufacturers, were not eliminated.

Before comparing the furnaces, it might be well to consider for a moment the primary requisites of a furnace. The earning power of any modern steam generator depends on its availability and its ability to stay on the line under sustained high-load operation. The availability depends to a very large extent on the provisions for preventing the fouling of the furnace, boiler, and superheater with ash or slag and to permit the removal of ash with the type of ash-removal system provided. It must, of course, simultaneously burn the fuel efficiently. The modern water-cooled furnace has therefore a double function. It must be so proportioned that the fuel will be burned economically and it must provide radiant heat-absorbing surface so that the gases will be reduced sufficiently in temperature to avoid excessive slagging of the boiler convection surface.

These requirements are to a large degree conflicting and obviously the responsibility for the final solution lies with the boiler manufacturers rather than with the users or the consulting engineer. The latter, however, must find some mechanics for producing specifications which first, will procure equipment to meet the requirements satisfactorily and second, will insure true comparability of the equipment offered by the various competitive manufacturers. It is, of course, a matter of primary importance to the manufacturers also that these two objectives should be realized.

It is therefore interesting to analyze the data available in Table 2 to see if any general relationship with respect to furnace design can be observed in terms of those characteristics which the engineer must, of necessity, transmit to the boiler manufacturer, namely, the characteristics of fuel, the type of ash-removal systems, etc. Since all of the furnaces listed in Table 2 are of the waterwall, dry-bottom type, such effect as the characteristics of ash-removal equipment can properly be considered as a constant in these comparisons.

In considering furnaces, it has long been customary, although now properly declaimed by the boiler manufacturers, for engineers and users to evidence some interest in heat release per cubic foot. It will be noted, in looking over the tabulated data, that there is a range of heat release from 19,700 to 36,800 Btu per cu ft, although this does not cover the extreme range of furnace designs found in representative installations in this area. It is apparent that there is no readily observable relation of heat release to boiler size.

Certainly, if the first three units which are utility installations are excepted, the steam release per foot of drum is so low it could not have been a controlling factor on furnace dimensions. A comparison of the furnace widths as actually installed with the permissible minimum widths, recommended by the manufacturers for burner spacing (assuming the number of burners, size, and type tabulated on this comparison) indicates that these furnaces as a whole, with one or two exceptions, are designed for minimum widths. This is logical, since, in general, the over-all cost of a boiler unit of a given capacity is appreciably reduced as the width of the furnace is decreased. The furnace depths as tabulated are also substantially the minimum depth permissible for the type and size of burner equipment installed.

It is when we come to the determination of the furnace height, dependent as it is upon the type and disposition of the waterwall surface and the characteristics of the fuel, that it becomes difficult to rationalize from the data available to the consulting engineer or the user (as contrasted with the boiler manufacturer) the characteristics found in the various units.

One manufacturer uses, as a preliminary criterion of the probable desirable furnace volume, the limitation of heat release, expressed as a per cent of the volatile in the fuel. It should be

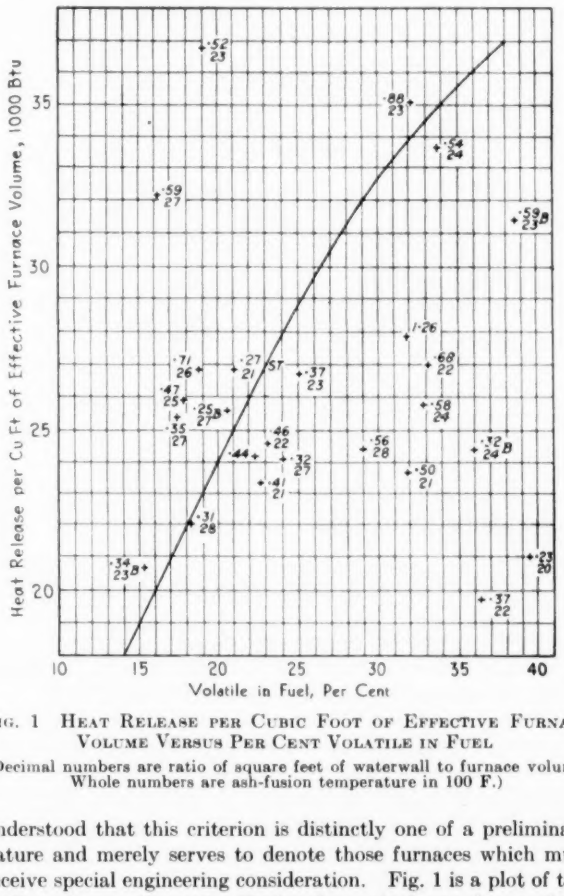

FIG. 1 HEAT RELEASE PER CUBIC FOOT OF EFFECTIVE FURNACE VOLUME VERSUS PER CENT VOLATILE IN FUEL

(Decimal numbers are ratio of square feet of waterwall to furnace volume. Whole numbers are ash-fusion temperature in 100 F.)

understood that this criterion is distinctly one of a preliminary nature and merely serves to denote those furnaces which must receive special engineering consideration. Fig. 1 is a plot of this preliminary requirement. It also shows the heat releases of the typical installations. On each point is noted, as a decimal number, the waterwall surface per cubic foot and, as a whole number, the fusion temperature of the ash expressed in hundreds of degrees F. While proportionately more of these furnaces have heat releases less than that indicated as permissible by this curve, an appreciable percentage of the installations exceed this preliminary maximum heat release. The tabulated installations do not appear to show any general trends such as might be

expected as a result of such a preliminary determinant. One might expect to find those installations, which had more water-cooled surface per cubic foot of effective furnace volume or those using fuel with the higher ash-fusion temperatures, operated at the higher heat releases, but no such general relationship is apparent.

Fig. 2 shows these same characteristics in terms of ash-fusion

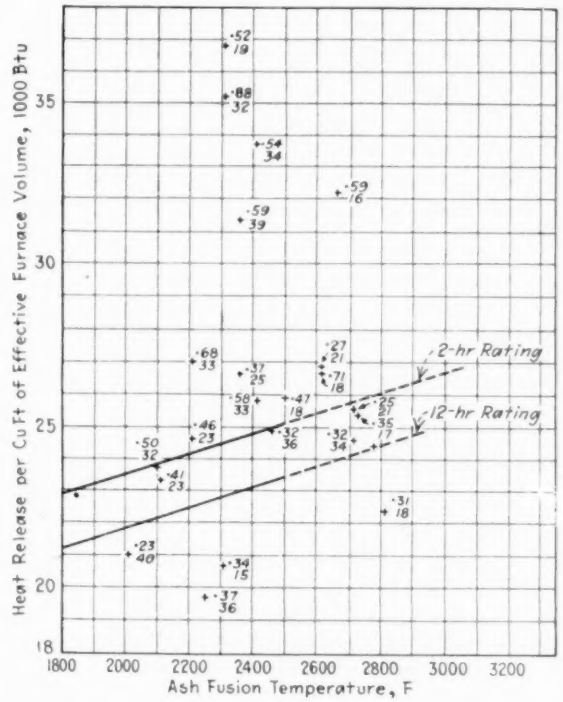

Fig. 2 Heat Release per Cubic Foot of Effective Furnace Volume Versus Ash-Fusion Temperature

(Decimal numbers are ratio of square feet of waterwall to furnace volume. Whole numbers are per cent volatile in fuel.)

temperature, together with a curve which another manufacturer uses as a preliminary criterion in determining the permissible heat releases per cubic foot. Again each point plotted on the chart has noted as a decimal number the waterwall surface per cubic foot of furnace volume, and in this instance, the whole number gives the per cent volatile in the fuel. It will be observed that those furnaces employing more waterwall surface per cubic foot, which might logically be expected to operate at higher heat releases for any given ash-fusion temperature, do not do so.

It could be argued rationally that, for any given ignition characteristics of the coal, it should be possible to operate at a higher heat-release value in a furnace which had more waterwall surface per cubic foot; and also, for the same ignition and water-wall characteristics, to operate at higher heat releases with fuels having higher ash-fusion temperatures. With this in mind, it is interesting to compare the furnaces against the product of the ash-fusion temperature and the waterwall surface ratio. This comparison is presented in Fig. 3. Each point is designated by the per cent volatile in the fuel, and here again, it will be noted that there is no readily observable relationship either to the points as a whole or to those points indicating fuels of approximately the same per cent volatile.

The only relationship generally observable in any of these three attempts at comparison is that most of the installations are working at heat releases of from 23,000 to 27,000 Btu per cu ft. It is certainly farthest from the author's mind to imply that operation should properly be limited to heat releases in that general range. It is rather the purpose of these three charts to point to successful installations at varying heat releases, and to the inability to express, in terms of any logical or empirical relationship to conditions which the engineer should specify to the boiler manufacturer, those values of heat release which have proved practicable. However, it may well be that owner's specifications or expressed desires have induced the manufacturers to keep their designs within this general range of heat release.

It should not be the function of the consulting engineer or the owner to assume responsibility for the proportioning of the boiler and its furnace. The successful combustion of fuel is obviously one of temperature control of the gases and, as such, the appropriate installation must be gaged to the type of surface and the particular arrangement of the surface employed by the manufacturer. It is however, necessary for the consulting engineer and the owner to devise some way of transmitting properly to the manufacturer the requirements of the installation and the characteristics of the fuels and other equipment associated with the furnace, which are not to be provided by the boiler manufacturer. The definition of the latter is simple, but the definition of the fuels is as yet far from simple. The difference in tendency of a

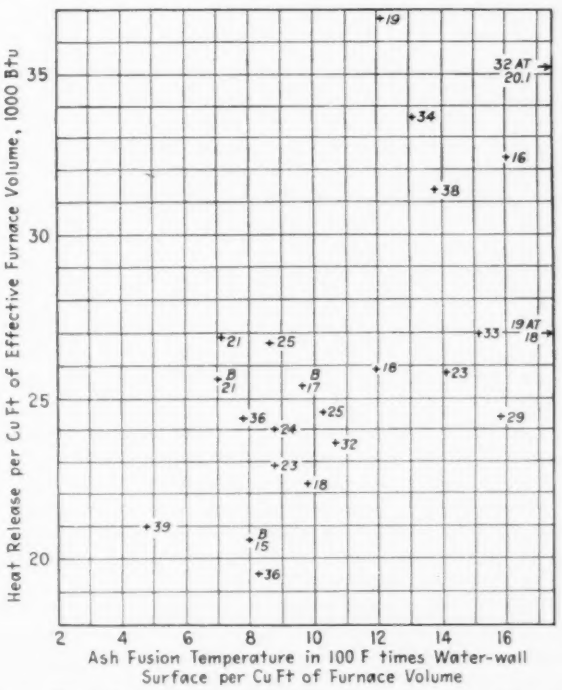

Fig. 3 Heat Release per Cubic Foot of Effective Furnace Volume Versus Ash-Fusion Temperature Times Waterwall Ratio

(Numbers in chart are per cent volatile in coal.)

noncoking coal and a coking coal to agglomerate in the furnace, and the effect of such agglomeration on the tendency to slag can be introduced only by experience. To date we have found no adequate mechanics for expressing these tendencies.

The industrial plants utilizing lower steam temperatures, as in general they do, are not suffering from this lack of information to the same degree as do the utilities operating at higher temperatures. The use of higher steam temperatures, involving as it does the necessity for higher gas temperatures on the desuperheaters and on the slag-screen tubes ahead of the superheater, is driving the boiler designers ever higher in the required gas temperatures

entering the slag screen. It is generally recognized as practicable to so proportion a furnace by reducing gas velocities that the heavier particles, which constitute the bulk of the slag nuisance, moving more slowly than the gas, can be cooled by the radiant action of the black surface to a lower temperature than the gas itself. In the past it has been quite general to specify that the gas temperature entering the slag screen shall be not higher than the ash-fusion temperature of the fuel. However, as we go higher in steam temperatures, and by necessity higher in the gas temperature entering the slag screen, the difficulty of keeping the gas temperatures to such low values, particularly where low ash-fusion-temperature coals are encountered, is forcing us to adopt gas temperatures in excess of the ash-fusion temperature.

Today there is relatively little known as to the differential in temperature of the slag particle and the gas except as it can be theoretically computed for an assumed size of particle. Also, there is relatively little knowledge as to the tendency of particles to agglomerate or the size of agglomerated particles, and hence estimates of particle temperatures are largely guesses. We, as engineers, charged with the duty of obtaining suitable equipment and procuring truly comparable competitive bids, find ourselves unable to define completely to the manufacturer those characteristics whose definition is our primary concern.

Comparison and Discussion of Firing Equipment and Pulverizer Applications

As a natural consequence of the type of furnaces (dry-bottom) compared in Table 2; practically all of the burner installations are of the horizontal type. It will be noted that the maximum sized burner has a capacity of approximately 7000 lb per hr, of coal (or approximately 75,000 lb per hr of steam). The choice of the number of burners was undoubtedly dictated by the characteristics of the load, and without complete knowledge of that it is impossible to comment.

The pulverizer tabulation does not disclose it, but all mills are of the direct-firing ball, or bowl, or impact type, with the exception of units for plants nos. 5 and 11 (which are of the storage type). Most of the pulverizer applications on the eastern seaboard are of these types, since relatively little of the low grindability fuels is used.

In general the pulverizers have a rated capacity at least 10 per cent in excess of the required capacity, corresponding to the recommendations of the pulverizer manufacturers. The limit to the amount of excess capacity which should be provided, either for wear allowances, protection of loads, or to permit the use of coals having a wide range of grindability, is dictated by the range of load swings to be handled.

Naturally the fineness of pulverization of the fuel to be provided is of primary importance even from the furnace viewpoint alone. Fig. 4 is a plot of the fineness of pulverization and the recommendation of one of the boiler manufacturers.

It is the author's belief that the trend in the future will be toward higher fineness and even higher values than those recommended by the manufacturers.

The fineness of pulverization is adequate if, under a given furnace design and operating conditions and for the range of fuels economically available, the incremental cost of further increasing the fineness exceeds the corresponding value of:

(*a*) The reduction in carbon loss due to the increase in fineness.

(*b*) The reduction in the cost of boiler cleaning and outage which can be effected by a reduced tube fouling and slagging, as increased fineness reduces the number and size of the particles impinging on the tubes; and either of the following:

(*c*) The reduction in the duty on dust-collecting equipment of the electrical type, which is adversely affected by increased particle size and increased carbon loss; or

(*d*) The reduction in stack nuisance, where no dust collectors or mechanical collectors are used, by increasing the whiteness of the stack discharge through reduction of the carbon content in the dust.

(*e*) The reduction in maintenance cost of slag-tap bottoms.

It is the author's opinion that manufacturers and users in the past have given consideration largely to (*a*), namely, the effect on carbon loss, and have considered this largely from a "coal-pile" point of view. At 30 per cent volatile, for example, an increase of 5 per cent in fineness over 70 per cent will reduce the carbon loss by approximately 20 per cent. This carbon loss, being of the order of 1 per cent, a change of 20 per cent in such a small quantity is relatively unimportant when viewed from the coal pile. However, for coking coals, whose particles tend to soften and agglomerate in the furnace, the increase in fineness may well be justified through the reduction in slagging tendency of the furnace.

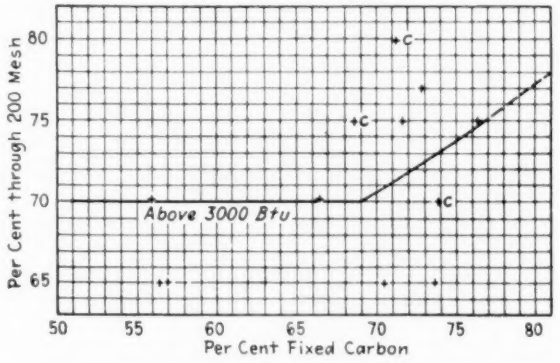

Fig. 4 Fineness of Pulverized Coal, Per Cent Above 200 Mesh Versus Fixed Carbon

A change of 20 per cent in the amount of carbon in the fly ash going through an electrostatic precipitator would markedly affect its efficiency. If, for example, the carbon formed 25 per cent in the dust, a reduction of $^1/_8$ would change the efficiency of the precipitator by approximately 2.5 per cent. Such a change in efficiency would decrease the emission from a stack, equipped with a precipitator to recover normally 90 per cent of the flue dust, by 25 per cent. The cost of providing a precipitator which would effect the same percentage recovery with the higher carbon content in the flue dust would materially exceed in the normal case the excess cost of the pulverizers and the increased power consumption.

These effects on the precipitator may not be as important with slag-tap or two-stage furnaces, since the carbon loss is somewhat lower than with dry-bottom furnaces. However, there is some evidence that increased fineness will help the slag-tap furnace under some conditions. It has been noted that an increase in fineness tends to reduce the deposition of iron sulphide in the slag pool, thus materially minimizing the hazards of punctured floor tubes and slag leaks.

Summary

If, for the purpose of one about to construct an industrial boiler plant on the eastern seaboard, a summary of the most pertinent suggestions were required, the author would abstract them as follows:

1 Ascertain with the help of a local fuel dealer, the cost of the available coals and oil, considering the entire range of fuels which could be reasonably applied to the type of plant in question.

2 If the plant is of low load factor and of a capacity less than

30,000 lb per hr, the probabilities are that an oil-fired or stoker-fired installation will prove most attractive, and that complete waterwalls will not be justified.

If the plant is of the range of 30,000 lb per hr to 150,000 lb per hr, unless it is in an area of high coal cost and unless the load factor is extremely high, the cost must be carefully ascertained for both pulverized-coal equipment and stoker-fired installations. For locations adjacent to tidewater, careful consideration should be given to the advantages accruing through the additional provision of oil-firing equipment in combination with pulverized-coal equipment. The choice between these two types of firing depends on many factors, such as the available coal, the load factor, the fixed charges on the initial investment, the cost of power, the required flexibility, the cost of ash disposal, and the necessity for providing a means for fly-ash removal. The arrangement of the plant may well have a controlling influence, particularly if the boilers are to be installed in an existing building with limited headroom.

If the plant is in excess of 150,000 lb per hr and of high load factor, in all probability a pulverized-coal-fired job (alone or in combination with oil) will prove to be economic.

3 In all probability bent-tube boilers will be found to be economic in the size of 30,000 to 40,000 lb per hr upward, except in those applications where existing conditions definitely control the type of boiler application. On the pulverized-coal or oil-fired installations, in the sizes of 30,000 to 150,000 lb per hr, the two-drum bent-tube type boiler with integral furnace will usually, except under unusual feedwater conditions, prove to be attractive.

4 If a pulverized-coal installation is indicated, it is advisable in the light of the recent trends in fuel prices to be as generous in fixing the capacity for range of fuels and degree of fineness as the variations in loads will permit.

5 While for ordinary moderate-capacity installations on the eastern seaboard, and particularly in New England, where high-grade coals only will prove to be in the economic range, it is most probable that a dry-bottom furnace will prove desirable, the final determination between the dry-bottom and the wet-bottom system should be made only after careful analysis of actual operating experience with similar fuels and similar boiler designs.

6 In determining upon the furnace and its proportions do not invade the field of the boiler manufacturer but give him that degree of freedom in his design which is necessary to meet his responsibility of providing a satisfactory installation. Supply the boiler manufacturers with as complete information on the load characteristics and the characteristics of the fuel as are practicable, and base your specifications on data from plants operating with comparable conditions.

In comparing the furnaces offered by the various manufacturers seek a boiler which has:

(*a*) A large furnace with as moderate a heat release as is consistent, under the load variations and fuel characteristics, with ignition requirements and completeness of combustion.

(*b*) Radiant-heat-absorbing surface to cool the ash particles in suspension to a chilled or solidified condition before they reach the furnace outlet and, where practicable within the limitations of the required superheat temperature, to cool the gas temperature also to the ash-fusion temperature.

(*c*) A furnace cross section such that the gas velocity in the clear space will be sufficiently low to permit the larger particles of fuel to hover or move more slowly than the gas, and a furnace height such that, in the time available after a particle leaves the flame and falls through the clear atmosphere to the bottom, it may radiate sufficient heat to the surrounding heat-absorbing surface to freeze at least to a sufficient crust thickness so that it will not stick to the furnace bottom.

(*d*) A relatively large furnace outlet so that the entrance velocity at the boiler aperture will be low to minimize the squashing of those ash globules or particles which are only surface-frozen.

(*e*) A furnace bottom so arranged with respect to the flame that: (1) With the slag-tap design the entire furnace atmosphere between the flame and the floor will be opaque in order that the particles may not be affected by an appreciable part of the black surface and thus remain in a molten condition; and (2) with the dry-bottom furnace, whether flat or of the hopper design, the entire furnace atmosphere between the flame and the bottom should be clear and entirely surrounded by radiant-heat-absorbing surface.

(*f*) Burner equipment that will produce a short flame without impingement, and which will distribute the heat evenly across the furnace.

(*g*) Where practicable, it should be so arranged that the particles are initially moving away from the boiler entrance aperture to minimize carbon loss, increase ash deposition in the furnace, and reduce impact of ash particles on the boiler tubes.

(*h*) A tube spacing in the boiler entrance aperture ahead of the superheater sufficiently wide so that no bridging of such slag as might stick can occur. Fortunately, we find under ordinary circumstances that the more economic installations for these particular sizes of boiler are of the bent-tube type in which the tubes in the boiler aperture and the superheater surface are arranged vertically or at a relatively sharp angle, thus providing a tendency toward self-cleaning.

Operating Methods and Problems of a Combined Hydro- and Steam-Electric System

By H. L. HARRINGTON[1] and E. B. STROWGER,[2] BUFFALO, N. Y.

Today a combined hydro- and steam-electric system requires the use of operating methods based upon the principles of economic loading together with satisfactory and reliable service to all customers, and it is essential to arrange for some plan of centralized supervision of the power-supply facilities in order to put these methods into effect.

Certain system changes, such as the proper interconnections of generating facilities and load areas will in general be required to make such a plan effective and, if input-output data regarding the hydro- and steam-generating facilities are not available, tests should be carried out to furnish this information for the load supervisors and plant operating personnel.

Further, maximum use should be obtained from all storage reservoirs, reserve-capacity requirements should be established on a system basis with the highest degree of service reliability reasonably possible, and satisfactory standards and methods for the maintenance of system frequency and voltage must be followed.

THE PURPOSE of this paper is to illustrate the operating problems and methods involved in the application of the principles of economic loading to a large interconnected electric power system, the power-supply facilities of which consist of hydro- and steam-electric generating stations, as well as interconnections with other electric systems. There is considered a state-wide integrated electric system which has been formed over a period of years by successive consolidation of local units, which formerly operated in more or less isolated areas. Physical interconnection has resulted in a system containing hydroelectric stations diversified as to location due to the inclusion of various drainage areas in the operating territory and diversified as to characteristics depending on the character of the water supply and the design adopted for a particular project. Some of these stations are located on streams with well-regulated flow, some on streams with practically no regulation, and others on streams where the regulation is a function of joint use for flood control and for power development. Steam-electric generating stations include plants of relatively high economy suitable for base-load operation, as well as older and less efficient stations which may be used for peak load or reserved for emergency use. In spite of any such diversified character of the various sources of supply, however, all types of stations, whether steam or hydro, have a definite function in the power-supply facilities of the main system, and their operations must be coordinated with the objective of securing their full inherent economy.

[1] System Load Supervisor for certain subsidiary operating companies of Niagara Hudson Power Corp.

[2] Engineer, The Niagara Falls Power Company. Mem. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Spring Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, St. Louis, Mo., June 20–23, 1938.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until March 10, 1939, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

With this general picture in mind it is apparent that a territorial grouping of the generating facilities would be a desirable step for setting up an operating organization to control the station output; that is, to dispatch loads to the various stations to effect a maximum of economy in operation. Such a territorial grouping should be made in accordance with more or less well-defined major load areas, with main trunk transmission lines interconnecting these areas and permitting a free interchange of power between them. To effect this interchange with a minimum of limitations due to transformer capacity between one voltage and another, transmission voltages should be standardized as far as reasonably possible.

If the system is further complicated by the fact that electric service is rendered at more than one frequency, adequate frequency-changer capacity should be provided to allow a transfer of energy from the system of one frequency to that of another.

These general statements regarding the main features of a large electrical system are given in order to present a general picture to which the principles of economical and reliable operation of combined hydroelectric and steam-electric generating facilities are to be applied.

Fundamental Objectives

The fundamental objectives for the operation of a system as described, or one of similar characteristics, may be briefly summarized as follows:

1 An adequate and reliable supply of electric power must be assured at all times to all load areas.

2 The maximum possible use should be made of all available hydro energy which, when utilized in conjunction with steam-generated energy, will meet the varying requirements of the system load at a minimum over-all cost to the system as a whole.

Specific Requirements

For the most successful application of the foregoing principles, the following specific requirements must be met:

1 All load and generation areas must be interconnected with tie lines of sufficient capacity (*a*) to transmit the required energy into a particular area from other sources when a deficiency of energy exists in that area, and (*b*) to allow the surplus energy of a particular area to be made available to other areas where it can be economically utilized.

2 In order that the maximum use may be made of all hydro energy available, with the resulting conservation of fuel-generated energy, it is essential that the operation of all generating facilities be coordinated through some form of centralized supervision, where complete and up-to-the-minute information is available as to load requirements, availability of water supply and generating facilities, and the cost of power production from all sources.

3 All generating stations, both steam and hydro, must be provided with input-output data which will assist in determining how each station should carry its assigned load with the minimum use of water or fuel as the case may be and to assist the system load supervisors in assigning loads to all stations for maximum over-all economy.

4 All storage reservoirs should be operated so as to secure full advantage of the storage available with the least possible limitations due to local requirements.

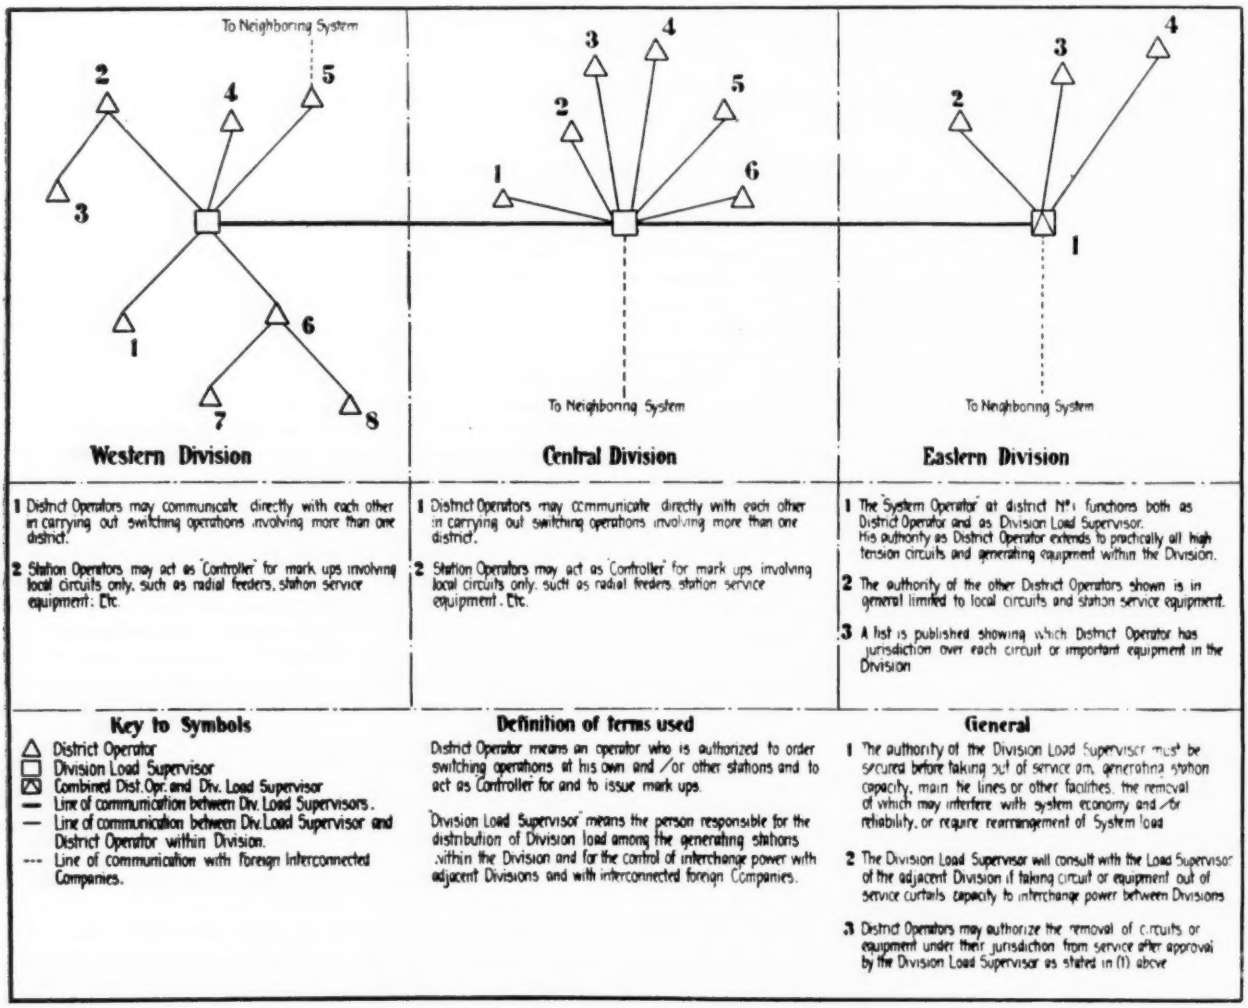

FIG. 1 OPERATING DIVISIONS OF A LARGE ELECTRIC UTILITY SYSTEM

5 Reserve capacity for protection against equipment failures should be limited to the smallest amount consistent with the highest degree of service reliability reasonably possible.

6 All the foregoing requirements must be related to maintenance of satisfactory system frequency and voltage. Scheduled tie-line loads between divisions and with other systems must be maintained in order that generating-station outputs may be produced as scheduled for maximum economy.

METHODS OF MEETING SPECIFIC REQUIREMENTS

1 *Interconnection of Generating Facilities and Load Areas.*

When the system under consideration has resulted from the consolidation of several formerly separate and more or less isolated units, additions and improvements to the existing transmission facilities made to effect a completely integrated system require careful planning and design to obtain the maximum advantage of the transmission facilities already provided. This requires a general survey and study of the system as a whole with special attention to

(*a*) Adequacy of transmission-line capacity to each load area.

(*b*) Standardization of voltages of the main transmission system to remove limitation due to capacity of step-up and step-down transformers.

(*c*) Interconnection with utilities serving adjoining load areas: (1) For possible marketing of surplus hydroelectric energy generated during high-flow periods through reduction of an equivalent amount of steam-generated energy, (2) for obtaining for each utility, additional capacity and energy sources during times of emergency, (3) for effecting a possible reduction in the maximum demand on steam plants by storing water in the ponds of hydrostations during light-load periods through the use of energy from other available sources so that this water can be used at times of peak demand, and (4) for reducing joint requirements for reserve capacity.

(*d*) Relay protection and circuit-breaker characteristics directed toward satisfactory operation of the system as a whole, both under normal and fault conditions.

2 *Centralized Supervision of Generating Facilities.*

Even with adequate interconnections, it is quite apparent that the power-supply facilities of the various areas of a system consisting of a multiplicity of steam- and hydro-generating stations, widely diversified as to location and character, together with interconnections with other systems, could not be operated independently as separate units and still develop their full inherent possibilities in meeting the requirements of the system load as a whole in the most economical manner possible. Some form of centralized control and supervision is, therefore, necessary. In the case of a compact system this may take the form of one central

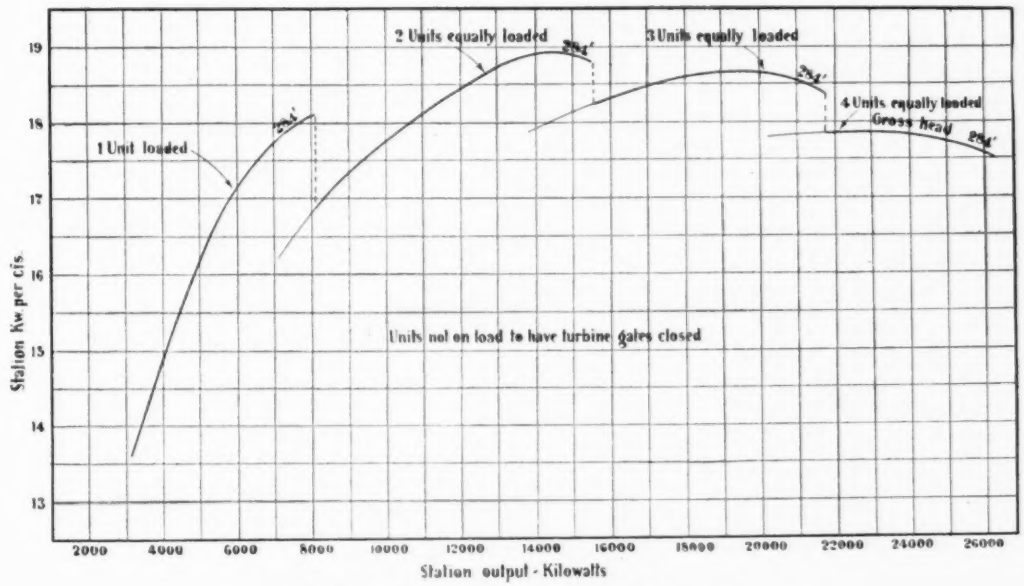

FIG. 2 LOAD DISPATCHING CURVE FOR STATION A

office from which control is exercised over all the plants in the territory. On the other hand, a large number of plants, an extensive operating territory, and complex local limitations may indicate that a completely centralized control would be cumbersome and would defeat the very objectives which it was set up to meet. In order to coordinate the operation of all the power-supply facilities and at the same time provide flexibility of control and close contact with local operating problems and limitations, it will prove to be desirable, in a widespread system, to set up a load-dispatching organization with offices in each of several major operating divisions, as indicated in Fig. 1. In the case shown, three division offices are indicated and are called the Western, Central, and Eastern. The location of these dispatching offices should correspond with the territorial grouping of principal load centers and power-supply facilities referred to previously. The dispatching offices should be connected with each other and with the generating stations in their respective divisions by direct telephone lines which will permit the prompt and frequent communication necessary in order to secure the most economical operation of the system as a whole. These lines of communication are indicated in Fig. 1. Competent and trained supervisors are required for duty at all times in each of these offices and each office should be under the direction of a chief supervisor responsible to the engineering and operating executives in his division. Coordination between divisions should be secured by constant contact, both by telephone and by frequent meetings of the chief supervisors and the engineering and operating personnel. At these meetings, current problems may be discussed and methods of procedure agreed upon.

It is the duty of the dispatching offices to keep informed as to system load conditions and power supply available at all times and to direct the load to be carried by the generating stations in the respective divisions in order that the varying requirements of the system load as a whole may be met in the most economical manner possible.

In order that maximum use may be made of all hydro power available, the load dispatchers must carry out the well-known rules of operation of a combined hydro and steam system, under which (*a*) during periods of low stream flow the steam stations operate on base load and the limited water supply at the hydro stations is used for carrying peak loads and (*b*) during periods of high stream flow the hydro stations on rivers with limited regulation of flow operate on base load with the steam plants and hydro plants on rivers which are highly regulated carrying the peak load.

A system completely balanced with respect to hydro and steam capacity will be able to carry its load throughout the year with little or no loss of hydro energy. However, such a balance may be difficult to obtain, particularly in a system not designed from the start with that objective in mind. There will probably be times during each year when all the available hydro energy cannot be fitted into the system load curve; hence, the desirability of interconnection with neighboring systems capable of absorbing surplus hydro energy during periods of high stream flow and light load.

In order that the dispatching offices may attain the foregoing objectives for the system, they must have complete and up-to-date information on hydro power available, the cost of power production from all sources, and on the efficiency characteristics of all stations.

3 *Data on Operating Characteristics of Generating Stations.*

In order that each hydro station may be operated so as to produce the maximum amount of energy from the water supply available, it is essential to know its operating characteristics. A knowledge of these will enable the station operators to divide any assigned load among the various units in such a way as to require the minimum use of water for that load and will likewise aid the load supervisors in assigning such a load to each station as may be most efficiently carried by it. The same principles, of course, are applied in the case of the steam stations.

Accordingly, if not already made, input-output tests should be carried out on most, if not all the generating stations, and the detail and refinement of the test for a given station should be commensurate with its importance and the possible gain to be made by ideal operation. In the case of hydroelectric plants the tests may be made by any accepted method such as those given by the A.S.M.E. Power Test Code for hydraulic prime movers. The measurements taken should include all those necessary to segregate the losses between the various component parts of the project such as the water conduit above the forebay, the penstock, the water wheel, the tailrace, and the generator.

The information derived from tests on hydro plants should be

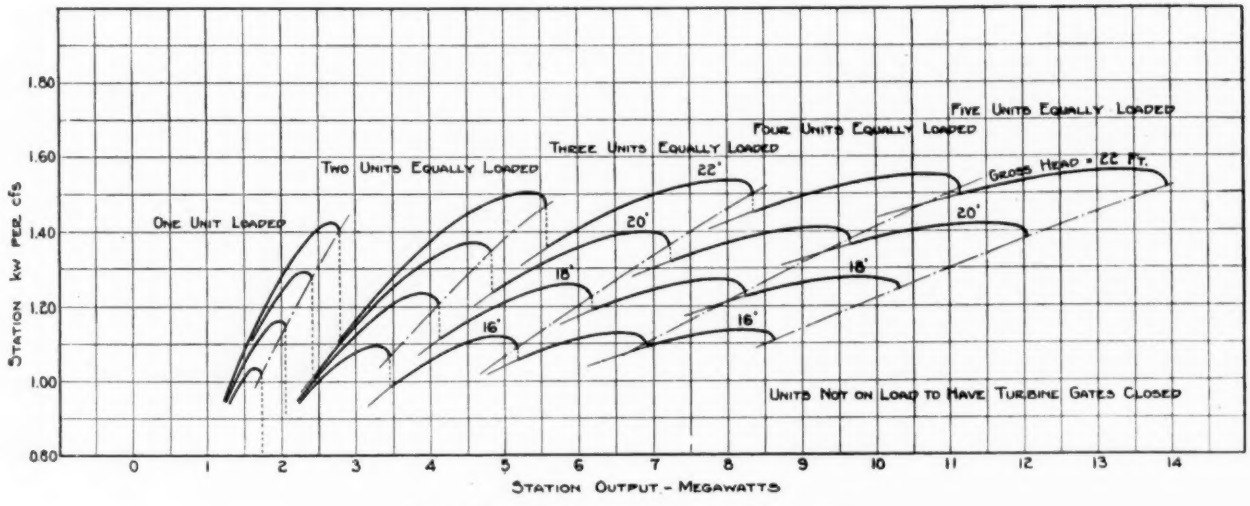

Fig. 3 Load Dispatching Curve for Station B

presented in the form of preferred-loading curves and tables, and in the case of at least one station on each river a manual of instructions should be prepared to enable the operators to keep a record of basic hydraulic information in the form of the "hydraulic log" as described hereinafter. Fig. 2 presents a preferred-loading curve for a hydroelectric station having a long pipe line which supplies four 10,000 hp units. For the sake of simplicity, the curve is given for only one gross head but actually the curve sheet would cover a family of gross heads ranging from 257 to 284 ft, which correspond to minimum and maximum reservoir elevations, respectively. It will be noted that for single-unit operation, the leakage of the other three units causes a relatively low over-all plant efficiency. As additional units are loaded up, the relative effect of leakage is reduced and plant efficiency is increased to the point where the effect of increased pipe-line loss overbalances the reduced leakage. Beyond this point the over-all efficiency begins to drop. In this case the point of best operation is reached with two units loaded to 14,500 kw and with the turbine wicket gates of the other two closed.

Fig. 3 shows curves for several heads for a station having individual penstocks. With this type of station the operating efficiency is progressively greater as units are put in operation, on account of eliminating the leakage loss in the stand-by units. From this curve it is apparent that, with a gross head of 20 ft and with one unit loaded, a maximum of 1.29 kw is obtained per cfs, but with five units operating under this head a maximum of 1.42 kw is obtained per cfs. Also for greatest economy of operation when the head is 20 ft five units should be operated with a total load of 11,500 kw. Information derived from these curves is put in the form of tables for the use of the station operators and the system load supervisors.

In assigning load to this and other similar stations, consideration must be given to the system requirement for peak capacity and to the water supply available. In all cases, however, the assigned load must be divided among the units according to the preferred-loading schedule.

For a station containing several units with unlike characteristics a loading "diagram" should supplement the preferred-load-

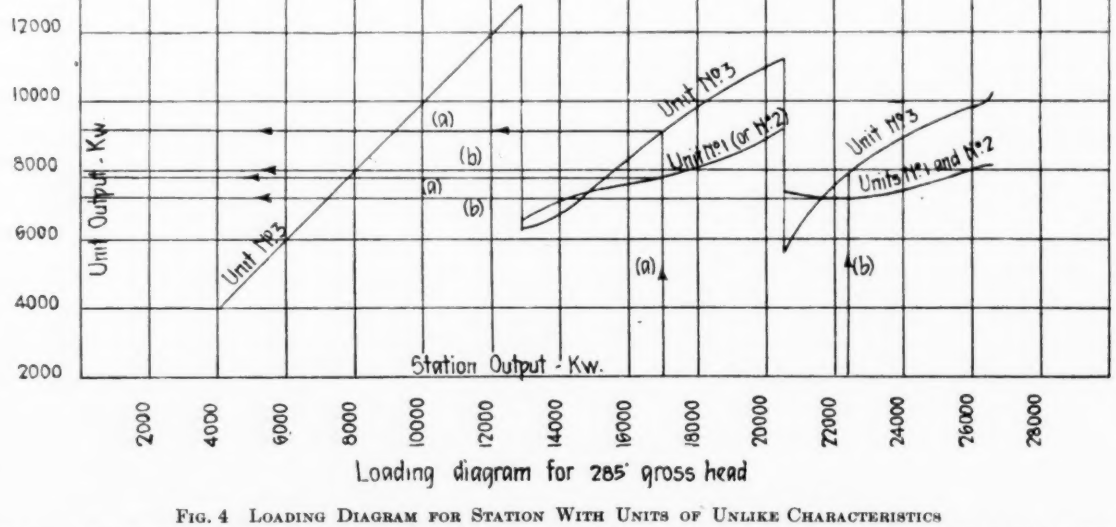

Fig. 4 Loading Diagram for Station With Units of Unlike Characteristics

(Examples: (*a*) For station load of 17,000 kw, follow vertical line from this point to intersections on curves. From these points follow horizontal lines to unit-output scale to determine load on each unit, viz.: No. 3 unit, 9150 kw; No. 1 (or No. 2) unit, 7850 kw. (*b*) For station load of 22,600 kw, unit-output figures are: No. 3 unit, 8000 kw; No. 1 and No. 2 units, 7200 kw each.)

FIG. 5 HYDRAULIC LOG

ing schedule in order to provide the allocation of loads between the units operating. An example of such a diagram is shown in Fig. 4.

Many companies have found that substantial improvements in hydro output have been obtained by the use of such curves and tables. It will prove to be of great advantage to maintain a constant check of operating results by means of the hydraulic log previously mentioned or by some similar routine. See Fig. 5. This sheet is designed to supplement the electrical log which is ordinarily kept by all hydroelectric stations. The data recorded can be arranged in such a way that the losses caused by departures from ideal loading can be readily determined and corrective measures taken.[3]

The manual of instructions for the use of the hydraulic log at a particular station should contain a complete explanation of all terms used and should give sample computations where they are considered necessary. Among the data tabulated in the manual there should appear the station capacity, preferred-loading tables, values of turbine-gate leakage, various constants, and discharge tables for spillway, log chute, and trash-and-ice chute.

It is highly desirable that complete input-output tests be made on all steam stations and that the results of such tests be continuously checked from operating records. The results of the test should show among other things (1) the no-load intercept for each combination of units, i.e., the fuel required to keep that number of units on the line without load (a theoretical condition only, as steam units must carry a certain definite minimum load in order that sufficient steam may pass through the turbine to dissipate the heat generated by friction at the high peripheral speeds of the low-pressure wheels), (2) the slope of the input-output curve over the whole capacity range for each combination of units when such units are loaded for maximum over-all economy, (3) a preferred-loading curve or table for each combination of units which will show the division of any given load among the units for maximum economy, (4) fuel consumption of boilers banked and

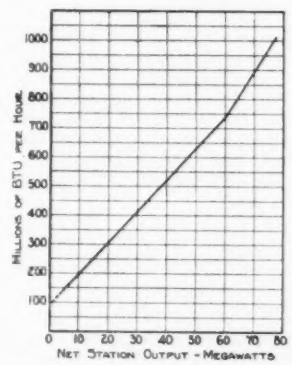

FIG. 6 INPUT-OUTPUT CURVE FOR TYPICAL STEAM UNIT

ready to pick up load, (5) the fuel required to start up each unit from a cold condition. Fig. 6 is a typical example of the input-output data obtained from the test of a large steam unit and its associated boilers and auxiliary equipment.

All these quantities will be required by the load dispatchers in planning the operation of the system for maximum over-all economy and in deciding which plants and units shall be in operation to provide the required running reserve generating capacity referred to later.

4 *Operation of Storage Reservoirs.*

Beside the economical operation of the hydro stations them-

[3] For a detailed presentation of the methods used and results obtained from the hydraulic log, reference may be made to an article, "How We Raise Hydro Efficiencies," by E. B. Strowger, *Electrical World*, vol. 103, April 14, 1934, p. 535.

selves, there is the operation of storage reservoirs to be considered. Instead of basing their operations upon the requirements of a relatively small or local section of the operating territory, as was done of necessity when certain parts of a system were formerly operated as more or less isolated units, they can now be made to function to the best advantage of the system as a whole. As a part of the larger system, full advantage can be taken of reservoir drawdown in anticipation of flood periods, because deficiencies occurring as a result of unexpected intervening periods of low flow can be made up from any available source on the combined system through the interconnected transmission facilities. In this way waste of water during high flow periods can be substantially reduced, with the resulting increase in annual hydro output. As a typical example, one company reports that since complete interconnection, it has increased the drawdown of one of the main reservoirs on its system by an average of 15 ft in anticipation of periods of high runoff. It has been estimated that in this case this type of operation has allowed an annual increase in system hydroelectric output of 75,000,000 kwhr which would otherwise have been wasted. Interconnection and coordinated operation has provided the outlet for the energy during the drawdown period as well as a backup source of supply to the area in case the reservoirs are overdrawn for an unexpected period of low flow.

5 *Reserve Capacity.*

As an example in setting up reserve generating-capacity requirements for protection against equipment failures, the following has been suggested by a company with a system similar to that described in the opening paragraphs, and is cited to show the influence of coordinated operation on the reserve generating capacity required.

1 There shall be installed on each system (25- and 60-cycle) sufficient reserve capacity to allow for the loss of the largest generating unit on that system at time of peak demand without reduction in load.

2 There shall be running on the 60-cycle system sufficient reserve generating capacity to allow for the loss of the largest unit on that system at all times. Under certain specified conditions, this 60-cycle running reserve may be reduced provided there is sufficient running reserve on the 25-cycle system available to the 60-cycle through the frequency changers or on neighboring interconnected systems to make up a total equivalent to the capacity of the largest unit. Running reserve is provided for the 25-cycle system either from the 60-cycle system through the frequency changers or on the 25-cycle system itself as may be required from time to time by operating conditions. The installed reserve allows the reestablishment of the running reserve in case of the loss or unavailability of the largest unit on either system at time of peak load.

The foregoing constitutes what is considered to be the minimum reserve generating capacity consistent with a high degree of service reliability. Operating conditions and the provision of generating capacity for growth of load will in general result in reserve capacities somewhat higher than the minimum required.

Here again, interconnection and coordinated operation have made substantial operating savings, for it is obvious that were the various units comprising the system operated separately while maintaining the same degree of service reliability, the amount of reserve capacity required, both installed and running, would be greatly increased.

6 *Regulation of System Frequency, Voltage, and Tie-Line Load.*

The regulation of system frequency, voltage, and tie-line loads is intimately connected with all the preceding requirements for economical and reliable operation. Satisfactory service to the customer requires maintenance of substantially constant voltage and frequency, and all other requirements of system operation must be coordinated to meet this condition. Within the last few years, the demand for accurate electric time service has introduced the further requirement of maintaining integrated frequency within what might be termed precision limits.

Maintenance of scheduled tie-line loads between divisions of the system and with neighboring systems is necessary in order that station outputs which have been scheduled to meet the total load with maximum over-all economy can be realized.

Again referring to the system outlined in the opening paragraphs, let it be assumed that electric service is rendered at both 25 and 60 cycles and that the two systems are connected together through a substantial capacity in variable-ratio frequency changers with positive and automatic control of load transfer within certain limits of variation of the two frequencies. The operating procedure as reported for such a setup may be described as follows:

In the preparation of programs for the operation of power-supply facilities, commonly called schedules, the 25- and 60-cycle systems may be considered separately in the initial steps. Referring to Fig. 1 the Western Division supervisor in whose territory the bulk of the 25-cycle system lies, prepares an estimate of the 25-cycle load for, say, the following day and schedules the operation of his power-supply sources to meet this load in accordance with the requirements stated previously. Any surplus or excess energy may then be scheduled for transfer through the frequency changers under positive load control. He also prepares a similar estimate and schedule for the Western division 60-cycle load and can then arrive at a combined excess or deficiency for the division as a whole. Similar schedules prepared by the Central and Eastern division supervisors, when combined with that for the Western division, will then show the over-all excess or deficiency of hydroelectric and other energy of low increment cost. Deficiency of energy of low increment cost must be made up by the steam plants which are then scheduled for operation in the order of their increment production costs with due allowance for losses from point of generation to point of use. Excess energy of low increment cost, if found to exist, is scheduled for sale to neighboring systems.

A complete operating schedule, prepared for the whole system in accordance with the requirements of maximum over-all economy, will call for definitely varying rates of transfer of energy between divisions and other systems throughout the whole period, the maintenance of which becomes the duty of the division load supervisors in addition to the fundamental requirements of maintaining system voltage and frequency. Transfer between the 25- and 60-cycle systems is under positive control and involves no serious problem. The transfer between divisions and with neighboring systems on the 60-cycle system, however, may present some complications in the matter of regulation. To illustrate: Suppose the economical operating schedule calls for a delivery of 100,000 kw to a neighboring system for a period of several hours. This represents possibly 5 per cent of the total generating capacity running in synchronism on the two systems combined. The transfer must be held within reasonably close limits if the greatest over-all economy is to be obtained, while at the same time the system frequency, both instantaneous and average, must be held within narrow limits.

One company reports that, in operating in parallel with another system, maintenance of instantaneous and average frequency was first handled by a large steam plant on the neighboring system by hand control and later by means of an automatic frequency controller of the frequency-bridge type. The company was charged with the responsibility of holding scheduled tie-line loads. This procedure resulted in certain difficulties, principally in rapid load changes on the regulating steam station during load-change periods with the attendant smoke nuisance and inefficient operation. This resulted from the fact that a load change anywhere on the combined systems resulted first in a corresponding change in sys-

tem frequency which was corrected by the regulating station regardless of the location of the load change. After the frequency returned to normal that part of the load change occurring on the company's system was reflected in a departure of the tie-line load from schedule, which departure would then be corrected by the company's load dispatchers, which then resulted in a further load change on the regulating station.

This situation was corrected by installing a blocking device, actuated by tie-line load and operating on the frequency controller of the regulating steam plant, together with the use of automatic frequency-control apparatus of the integrated-time-error type on the company's system. The blocking device on the tie line prevents the operation of the frequency controller at the steam station, if its operation as called for by system frequency would tend to throw the tie-line load off schedule. Thus a correction for deviation of frequency due to a load change is forced on the system upon which the load change occurs and the regulating duty is divided between the two systems in proportion to the load changes occurring on each.

Accurate integrated frequency for electric time service has been secured by use of a standard 60-cycle wave supplied to the regulating steam station by means of a crystal-controlled oscillator and accurate within precision limits. This frequency is applied to one circuit of a synchronoscope and system frequency to the other; thus the system time error in cycles (sixtieths of a second) is indicated by the revolutions of the synchronoscope. The rotation of the synchronoscope may be used to unbalance the bridge circuit of the frequency controller, thus causing it to regulate for a higher or lower frequency until the time error is corrected. Or the time error thus measured may be communicated to a large plant on the company's system having an integrated time-error type of frequency controller, used as a check on the master clock at that station, and as a guide in setting the time-error corrector. The time-error corrector is a device on the integrated time-error frequency controller which has a somewhat similar effect to unbalancing the frequency bridge of the controller at the regulating steam plant.

The results from this procedure have been satisfactory in that scheduled tie-line loads have been held within close limits, while at the same time instantaneous frequency is normally held within a band of ± 0.1 cycle per sec in 60 cycles per sec and maximum time error within $\pm$ 1 sec.

FIG. 1 GENERAL VIEW OF BONNEVILLE PROJECT ON THE COLUMBIA RIVER

The Kaplan Turbines at Bonneville

BY PAUL L. HESLOP[1] AND GEORGE A. JESSOP[2]

The Bonneville project has an initial installation of two 66,000-hp Kaplan turbines designed to operate under heads varying from 30 to 69 ft. Noteworthy features are the physical size of the units, the extensive model tests, pioneering in the use of welded construction, new ideas in auxiliaries, and the care exercised in setting embedded parts.

GENERAL DESCRIPTION OF PROJECT

THE BONNEVILLE project is at tidewater on the Columbia River 42 miles east of Portland, Oregon. It is the lowest of the ten dam sites selected by the U. S. Army Engineers as part of a projected scheme of river development.[3] Of these ten, Rock Island was constructed as a private power project some years ago, Grand Coulee (the uppermost) is under construction, and Bonneville is approaching completion. Navigation and power are provided by the Bonneville Dam, but navigation requirements at the dam or in the river will not affect operations of the power plant. River conditions are given in Table 1.

There is no seasonal storage available in the Bonneville pool, but daily load fluctuations can readily be accommodated with 3 ft or less of drawdown. The record flood of 1894, and more, has been provided for in spillway design but so large a flow is not expected again due to increased and increasing upriver storage. Consideration of these facts and other data led to the decision that the turbines should operate under heads of from 30 to 69 ft. With the authorization of Bonneville there was projected into the northwest territory a power development of large proportions with character of load, shape of load curve, immediate demand, probable rate of growth, and interconnections—all matters for conjecture. For such conditions with low variable head and variable output the Kaplan adjustable-blade turbine is well adapted to give the highest efficiency over the widest range.

The size of the turbines was given careful consideration. The units are about as large as is practicable under existing shop conditions. There are also certain practical mechanical limitations, of which might be mentioned the enormous vertical thrust and the high pressure on the bearings of the overhung turbine blades. Reduction of form work for fewer units is partially offset by the expense of longer structural spans, heavier cranes, and larger gates. As finally designed, the turbines have a rating of 66,000 hp under 50 ft head. They are the largest Kaplans in this country, the highest powered Kaplans ever built, and the generators they drive are the largest in physical dimensions so far constructed. Various characteristics are given in Table 2.

TABLE 1 RIVER HYDROLOGY

	Cfs	Cfs per sq mile[a]	Corresponding head, ft
Mean annual flow	211000	0.88	54
Minimum flow	40000	0.166	65[b]
Normal high flow	800000	3.23	40
1894 flood, maximum	1170000	4.65	25.7[c]

[a] Drainage area, 240,000 sq miles.
[b] The head can be 69 ft under certain conditions.
[c] Estimated.

Contributed by the Hydraulic Division and presented at the Spring Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Los Angeles, Calif., March 23–25, 1938.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until March 10, 1939, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 2 TURBINE DESIGN DATA

	Main turbines	Station-service turbine
Type	Kaplan	Kaplan
Blade adjustment	Automatic	Manual
Number, present	2	1
Number, ultimate	10	1 or 2
Diameter of runner (throat), in.	280	81.0
Number of blades	5	5
Rated horsepower	66000	5000
Rated head, ft	50	50
Rated discharge, cfs	13000	1025
Rated speed, rpm	75	257
Runaway speed, 69-ft head, rpm	216	750
Range of head, ft	30 to 69	30 to 69
Usual minimum head, ft	40	40
Usual minimum tail water, el, ft	7	7
Possible minimum tail water, estimated, el, ft	3	3
Usual maximum tail water, el, ft	40	40
Maximum tail water for design, el, ft	53	53
Specific speed at rating	145	137
Phi at rating	1.61	1.59
Peripheral speed, turbine, normal, fpm	5498	5450
Peripheral speed, turbine, runaway, fpm	15800	15800
Peripheral speed, generator, normal, fpm	7975	8070
Peripheral speed, generator, runaway, fpm	22950	23400
Coef of gates as orifice, C in $CA\sqrt{(2gh)}$, at rating	0.455	
Center line of speed ring, el, ft	12.5	10
Center line of runner, el, ft	3.9167	7.516
Center to center of units, ft	82	
Weight of rotating element, lb	1500000	120000
Hydraulic thrust at 69-ft head, lb	1500000	
Total load on thrust bearing, lb	3000000	
WR^2 of turbine and generator, ft²-lb	158000000	920,000
Type of scroll	Concrete	Plate steel
Velocity at entrance to turbine scroll, fps	6.5	10.04
Type of draft tube	Elbow, horizontal splitter	Elbow, horizontal splitter
Number of intermediate piers in draft tube (see text)	1	1
Velocity, draft-tube exit, fps	6.3	7.1
Velocity through trash racks, gross area, fps	2.89	
Velocity through trash racks, net area, fps	3.75	
Manufacturer	S. Morgan Smith	S. Morgan Smith

The initial installation will consist of two main units and a station-service unit of 5000 hp capacity. Foundations are built for four more main units. At the site of the project the Columbia River divides into two parts around Bradford Island, as shown in Fig. 1. The power plant is located in the smaller of the two channels and the space required for the present installation plus four future units nicely forms a dam across the channel. The installation of the last four of the ultimate ten units will require further major operations of cofferdamming and excavating.

The conditions under which the turbines must operate are graphically illustrated by the power-duration curves shown in Fig. 2. The curve of flow Q is a 55-year hydrograph of the Columbia River plotted in duration form. Any vertical line contains simultaneous values of flow Q, headwater elevation, tail-water elevation, head H, and power. The curves are for the run of the river without any regulation. At low and moderate river stages, or about three fourths of the time, the pool will be held at elevation 72, which is the approximate level of the top of the spillway gates. As the river flow approaches 250,000 cfs the rise in tail water threatens to decrease the head sufficiently to limit output, but for flows up to around 500,000 cfs the effect of the rise in tail water can be counteracted by raising the headgates and the pool level to maintain the rated power output of the units. This can be carried on until headwater reaches elevation 82.5 when upriver culture prevents further adjustment. For flows above 800,000 cfs the spillway gates must be opened wide and the turbines left to do the best they can. For such conditions maximum output under the head then existing is the desired quality.

Based on past records, the head may get down to 40 ft almost any year, but would not have gone below that in the last 30 years. There are enough years of record to indicate the necessity for specifications of a 30-ft head, but the extreme minimum of 1894 should not occur again.

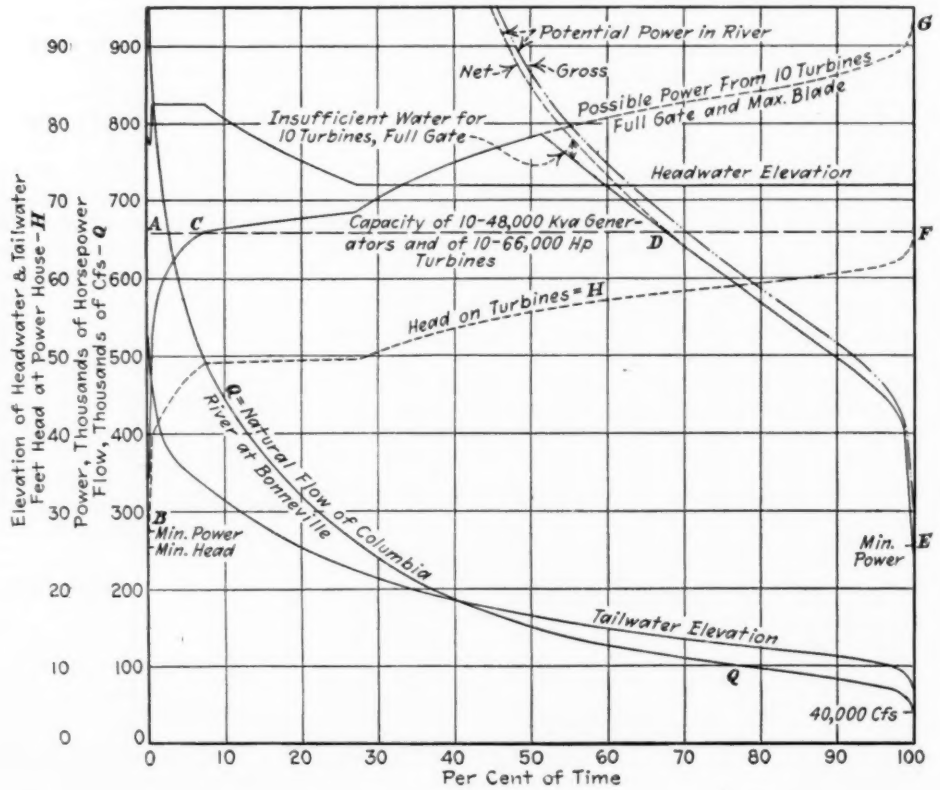

FIG. 2 HEAD AND POWER AT BONNEVILLE HYDROELECTRIC PLANT

(Curves showing hydraulic conditions at Bonneville, expressed in duration form; 55 years are covered, including the maximum flood of record in 1894. The initial installation consists of two 66,000-hp turbines designed for 50-ft head. Ultimately 10 units are to be installed.)

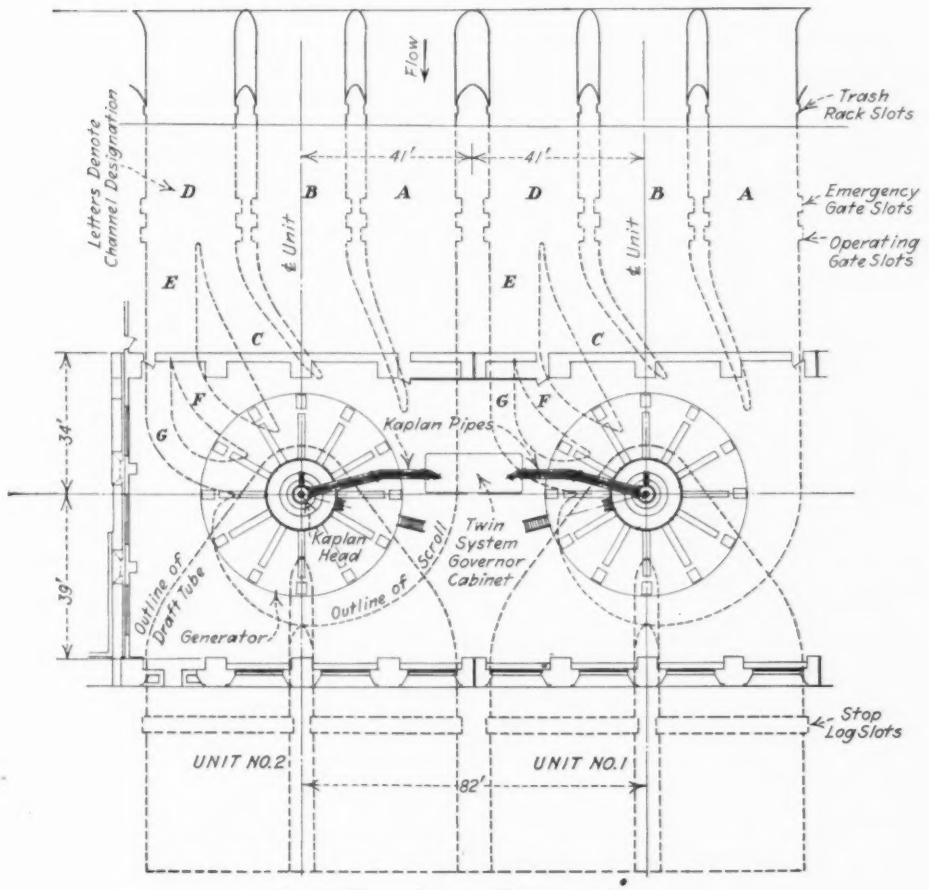

FIG. 3 FLOOR PLAN OF GENERATOR ROOM
(Units and governor shown superimposed on outlines of intakes, scrolls, and draft tubes.)

In Fig. 2, two curves are drawn indicating the potential power of the river, the lower of which allows for an estimated use of water for the fishways. Other than this, the extensive fishway apparatus does not affect the power-plant operation. It will be seen that for about one third of the time there is not sufficient water to operate 10 turbines at their rated capacity. The deficiency in possible output is represented by the area *DEF*. At such times maximum efficiency is to be desired. Depending upon the character of the future load, much of this deficiency may not occur in practice as there is ample pondage for daily regulation at any reasonable daily load factor. Also, now that the Grand Coulee is being constructed, there is a strong probability of regulation helpful to the low water flow.

The power-duration curves show the maximum head at 65 ft, while the turbines are specified and designed for 69 ft head. After the proposed dredging of the channel below Bonneville for navigation, there are certain combinations of low tide coupled with temporary shutdown of all or some of the units that could result in a 69-ft head, and safety requires that provision therefor be made.

The curve, "possible power for 10 turbines," represents the power that could be obtained hydraulically from the ten turbines, with water passages and blades like the two now installed. Actually the present turbines are designed mechanically for only 66,000 hp under 69 ft head with usual factors of safety. This capacity is required for driving a 48,000-kva generator at unity power factor. Standard and special devices are incorporated in the governors to prevent excess output.

Bonneville was authorized in October, 1933, by the Public Works Administration and it was desired that the maximum number of men be put to work at the earliest possible date. It was a comparatively easy matter to place an earth cofferdam in Bradford Slough and commence construction of the powerhouse quickly. Therefore it was necessary that the general features of the design of the turbine water passages be settled at the earliest possible moment. Experimental studies of the shape and type of the intake and draft tube were made at the U. S. Engineers' hydraulic laboratory near Portland. From the results of these studies and a consideration of structural features, plans for an intake with two intermediate piers and two islands were drawn and the type and controlling features of the draft tube were set. Data from manufacturers were checked against the engineer department studies and indicated a center-to-center spacing of units of 82 ft. Fig. 3 shows in plan the final layout of intake, scroll, and draft tube that resulted from the model tests and studies described herein. Fig. 4 is a general cross-sectional view of the powerhouse.

MODELS AND TESTS

In the U. S. Engineers' laboratory models were constructed for developing the proper intake, scroll, and draft tube. The general shape of the intake in vertical section was more or less established to fit in with the construction of a combined trash, ice, and fingerling sluiceway across the upstream face of the powerhouse. The other properties of the intake and scroll were developed by visual analysis with transparent models on a scale of 1 to 46. Sawdust was introduced into the flowing water and moving-picture films were made and studied by the experimenters

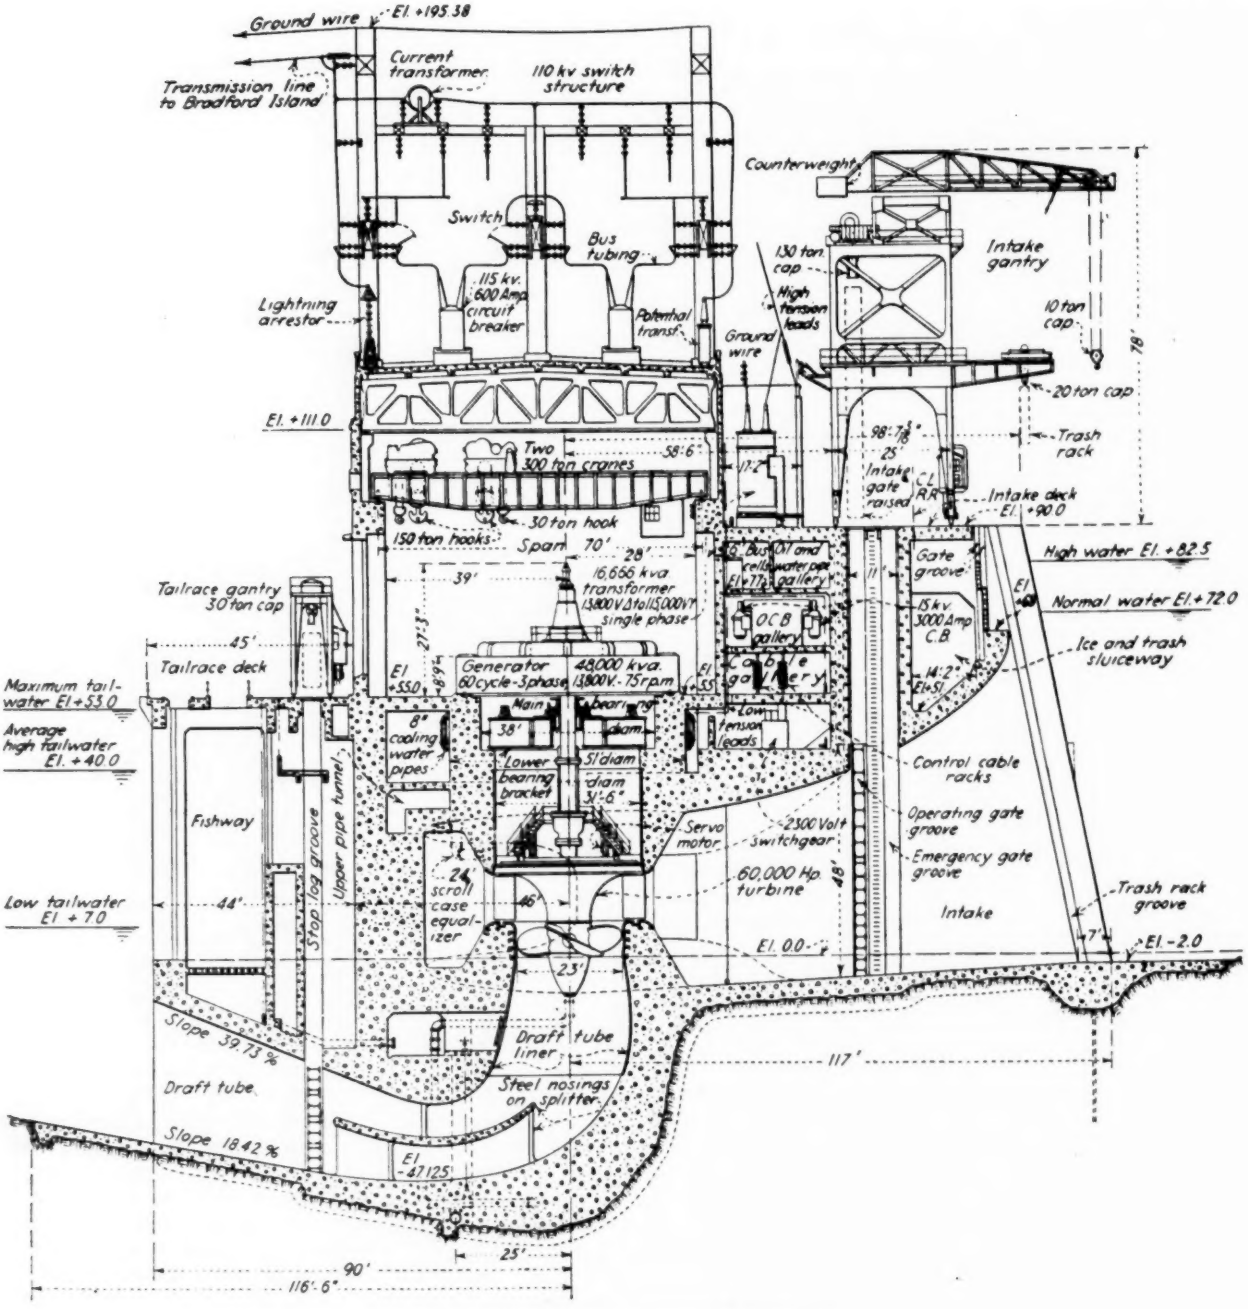

FIG. 4 CROSS SECTION THROUGH POWERHOUSE

and by the consulting engineers. From the results of many trials the best results were obtained with a constant-velocity scroll with water in the prototype flowing at 10 fps. An accelerating scroll was tried, but there was difficulty in getting a scroll in which the water would actually accelerate. A decelerating scroll was also tested but there was a tendency to form eddies, particularly at the small end of the scroll, and there was evidence of dead space. Transparent molded pyralin models of draft tubes were made and studied. The object was to get a workable draft tube to set dimensions for the structure. The most valuable result of the engineers' studies was the development of the horizontal splitter, which was found to improve conditions in most of the draft tubes investigated.

The contract for the turbines provided for acceptance of efficiency of the main units on the basis of model tests in the manufacturer's laboratory stepped up for size according to the Moody formula

$$Eff_a = 100 - (100 - Eff_m)(D_m/D_a)^{1/4}$$

Wherein Eff = efficiency, D = diameter of runner, and subscripts a and m refer to prototype and model, respectively.

The manufacturer was obligated to construct and test homologous models including intake, scroll, draft tube, and a runner of 16 in. diam arranged for substitution of blades of alternate design. From the results of the laboratory experiments at Portland, the U. S. Engineers designed an intake and scroll, also a discharge

tube, and established the dimensions of the intake up to a point within 34 ft, and of the horizontal leg of the draft tube to a point within 39 ft of the center line of the unit. Between these two points the manufacturer had a free hand for his designs.

It was not possible to use a scroll with more than slight changes from the original design, because of the islands and piers used to guide the water, sloping ceilings and floors between the piers, and the completion of a substantial amount of this work in the field prior to the conclusion of the tests. Such modifications as could be made did not indicate important changes in horsepower or efficiency and the original design of scroll was used.

The manufacturer exercised his rights under the contract and built a model draft tube laid out in so far as possible to follow the experience secured in many field and model tests. After tests in his laboratory the manufacturer elected to use his own design. This tube contains a horizontal splitter with a vertical supporting pier under it extending to its upstream edge. A heavy vertical pier is placed in the center of the horizontal leg of the tube starting at about the end of the elbow and continuing to the outlet. The splitter supporting pier is a continuation of this main pier below the splitter. The downstream end of the splitter is afforded additional support by two short piers.

The manufacturer made two sets of runner blades, selected the one giving the best results for the final tests, and used this design

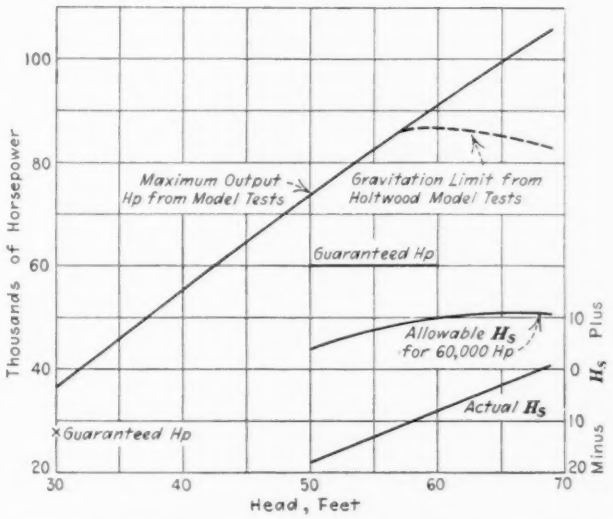

FIG. 5 SAFETY AGAINST CAVITATION AS DETERMINED BY TESTS IN THE HOLTWOOD HYDRAULIC LABORATORY

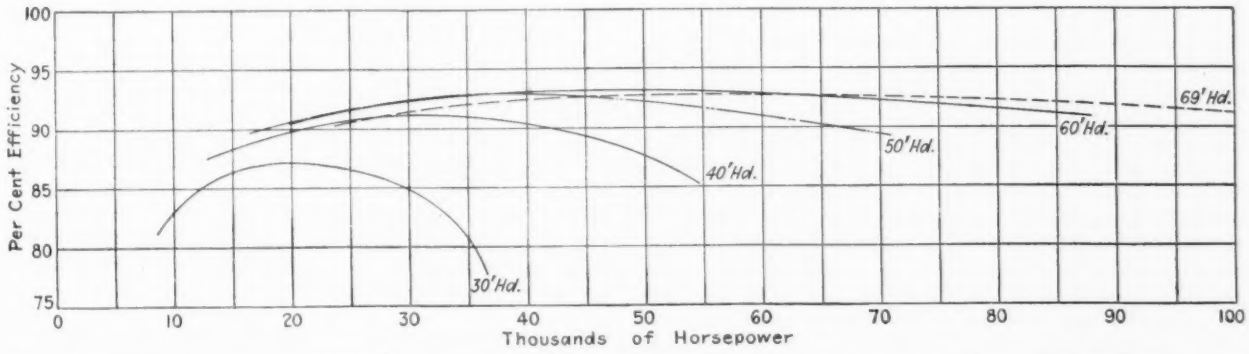

FIG. 7 HORSEPOWER AND EFFICIENCY CURVES OF THE LARGE UNITS OBTAINED BY INCREASING MODEL EFFICIENCIES BY THE APPLICATION OF THE MOODY FORMULA

for the 280-in. runners. The model runners were made of bronze and the scroll and draft tubes of welded plate steel. It was required that the models have sufficient strength for testing under a 69-ft head. The plates forming the elbow of the draft tube were die-pressed and the scroll was carefully shaped to templates. Great care was used to have the models exactly similar to the prototypes in all respects.

A model of the station-service unit was made and tested and since this unit will be field-tested, a further check between the laboratory and field results will be obtained. The acceptance tests for the service unit will be made by the Allen salt-velocity method. All of the horsepower-efficiency tests on the manufacturer's models were made in his laboratory at York, Pennsylvania.

There are many reasons for relying on model rather than field tests for a power plant like Bonneville. Because of the large cross-sectional area of the water passages of the unit, their relatively short length, and continually changing cross section in the direction of flow, it was considered to be unusually difficult to measure accurately the large quantities of water involved. Model tests as provided for by the Bonneville engineers disclose any faults there may be in design and lead the way to the elimination of the trouble at minimum expense. A choice can be made between several designs, thus securing the best possible results. Much more comprehensive data can be secured from model tests, a particularly valuable feature in a plant with a greatly varying head. Complete data are especially advantageous for Kaplan turbines. At Bonneville the model data will be supplemented by exhaustive tests using the index method for checking the best relationships between gate and blades.

The model efficiencies were stepped up according to the Moody formula to determine whether the guarantees were met and to obtain the expected field results. The model horsepower was stepped up in the usual manner without allowing for any extra capacity due to the increase in size. Fig. 7 shows the horsepower-efficiency curves for the full-size 280-in. turbine over the entire range of head. Expected and guaranteed results were exceeded by substantial margins due to improvements in the design of the turbine and the water passages. The preliminary and final investigations in the hydraulic laboratory were more than justified.

The relationship between headwater and tail water at Bonneville is such that the high head occurs with low tail water. Since the maximum operating head may be as high as 69 ft, cavitation tests become of great importance. While the elevation of the units with respect to tail water could be determined with reasonable accuracy from past experience and former tests, it was deemed necessary that additional cavitation tests be run. These were made in the Holtwood hydraulic laboratory by the testing staff of the Pennsylvania Water & Power Company. The complete model was set up, including the scroll case and draft tube, using designs which gave highest efficiencies in the manufacturer's flume. Check tests were also made on power and efficiency.

The results of the cavitation tests show a large safety whether considered in horsepower or in feet head. Fig. 5 shows that under 69 ft head, there is a safety of about 10 ft and under 50 ft head, a safety of about 22 ft. Actual H_s represents the elevation of tail water over the range of head shown. Allowable H_s is the elevation of tail water at which the turbines could develop 60,000 hp according to the cavitation tests but without any margin of safety. The center line of the turbine gates is at elevation plus 12.5 and the center line of the blades is at elevation plus 3.9167 (main units). A detailed account[4] of the procedure followed in cavitation testing at the Holtwood laboratory has been published in a previous paper presented before the Society.

Fig. 5 also shows the horsepower limits as determined by the maximum capacity of the wheel up to a head of 57 ft and then as limited by cavitation to a head of 69 ft. Since the guaranteed capacity of the turbine is 60,000 hp and the maximum load of the generator at rated capacity is 66,000 hp, ample safety is provided for any condition.

The horsepower and efficiency obtained at the S. Morgan Smith flume and at the Holtwood flume show remarkable agreement. Fig. 6 presents the comparative data reduced to 1 ft head for the model size, at unit speeds corresponding to the speed of the prototype at heads of 60, 50, 40, and 30 ft.

Turbine Design and Construction

The Bonneville turbines are much larger than any heretofore built and a thorough study was made of materials and types of construction. Because of the large size and complicated shapes of many of the parts and the consequent hazard of using steel castings, careful consideration was given to the possibility of fabricating by welding. A background of many years' experience was available and opportunities were afforded to the manufacturer to compare his practices and past experience with that of others who had used welded construction for large machinery.

It was apparent that a number of advantages could be realized by the use of welded members. There was an elimination of a large percentage of patterns, part of which advantage, however, was lost because of the necessity for making a number of dies. The parts were placed in the shop more quickly for machining and assembly, and shipping was thus expedited. There was practically absolute assurance that machine work would not expose defects with resultant rejection, replacement, and delay and, in view of the necessity for quick delivery, it was most important to be able to set and follow a precise schedule. The weights could be almost exactly figured thus making it possible to hold to accurate estimates of cost. The amount of metal allowed for finishing was reduced greatly over that required for castings and machining time also was thus cut to a minimum. The cost of welding, assembling, and handling was possible of accurate estimation, although some misgivings were felt in regard to contingency, the principal concern being the possibility of distortion.

Special additional equipment was provided at the manufacturer's shops, such as welding machines, cutting tools, tilting tables, and large machine-finished floor plates. Some idea of the task involved can be gained when it is stated that nearly 800 tons of rolled steel plate varying from $^3/_4$ in. to $3^1/_2$ in. were used. There was required about 16,000 linear feet of machine gas cutting, 24,000 linear feet of welding, and 29 tons of weld electrode for the two units. It was decided that all of the welding was to be done with the work in a horizontal position. This positioning was necessary both for economy and assurance of quality. All of the parts were stress-relieved, excepting the pit liner, which is subject to little stress.

The expected advantages of the welded construction were fully realized. There was no trouble on account of distortion and the metal to be removed by machining was remarkably uniform in depth. Time and costs were within close limits of the estimates. No cracks or defects developed in the welds or in the other parts of the structures, either before or after stress relieving. Figs. 9 and 10 show some of the welded parts in process of manufacture. Details of this welding job are available in published[5] articles.

The design of the turbine members and the work they have to perform, particularly the top structure or cover plates, are such

[4] "Cavitation Testing of Model Hydraulic Turbines and Its Bearing on Design and Operation," by L. M. Davis, Trans. A.S.M.E., vol. 57, 1935, paper HYD-57-13, pp. 455–462.

"Giant Turbines for Bonneville," by Curtis W. Lau, *American Machinist*, Feb. 24, 1937.

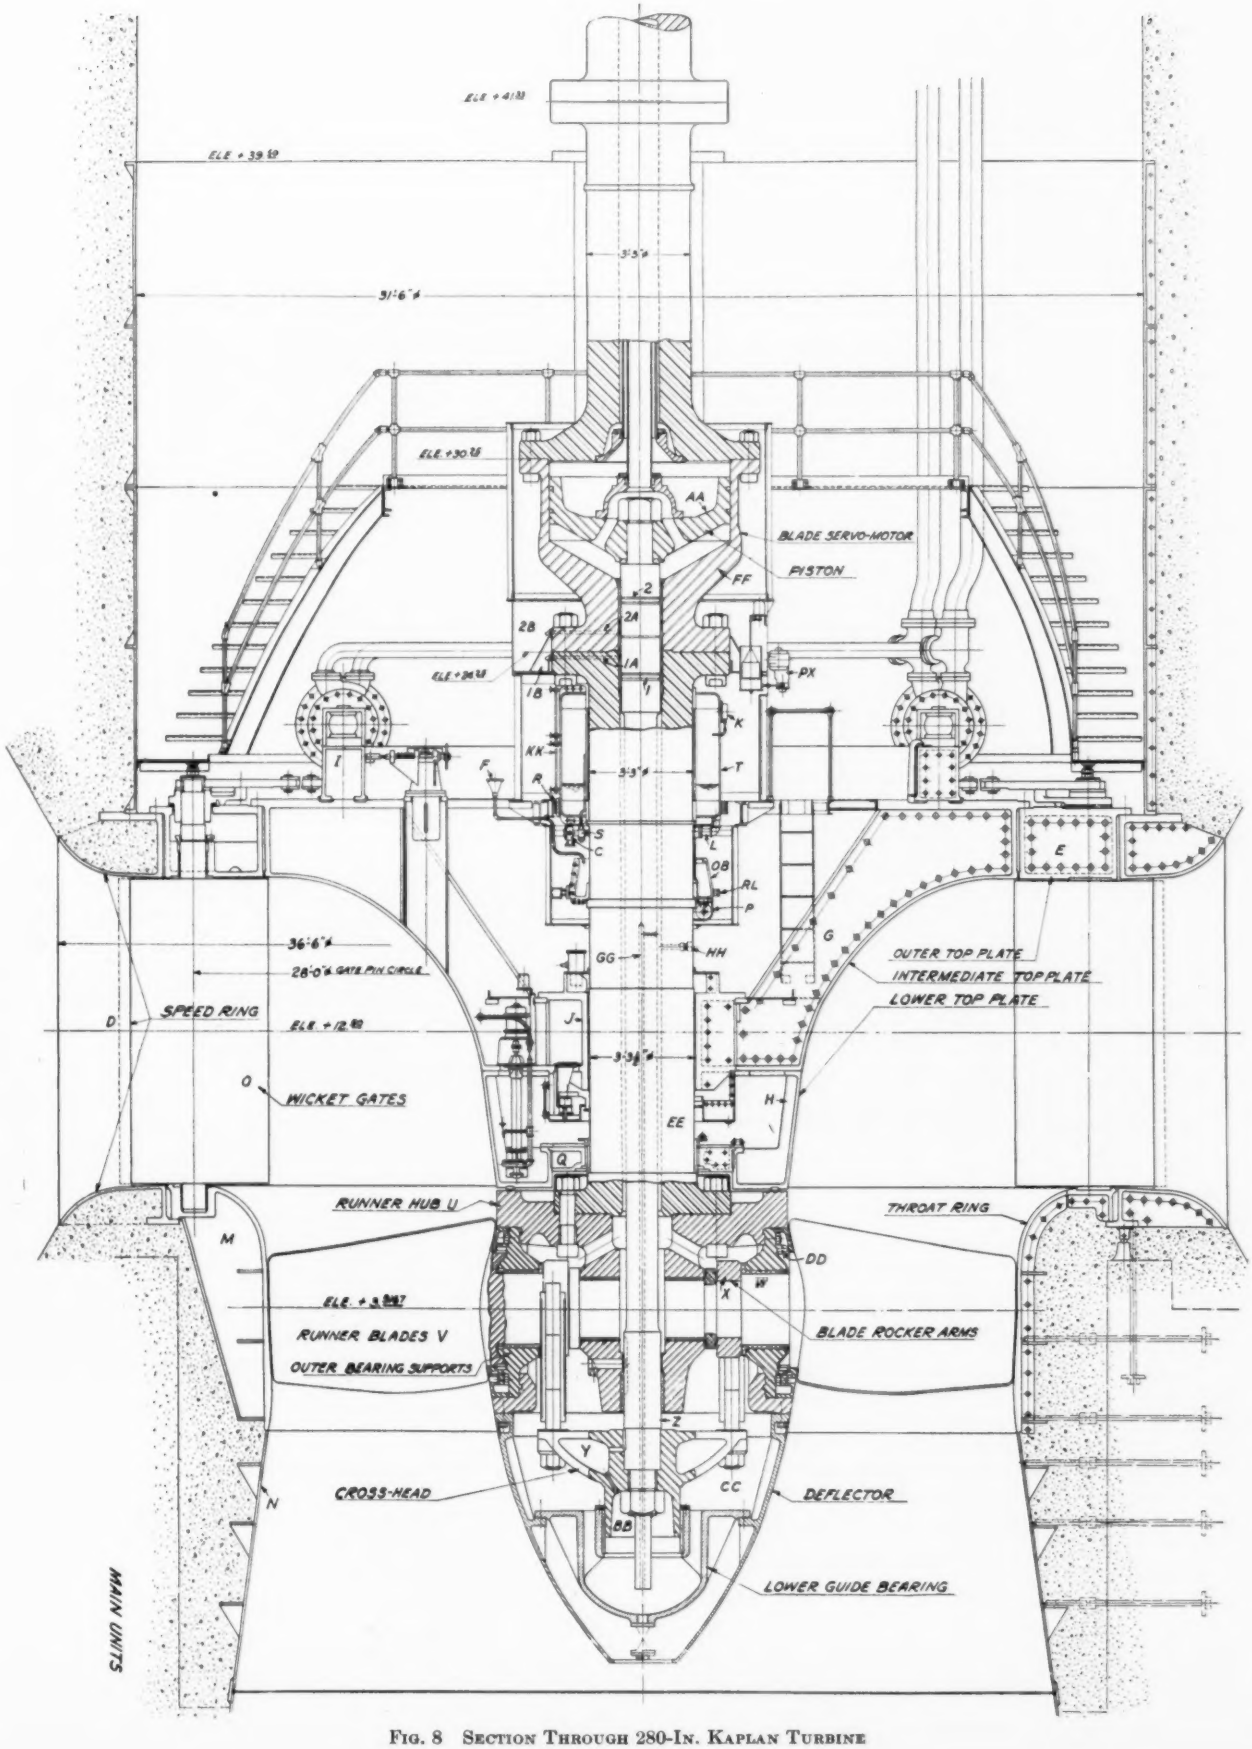

FIG. 8 SECTION THROUGH 280-IN. KAPLAN TURBINE

that an exact analysis of the stresses is impossible. From field investigations on similar installations, the loading was accurately known and an analysis showed that a test model could be constructed and loaded in such a way as to produce stresses closely comparable to those imposed on the parts in actual field service. Using a ratio of four to one, the model, Fig. 11, could be made of reasonable size with the parts of exactly the same material welded in the same manner and of the right proportional thickness. Stresses in the model were determined by means of a battery of strain gages and deflections were measured at many points. Both tangential and radial stresses were determined and concentrated stresses were carefully investigated. The information obtained from the tests proved to be of great value in designing the Bonneville turbines and the data are applicable to the preparation of plans for similar units.

The parts made of welded construction, Fig. 8, are the speed ring *D*, the outer top plate *E*, intermediate top plate *G*, lower top plate *H*, the gate or shifting ring *I*, the bearing *J*, the throat ring *M*, and a number of the smaller parts of the equipment. The

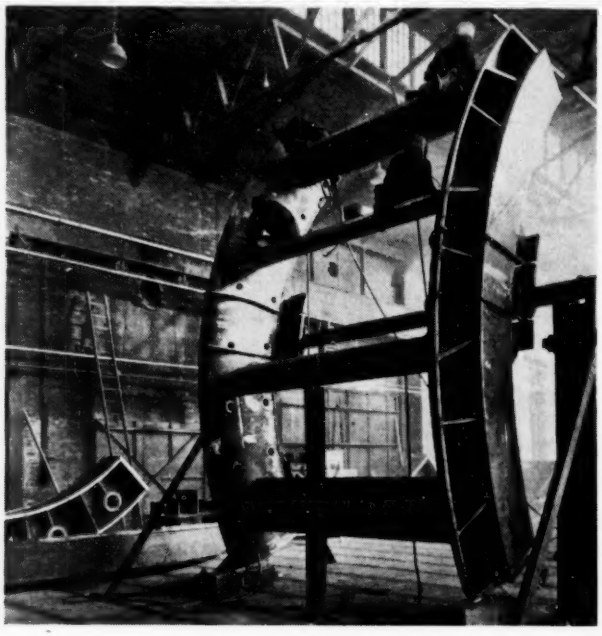

FIG. 9 BUILDING SPEED RING IN SHOP
(Welding together formed plates of rolled steel. All welding was done in a horizontal position.)

draft-tube liner, which extends to an elevation 37 ft below the center line of the gates, is welded at the upper part and riveted at the lower part. The throat ring is bolted to the speed ring and, in addition, has a continuous field weld. The draft-tube liner is field-welded to the lower part of the throat ring.

The speed ring is made in five sections, the outer top plate in four sections, the intermediate top plate in two sections, the lower top plate in one section, the throat ring in two sections, and the shifting ring in two sections. The speed ring has 20 vanes, one for each of the wicket gates. These vanes are shaped to guide the water properly toward the wicket gates but because of the special conditions of flow imposed by the supply passages, it is necessary to have a number of them specially shaped. The nose pieces or interior edges of the vanes were made from bar stock machined to the proper size and shape. The vanes act as columns and carry about 9,000,000 lb of dead load when the scroll is empty, although some of the vanes, at the large part of the scroll and at the intake, are in tension under the most severe pressure conditions. The total weight of the speed ring is about 177,000 lb.

The wicket gates *O*, are cast steel with integral stems. They are tapered toward the bottom to reduce disturbance under the gates and to allow the streams of water from the two sides of the gate to come together before coming in contact with the runner blades. The gates are supported by three bearings, one in the throat ring and two in the outer top plate.

The main guide bearing *J*, the only bearing on the turbine, is babbitt-lined and oil-lubricated. A pump, gear-driven from the

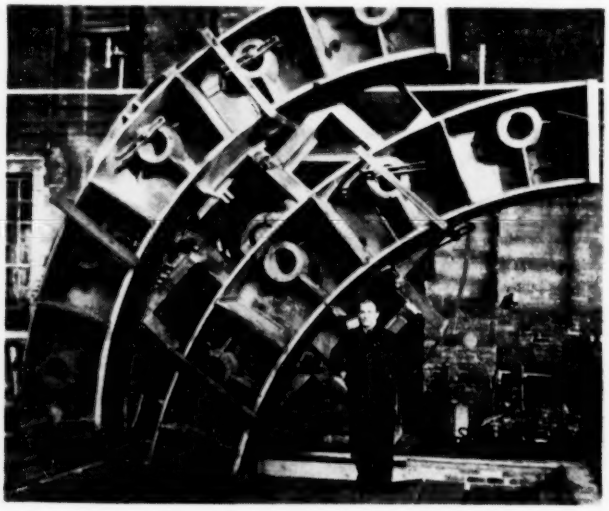

FIG. 10 SECTIONS OF OUTER TOP PLATE

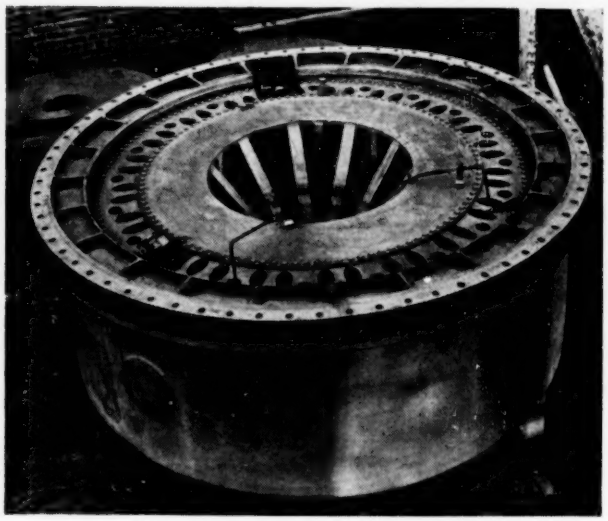

FIG. 11 MODEL HEAD COVER, ONE-QUARTER SIZE

shaft, is provided to return the oil from the bottom to the top of the bearing and there is a spare motor-driven pump, float-controlled. There is a packing box under the bearing in which an acceptable square packing is to be used. Domestic water can be applied to the packing if desired.

Below the packing box *Q* is a hollow rubber tube surrounding the shaft and normally clear of it. With unit stationary, this tube can be inflated to seal off the tail water. By this means the packing, which is always lower than tail water elevation, can be ad-

justed or renewed without lowering head gates and tail gates and unwatering the unit.

The Kaplan hub *U* is made of cast steel and weighs 100,000 lb. Each of the five blades *V* is cast steel of better quality and weighs 27,000 lb with the integral stem *W*. The outer bearings for the blades are removable and one slot for each blade is cast into the hub so that a blade can be inserted or removed with its rocker arm *X* and thrust washer attached. The rocker arms are shrunk as well as keyed to the stems and it is advantageous to be able to assemble or remove them in the open. The outer bearing supports, the rocker arms and thrust rings, the links, pins, and crosshead *Y* are all of high-strength steel.

The crosshead is moved up and down by a special steel push-and-pull rod *Z* actuated by the blade servomotor piston *AA*. This operating rod has three bearings, one under the piston, one just above the crosshead, and one just below it. The lowest of the three bearings *BB* is mounted in the cast-iron deflector *CC* and contains at the bottom a substantial reservoir for the accumulation of water should there be any leakage or gathering of condensation or moisture inherent in the oil. To prevent leakage of water in or oil out along the blade disks, a chevron-type packing *DD* is provided and held in place by a split gland. The glands can be removed and the packing replaced without dismantling the blades from the hub.

Each blade is supported by two bronze-bushed bearings. Because of the large thrust and torque on the overhanging blades, the service required of these bearings is severe, the bearing pressure is high, and the movement of the blades normally slow. Tests were made on many materials and with numerous types of grooving in order to secure the best bushings. The hub is filled with oil under low pressure and careful investigation was made to secure a lubricant with the proper film strength and lubricating properties.

The runner blades for one unit are machine-finished on a die-sinking machine to the exact shape of the layout. See Fig. 12. The blades of the other unit were given a good ground finish. Both finished and unfinished blades are prewelded with stainless steel over certain areas on the underside of the blade and also at the periphery as an extra protection against pitting and deterioration. As the units are operated, an interesting and valuable comparison can be made between the freedom from pitting and the smoothness of operation of the machine-finished compared with the ground blades. Machining by the die-sinking method produces a finish without the slightest irregularity or unevenness and is superior to any other process.

The turbine shaft is of forged steel and the blade-servomotor piston and cylinder *FF* are of cast steel. The turbine shaft, blade-servomotor cylinder, shaft extension, and generator shaft were tested in the turbine manufacturer's works for trueness by mounting vertically on a revolving table. The over-all length of the shaft was so great that it could not be tested in its entirety at one time. The lower shaft, servomotor cylinder, and intermediate shaft were first tested and then the intermediate shaft was tested with the generator shaft. The table was revolved slowly and readings were taken by means of shaft deflection gages. The vertical method of checking is much more accurate than the horizontal method.

Testing for Water in the Kaplan Hub

While every precaution has been taken to prevent the leakage of water into the Kaplan hub, it was still deemed desirable to have a positive method for checking the presence of water and for the removal of it, if found. For this purpose, the operating shaft is extended on the lower end as shown in Fig. 8 and is bored with a small hole *GG* to an elevation just above the main bearing. At the upper end a hole is drilled from the central hole to the outside of the operating shaft. In the outer shaft *EE* a corresponding hole *HH* is drilled having the same angular position as the hole in the operating shaft. The operating and main shaft always have the same relative angular position. The vertical location of the two holes is such that when the operating shaft is in its lowest position, the holes are at the same elevation. The hole in the main shaft contains a specially designed and constructed valve and plug. When the two holes are lined up, the outer valve is screwed inward until it enters the hole in the operating rod. A flexible hose is then screwed into the valve, automatically opening a passage for the drainage of oil or oil and water. The lower part of the operating rod is now close to the bottom of the reservoir in the guide bearing in the hub deflector. If there is any water in the hub, it will gather at this location when the turbine is shut down. There is sufficient pressure, as explained later, in the hub and deflector to force oil or water through the hole in the operating rod and out through the outer shaft. The hole in the rod will be filled with oil but only a few gallons must be drained away before it will be definitely known whether or not there is water in the hub. If water is found, it is necessary to let it drain until clear oil is discharged.

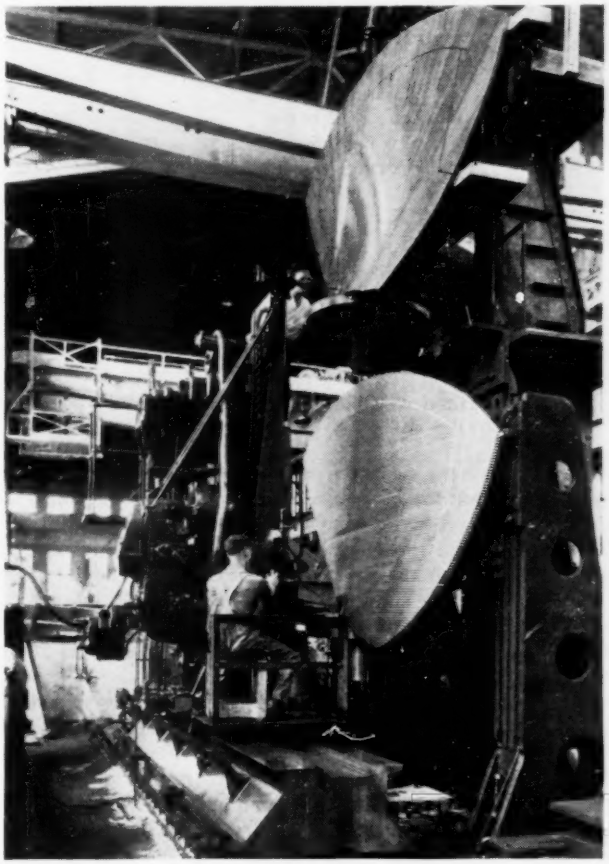

Fig. 12 Keller Profiling Machine
(Used for machine-finishing turbine blades. The top blade is a polished wooden model. The cutter on the steel blade below follows the path of the magnetic pointer above.)

For completely emptying the hub, a large drain valve is provided at the bottom of the reservoir in the lower guide bearing.

Auxiliaries

The turbine has several pieces of auxiliary equipment that are unique in the manner of their application. The Kaplan mecha-

nism inside the rubber hub must of course have lubrication. Both grease and oil have been used in the past for this purpose in Europe and in America, with oil now the usual medium, and a heavy oil is used at Bonneville. It is much more important to keep the water from leaking into the hub than to keep the oil from leaking out. The packing used around the blade shanks has worked almost to perfection in the tests, but future wear may permit a small amount of leakage. The hub is always below tail water and, therefore, when shut down, is subject to water pressure of from 3 to 50 ft. When in operation and developing power, the pressure underneath the buckets is decreased below the static pressure of the tail water and the pressure above

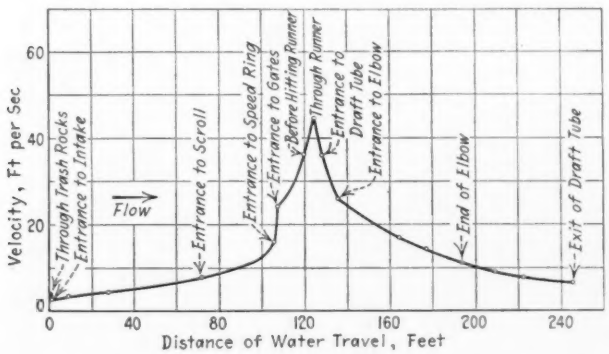

FIG. 13 VELOCITIES THROUGH 66,000 HP KAPLAN TURBINE
(For flow of 13,000 cfs at rated head and output.)

the buckets is increased by the partial closure of the blades. It is required to keep the oil pressure at a point sufficiently high to overcome the pressure above the blades when the turbine is operating and this pressure will, in fact, be sufficiently high to prevent leakage inward of water even at the maximum tail water elevation when the units are shut down. It is of interest to note that as the operating shaft for the blades moves down in the hub, oil is forced out of the hub into the pressure tank, described later, and will increase the pressure within the tank. The tank has been made of such size that the difference in air pressure in the tank between the extremes of operating-shaft travel is not of troublesome amount. The oil pressure within the hub at the level of the blade shanks, where the leakage may occur, is increased by the height of the oil column in the shaft and by centrifugal force when the unit is running. To overcome the outside pressure the oil inside the hub is kept continually under a higher pressure by means of a revolving pressure tank T, Fig. 8, surrounding the shaft and connected to the hollow space inside by the pipe L. Gage K shows the air pressure in the tank above the oil. To maintain the pressure in the tank at a predetermined desirable value, a pressure switch S operates a small compressor C, both of which are revolving and are supplied with current through collector rings R. A by-pass circuit also permits manual control of the compressor without shutting down the unit.

In case of loss of oil for any reason, as shown by the gage glasses KK, more oil can be added without shutting down the unit. The oil is poured into the funnel F, runs into a revolving oil basin OB, and a revolving oil pump P then pumps the oil into the pressure tank. The oil pump P is controlled manually by current supplied through collector rings RL.

Oil-level marks are provided on the gage glasses (KK) for both still and running conditions of the unit. If the oil level decreases, oil must be leaking out. If the oil level increases water must be leaking in and an investigation of the cause can be made by means of the testing devices described elsewhere. Prior to completion of the design of the turbine the chief engineer of the manufacturer made a trip to Europe to get the benefit of experience over there. The arrangement of auxiliaries was worked out between the manufacturer and engineers of the Bonneville project. In comparable European plants leakage is from ten to twelve gallons per month but in spite of their size the Bonneville units are not expected to leak one third as much.

The governor-pressure oil is much lighter than the runner-hub oil and the two must be kept separate. A triplicate system of piston rings is provided at the top of the blade-operating rod. Runner-hub oil that leaks past rings 1 will flow out of pipe 1A into chamber 1B and can be withdrawn. As the runner-hub pressure will never be over 20 psi, the leakage should be small. Governor-pressure oil that leaks past piston rings 2 will flow out pipe 2A into chamber 2B and be pumped up to the governor sump tank by the pump PX.

The remaining auxiliaries to the turbine are more or less conventional. Each unit has a motor-driven guide-bearing oil pump, a gear-driven companion oil pump, and two motor-driven sump pumps. The main guide bearing has two temperature

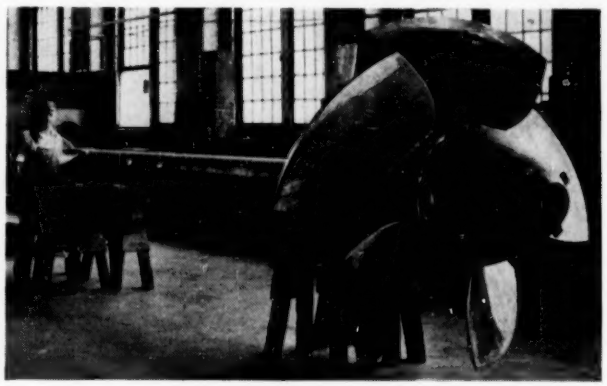

FIG. 14 KAPLAN RUNNER, 81 IN. DIAM
(For Bonneville station-service unit. Blades full open.)

indicators and two temperature relays for alarm or, if desired, for automatic shutdown.

Winter-Kennedy taps are provided in each scroll for use in making index tests of efficiency and for determining best gate-blade relations.

Provision is made for the admission of compressed air to the draft tube in event of sudden load rejection. A cam on the shifting ring opens a valve in the air line and admits air at 100 lb pressure. The valve is operated by a dashpot mechanism and in event of slow shutdown the valve gate will not open.

SETTING EMBEDDED PARTS

On account of the unusual size of the Bonneville turbines there were no parallel examples of setting from which to plan erection methods by direct experience. The speed ring is 36 ft 6 in. diam, 12 ft 9 in. high, and weighs 80 tons complete. It is made in five segmental sections. The throat ring has an outside diameter of 23 ft 4½ in., weighs 60 tons, and is made in halves. Although conservatively designed the loads are so heavy that deflections must be given careful consideration. Troubles have occurred in setting smaller units and it was earnestly desired that their repetition be avoided.

The detailed procedure of setting the embedded parts for one unit will now be described. The key numbers in parentheses refer to corresponding items in Fig. 15. Twenty rectangular concrete piers, shown as A in the figure, were poured in the original substructure within the confines of the lower supporting cone of the speed ring. Embedded in the piers at time of pour were verti-

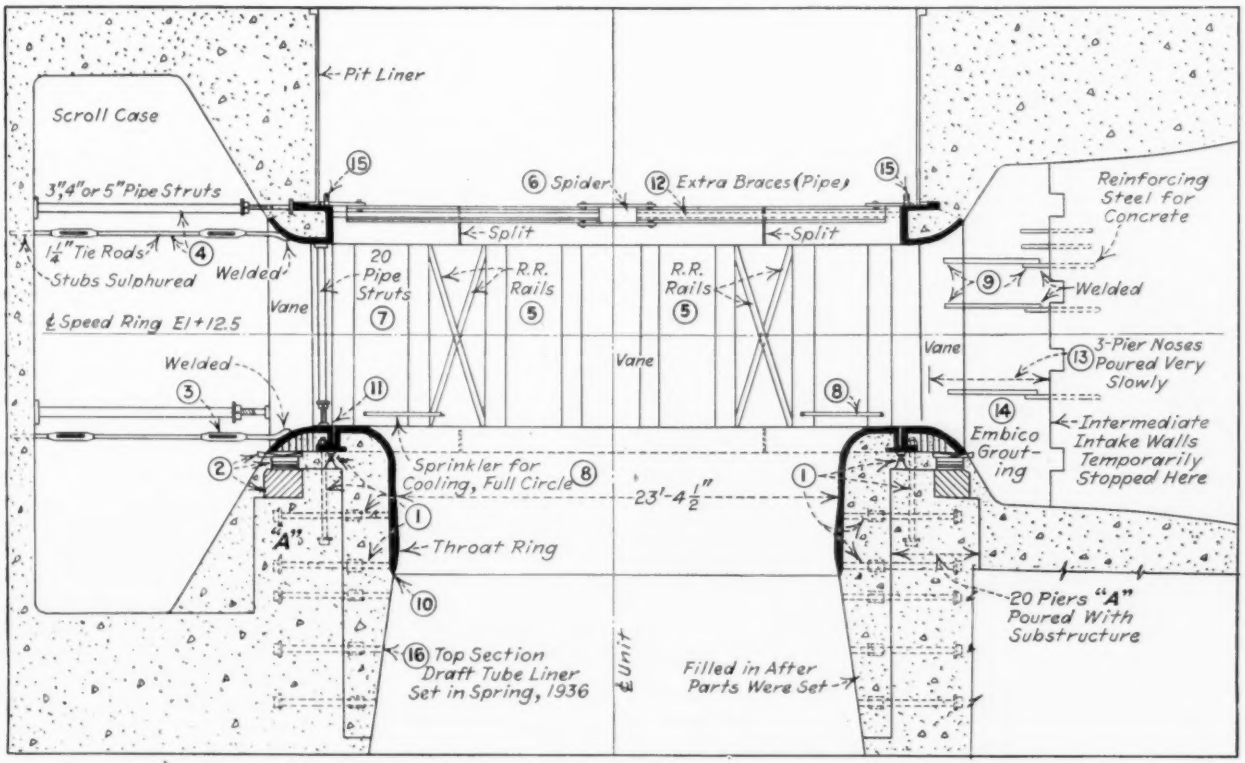

FIG. 15 SETTING EMBEDDED PARTS (EXPLANATORY DIAGRAM TO ILLUSTRATE TEXT)

cal anchor bolts (1), and horizontal jack bolts with sleeve nuts (1). Jacks (1) were set upon the top of the piers for supporting the speed ring. All of these features numbered (1) form the primary apparatus for supporting the speed ring and throat ring. To furnish additional support small concrete blocks (2) were poured on top of the piers, as shown by crosshatched area, *B*. Railroad rails (2) and wedges were used to support the ribs of the lower ring and tie rods and pipe struts (3) held it firmly in position. Similar pipe struts (4) and ties (4) were used at the top ring. To prevent racking, cross bracing of railroad rails (5), wedged and welded, was placed between the adjacent vanes of each of the five splits. A heavy steel spider (6) with eight arms, each an 8 × 8-in. H-beam, with adjusting jacks at the ends of the arms, further held the top ring of the speed ring in a truly round condition. Tie rods (9) were welded to projecting reinforcing bars and to the corresponding vanes of the speed ring, to prevent movement of the speed ring during pouring of concrete in the intake pier noses. As an added precaution, two extra pipe braces (12) were placed against the pier noses.

After the speed ring was set, lined, and leveled, the assembled throat ring was lowered by the crane, jacked into final position on top of inner ledge of lower ring of the speed ring, and then bolted firmly to the speed ring by bolts. The speed ring was again checked for line and level, adjusted as required, and when correct all wedges and railroad rails were spot-welded to prevent shifting.

Twenty vertical pipe struts (7), 4 in. or 5 in. in diam, with jack bolts, were installed between the upper and lower flanges of the speed ring. Two extra horizontal braces (12) at ends of pier noses were inserted to prevent pressure of concrete back of pier noses from locally distorting the speed-ring flanges.

Final adjustment of all braces and jacks was made and concrete poured up to and slightly above the bottom of the ribs and skirt of the bottom ring of the speed ring. A complete annular ring of sprinkler pipe (8) was placed above the throat ring and cooling water sprayed therefrom for some ten days after pouring. Later the throat ring was welded (10) to the draft-tube liner and the speed ring was welded (11) to the throat ring.

The ends of intake piers that join the speed ring were left unpoured until the speed ring was set (13). The amount of concrete was small and the height of pour was about 12 ft. Over six hours were spent in pouring these piers in order not to build up an appreciable hydrostatic head against the speed ring.

Finally, after an elapse of many days to permit shrinkage of the foundation cone, Embeco grout was poured under the speed ring to make a nonshrinking foundation. These precautions resulted in variations from zero tolerance or perfection, as follows:

	Unit 1	Unit 2
Maximum variation from round, on radius:		
Throat ring opposite runner	0.026 in.	0.027 in.
Top of speed ring	0.063 in.	0.076 in.
Maximum variations from level, range from low to high:		
Top of speed ring	0.016 in.	0.027 in.
Top of throat ring	0.018 in.	0.016 in.

These readings were taken after the superimposed foundation on top of the speed ring had been poured and cured.

Thermocouples were embedded in the cone supporting the speed ring of each unit, and readings were taken at regular intervals during the setting of the concrete, which was made with ordinary Portland cement. The couples were some two feet from the throat ring. The maximum temperature occurred on the fifth day following the pour and the indicated temperature rises varied among four couples in two cones from 50 to 57 F.

STATION-SERVICE UNIT

There is provided at Bonneville a station-service unit of 5000 hp that drives a 5000-kva generator. See Fig. 14. The service

turbine itself is homologous with the main turbine and the model, but has a plate-steel spiral scroll at the lower end of a 13-ft-diam penstock 78 ft long The draft tube is of the same general type as for the main units, but varies slightly in shape for structural reasons. The difference in specific speed between main units and service unit noted in Table 2 is due to rounding off the figures of the stated rating. For the present the blades are manually adjusted but automatically adjustable mechanism could later

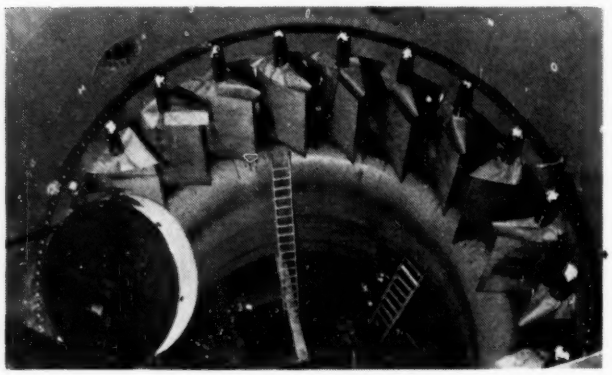

FIG. 16 TURBINE PIT FOR MAIN UNIT

be installed. The size of the service unit is larger than required for auxiliaries or even for all the load on the project including cranes, hoists, and residences, but it appeared economically advisable to build a unit as large as could be placed in one structural bay of the powerhouse. The service unit can be used to generate power for sale or can be left as stand-by for service, in which case the controls are arranged to start the unit automatically in case of failure of excitation supply for the main units. The blades of the service unit are given the usual hand-ground finish. Provision for maintaining oil pressure in the runner hub is similar to that in the main units, but is simpler in that no revolving compressors or pumps are provided. Instead it is necessary to shut down the unit for the required servicing. Provision for testing and withdrawing water from the runner hub is identical in principle with that for the large units.

GOVERNORS

The two turbines are controlled by the latest type Woodward twin-system cabinet-type governor. In one cabinet 23 ft long × 9 ft 6 in. wide on the main operating floor are located the two governor heads (one for each unit), two gate-control-valve assemblies, two blade-control-valve assemblies, motor-driven rotary-gear-type oil-pressure pumps, an oil sump with sufficient storage space for all of the oil of the system, and all of the control mechanism and devices. The pressure tanks for oil and air are located on the floor below. For each governing unit there is provided one 100-gpm oil pump and one 600-gpm pump and by means of an Eschelon control the smaller pump can be put into action first and take care of the minor regulating demand. The sump, the oil pressure tanks, and the piping can be sectionalized so that both units can be governed by a part of the equipment while other parts are isolated for inspection and servicing. The governors are equipped with the more or less standard apparatus for load limits, speed droop, emergency shutdown and alarms, remote control, remote indication, and automatic intermittent brake application. It is not within the province of this paper to describe the governors in detail, but two special features that affect turbine operation should be described.

At the higher heads both the designed physical capacity of the turbine and the rated electrical capacity of the generator can be greatly exceeded with large gate openings. To hold the output of the unit within safe limits there is provided a net-head gate limiter. Slide-wire transmitters bring headwater and tailwater indications to the control room, where through differential recording in a net-head recorder both are interpreted in terms of net head. Additional slide wires carry the net-head reading to the load limits on the governors, where the load limit is rendered ineffective if turned beyond the gate opening corresponding to the limiting power for the net head then effective. Slide wires and recorders were manufactured by the Leeds &Northrup Co.

The best relation between gate and blade varies with different heads. Careful analysis of Bonneville model data and experience with other plants led to the decision that four gate-blade cams for the entire range of heads from 30 to 69 ft would be sufficient. Cams were selected to be correct at heads of 61, 55, 50, and 45 ft. Based upon model tests, the employment of the 61-ft-head cam at 65-ft head lowers the point of best efficiency about 0.1 per cent, and the same cam lowers the best efficiency at 58-ft head about 0.15 per cent. The losses in best efficiency are about the same down to the 50-ft-head cam at 47.5 ft. The 45-ft-head cam shows a greater loss of best efficiency than this, increasing as the head lowers. However, at about 46 ft head full gate and blade are required to develop the full 66,000 hp and the turbine will go to full gate and blade on demand. At such head capacity and not efficiency is the deciding factor. The four cam curves are cut on the periphery of one cam wheel which is secured with centering pins and thumbscrews. With change of head the cam is manually rotated one-quarter turn. In normal operation change of cam position will occur only at intervals of weeks or months.

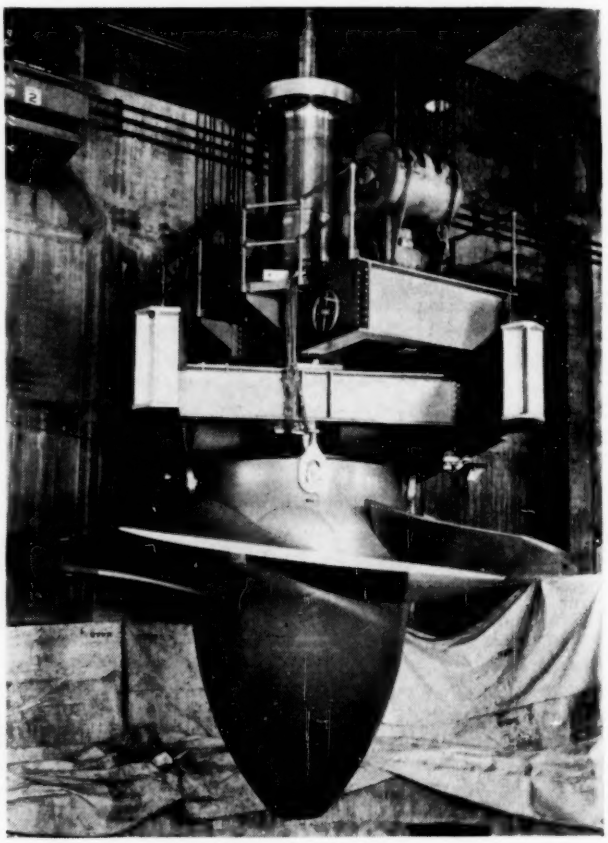

FIG. 17 MAIN TURBINE READY FOR PLACING

(Blades at 6 deg or closed. Upper frame with hand wheel is the lifting beam. The framed beams just above runner will support the turbine during erection and will then be removed. Total load 250 tons.)

Theory of Resonance in Pressure Conduits

By CHARLES JAEGER,[1] VILLARS SUR OLLON, SWITZERLAND

This paper represents one of the contributions to the Second Symposium on Water Hammer and deals with the analysis of critical conditions in pipe lines where initial surges are augmented by the characteristics of the conduit. The paper is the first treatment in English of this subject, and should prove a valuable contribution to the knowledge of water hammer.

HYDRAULIC engineers have always been interested in cases of rhythmic variations of pressure surges in conduits; surges whose periodic oscillations and resonance properties are of great importance.

All operations of total closure are transformed little by little into periodic oscillations, whose essential properties are known, thanks to the work of de Sparre and Camichel.[2] Foch has considered the case of oscillations in a conduit with an air chamber, and the author has studied the generalization of the problem for a network of conduits. One might imagine that at the present time we have sufficient knowledge of the mode of generation of these periodic oscillations and their main characteristics. On the contrary, we know very little of their determination.

The study of resonance cases has held alike the attention of Allievi, de Sparre, and Camichel, to whom we are indebted for some very fine experimental researches. Let us sum up what we know of the subject at the present time.

Allievi has analyzed, in note V of his "Theory of Water Hammer," the formation of the initial wave in a pipe of constant section, due to partial rhythmic movements of opening and closing, following each other without ceasing. His elegant proofs remain classic. Assuming that the openings η_i of the gate at odd periods are

$$\eta_1 = \eta_3 = \eta_5 = \text{etc.} \ldots\ldots = \text{constant}$$

and at even periods, are

$$\eta_0 = \eta_2 = \eta_4 = \text{etc.} \ldots\ldots = \text{constant}$$

he shows that the relative surges, even and odd, $\xi_i^2 = H_i/H_0$ approach, respectively, two limits, Z_1^2 and Z_2^2, such that

$$Z_1^2 + Z_2^2 - 2 = 0 \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

Let us note that Löwy had readily given a graphical method in order to follow the formation of any resonance in a pipe of constant section. The graphical process of Löwy has subsequently been used by other authors.

Among all the possible rhythmic movements, classed by Allievi, we will take just one case for a systematic study, one which has already solicited the attention of Camichel, and to which the author has devoted a paragraph in his "General Theory." This is the case where one of the series of relative surges, ξ_i^2, tends to the limit zero. It follows that

$$Z_1^2 = 0, \quad \text{and} \quad Z_2^2 = 2 \ldots\ldots\ldots\ldots [2]$$

The other series of values ξ_i^2 thus tends to the limit 2, and we have twice the static pressure at the bottom of the conduit. Camichel has shown that this case of resonance is not possible unless the static pressure $h_0 > av_0/g$, which is almost evident. The author, applying the graphical method devised by Allievi, had shown that the limit of positive pressures, without reaching the value 2, nevertheless has very high values, when the initial opening is not zero but small.

It is fitting to mention here the good theoretical researches of Camichel and de Sparre, and the numerous experiments and calculations made at the Laboratory of Toulouse by Camichel, and those of Eydoux on high-head installations. These tests are of the greatest interest.

Camichel has shown that when one considers a conduit with variable characteristics, e.g., with variable diameter, using the "method of abrupt pressure drops"—a method which consists in causing an abrupt opening of the gates at the bottom of the conduit, followed by a closure no less abrupt at the end of the period—one records a period for the conduit which is the sum of the individual periods of each sector of constant section. We will say, following Camichel, that this period is the theoretical period of oscillation of the conduit.

If, on the contrary, we consider such a movement as the periodic return of the maximum surge following a slow closure of the gate, we verify the existence of a period differing from the preceding—in general, shorter—called the "apparent period" of the conduit.

Camichel and his followers have shown that the odd harmonics of pressure conduits have a period which is an integral fraction (e.g., $1/\eta$) of the theoretical period of oscillation of the conduit, then (also) that the period of the fundamental of a conduit having variable characteristics—which fundamental may always be produced in a similar conduit—is on the contrary equal to the apparent period of oscillation.

Assuming these experimental data, it seems that the theory for the harmonics should be quite different from the theory for the resonance of the fundamental. The latter, in contrast, should probably be linked with the studies of periodic oscillations, whose period is equal to the apparent period. The author has given the complete theory of periodic oscillations in two earlier articles in *La Houille Blanche*. The field is thus ready for the general theoretical study of resonances. We shall begin by explaining the theory for resonance of harmonics.

1—RESONANCE OF HARMONICS IN A CONDUIT WITH MULTIPLE CHARACTERISTICS

General Theorem

Let us consider a complex system of conduits, such as is shown in Fig. 1. The gate is at O, and A is any point, not necessarily a point of discontinuity. However, the sector OA is supposed to have a constant section.

Let us actuate the gate with rhythmic alternating movements, whose period is supposed to synchronize with the period of OA. We distinguish between even epochs and odd epochs; e.g., for even epochs the gate is assumed closed, and for odd epochs it will be open.

Let us suppose that a movement of resonance should have been established, and should have given rise to a permanent régime. We will write the conditions at the lower end of the conduit and

---

[2] The articles published by the various authors mentioned in this paper are given in the Bibliography at the end of this paper.

Contributed by the Hydraulics Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., December 6–10, 1937.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

inquire for what conditions in the conduit itself the régime may exist.

At even epochs $2n-2$, $2n$, $2n+2$, ..., the gate mechanism being closed, the velocity at the gate is zero, and $v_{2n-2} = v_{2n} =$

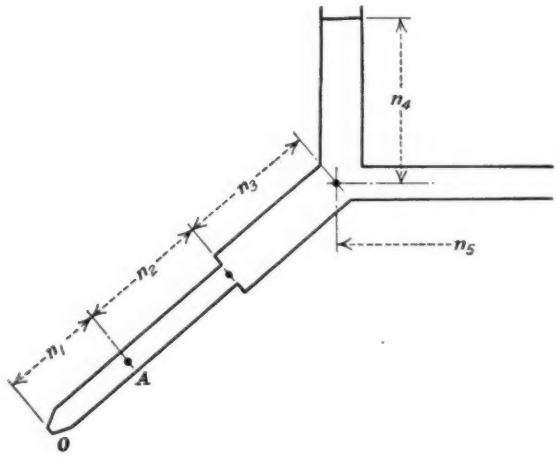

FIG. 1

$v_{2n+2} = 0$. If the permanent régime is really established, the pressure at the gate should always be the same, or

$$H_{2n-2} = H_{2n} = H_{2n+2} = \text{etc.} \quad \ldots\ldots [3]$$

At odd epochs, the gate is open. But when the régime of rhythmic oscillations is established, as experience shows, the velocity at the gate must be zero,[3] so long as one neglects the losses of head in friction, and the pressure at the same point must be equal to atmospheric.

Hence

$$v_{2n-3} = v_{2n-1} = v_{2n+1} = 0 \quad \ldots\ldots [4]$$

$$H_{2n-3} = H_{2n-1} = H_{2n+1} = 0 \quad \ldots\ldots [5]$$

Equations [4] and [5] are also connected by the Bernoulli theorem, which is considered as always valid in the theory of water hammer.

Such are the limiting conditions at the bottom of the conduit. The limiting conditions at the top will be given by the form of the conduit.

There are no other conditions. In particular, we cannot prescribe any form for the periodic curve of surge pressures at the gate. We know from the work of various authors that this curve will have sometimes a sinusoidal form, sometimes a rectangular outline (case of an automatic check valve—Camichel), or again a shape rounded at the minima and sharp-cornered at the maxima, when the conduit is provided with an air chamber (as considered by Foch).

We can write for the sector OA of the conduit

$$\left.\begin{aligned} H &= H_0 + F(t) + f(t) \\ v &= v_0 - (g/a)[F(t) - f(t)] \end{aligned}\right\} \quad \ldots\ldots [6]$$

The period of a complete oscillation in OA will be

$$\mu_1 = 2L_1/a_1 \quad \ldots\ldots [7]$$

which we take as unit time, putting $n_1 = 1$.

[3] "Étude théorique et experimentale des coups de bélier," by C. Camichel, D. Eydoux, and M. Gariel, Dunod, Paris, 1919, p. 98.

Using Equations [4] and [5], there result

$$H_{2n+1} - H_0 = F_{2n+1} + f_{2n+1} = F_{2n-1} + f_{2n-1} = \text{etc.} = -H_0$$
$$v_{2n+1} - v_0 = -g/a[f_{2n+1} - f_{2n+1}] = -(g/a)[F_{2n-1} - f_{2n-1}]$$
$$= -v_0$$

From these we obtain

$$\left.\begin{aligned} F_{2n+1} &= (av_0/2g) - {}^1/_2H_0 \\ f_{2n+1} &= -(av_0/2g) - {}^1/_2H_0 \end{aligned}\right\} \quad \ldots\ldots [8]$$

We will now use the fundamental relation which was defined at the beginning of the author's "Théorie Générale," and write

$$f_n = -\alpha_{n-1} F_{n-1} \quad \ldots\ldots [9]$$

where α_{n-1} is an unknown function, which depends, as shown in the author's "Théorie Générale," on the geometric form of the conduit and on the movements of the gate.

We obtain from our definition $F_{2n} = -f_{2n+1}/\alpha_{2n}$, and $f_{2n} = -\alpha_{2n-1} F_{2n-1}$.

Hence we write, at even epochs

$$H_{2n} = H_0 + F_{2n} + f_{2n}$$
$$= H_0 - (f_{2n+1}/\alpha_{2n}) - (\alpha_{2n-1}F_{2n-1})$$
$$= H_0 + \frac{1}{\alpha_{2n}}[(av_0/2g) + {}^1/_2H_0] - \alpha_{2n-1}[(av_0/2g) - ({}^1/_2H_0)]$$

or, on reduction

$$H_{2n} = H_0 + (av_0/2g)[(1/\alpha_{2n}) - (\alpha_{2n-1})] + {}^1/_2H_0[(1/\alpha_{2n}) + (\alpha_{2n-1})] \quad \ldots\ldots [10]$$

We may determine also

$$v_{2n} = v_0 - {}^1/_2v_0[(1/\alpha_{2n}) + (\alpha_{2n-1})] - (gH_0/2a)[(1/\alpha_{2n}) - (\alpha_{2n-1})] \quad \ldots\ldots [11]$$

As may be verified, we have for odd epochs

$$H_{2n+1} = H_0 + F_{2n+1} - \alpha_{2n}F_{2n} = H_0 + (av_0/2g) - {}^1/_2H_0 - (av_0/2g) - {}^1/_2H_0 \equiv 0$$

Consider again Equations [10] and [11]. The limiting conditions require, at even epochs, since the gate is supposed closed, that $v_{2n} \equiv 0$, whatever v_0 and H_0 may be. A necessary result of this is that

$(1/\alpha_{2n}) - (\alpha_{2n-1}) = 0$, i.e., $1/\alpha_{2n} = \alpha_{2n-1}$, and also that $(1/\alpha_{2n}) + (\alpha_{2n-1}) = 2$, whence

$$\alpha_{2n} = \alpha_{2n-1} = 1 \quad \ldots\ldots [12]$$

a relation which is true for both even and odd epochs. We deduce, for the same epochs, that $f_n = -F_{n-1}$, and

$$\left.\begin{aligned} F_{2n} &= -f_{2n-1} = (av_0/2g) + {}^1/_2H_0 \\ f_{2n} &= -F_{2n-1} = -(av_0/2g) + {}^1/_2H_0 \end{aligned}\right\} \quad \ldots\ldots [13]$$

and finally

$$H_{2n-2} = H_{2n} = H_{2n+2} = \text{etc.} \ldots\ldots = 2H_0 \quad \ldots\ldots [14]$$

Therefore, we can state that the functions F and f are represented by periodic curves, with a period of $\theta_1 = 4L_1/a_1 = 2\mu_1$, and that the head H is also periodic, having the same period. The values $H = 0$ and $H = 2H_0$ are necessarily the minimum and maximum of this latter function. Therefore, we verify that the phenomenon of the doubling of the pressure necessarily occurs, and that there is no other solution.

It has been shown in the author's "Théorie Générale" that, denoting by n_2, n_3, n_4, etc., the corresponding times of oscillation in the various sectors of the conduit, one can always express α_n in the form

$$\alpha_n F_n = a_0 + a_1 F_{n-n_2} + a_2 F_{n-2n_2} + a_3 F_{n-3n_2} + a_{10} F_{n-n_3} + a_{11} F_{n-n_2-n_3} + a_{12} F_{n-n_2-2n_3} + a_{20} F_{n-n_4} + a_{21} F_{n-n_2-n_4} + \ldots\ldots\ldots\ldots\ldots [15]$$

where $a_0, a_1, a_2, \ldots\ldots a_{10}, a_{11}, a_{12}, \ldots\ldots a_{20}, \ldots\ldots$ are coefficients depending only on the geometric form of the conduit.

Let us assume that $n_2, n_3, n_4, \ldots\ldots$ are integral multiples of n_1, and therefore integers, since $n_1 = 1$. Collect the coefficients into even and odd groups. Let A be the sum of the even coefficients, and B the sum of the odd coefficients. We know that, in every case, $A + B = 1$, as proved in the author's "Théorie Générale." Hence we may write

$$\alpha_n = A(F_{n-2}/F_n) + B(F_{n-1}/F_n) = A + B(F_{n-1}/F_n)$$

In order that $\alpha = 1$ at even and odd epochs, it is necessary and sufficient that $B = 0$ (or again that there be no function of odd order), which implies that the conduit must satisfy certain conditions of geometrical type which we will specify later with numerical examples. Recalling that A and B are, for each conduit, constants not affected by movements of the gate, and that F_n is a periodic function of period θ, such that at each instant $F_n = F_{n-2}$, we conclude (making the single reservation that the numbers $n_2, n_3, n_4, \ldots$ are integers), that for $\alpha = 1$ at even and odd epochs, it will also be unity at intermediate moments, and that we have $\alpha \equiv 1$ and $f_n \equiv -F_{n-1}$ at every instant.

This mathematical condition has a physical significance; $\alpha \equiv 1$ signifies that there is at every instant a *total reflection* of the ascending waves, and that there exists at the point A a loop of the oscillating periodic system.

But a loop is essentially stable. This would not have been so if $n_2, n_3, \ldots$ had not been integral multiples of n_1. Therefore, we must suppose that in this case it would be either impossible to have oscillations in the conduit other than fundamental—always possible, the author believes—or that the oscillations follow laws analogous to those of the fundamental, laws which we will study later.

We have seen that the limiting conditions are such that $v = 0$ at even and odd epochs. Let us study two points on the periodic curve F whose abscissas differ by $\mu_1 = {}^1/_2\,\theta$. Then

$$F_n = (av_0/2g) + \gamma_1 \text{ and } F_{n-n_1} = (av_0/2g) - \gamma_2$$

But certain curves F_1 produced by rhythmic movements, e.g., when F is a sinusoid, present characteristics of symmetry such that $\gamma_1 \equiv \gamma_2$, even if the instant n does not correspond to an instant of complete rhythm. In this case

$$v = v_0 - (g/a)[(av_0/2g) + \gamma_1 - (av_0/2g) - \gamma_1] \equiv 0$$

Hence, if the curve F shows a symmetry definable by $\gamma_1 = \gamma_2$, we have $v \equiv 0$, regardless of the instant. We know that Camichel has actually obtained discharges almost zero in the course of his experiments with the turning cock.

Statement of the Theorem. To develop over a uniform sector OA of any conduit an oscillation of permanent régime as a result of rhythmic movements of the gate, it is necessary that there be at A a stable loop. Mathematically, this means the assumption at A of the condition $\alpha \equiv 1$.

In this case, the pressure at O varies between $H_{2n-1} = 0$ and $H_{2n} = 2H_0$. This is the phenomenon of the doubling of the pressure observed by all experimenters, and whose reality had been proved by de Sparre and Allievi, for the case of resonance of the fundamental in conduits of uniform characteristics.

For these conditions to be fulfilled, and an oscillation of resonance to be possible, the conduit must satisfy certain geometrical conditions. We will illustrate the general theorem by studying a few particular cases.

Particular Examples

(*1*) *Resonance of the Fundamental in a Conduit With Uniform Characteristics, Discharging at A From an Infinitely Large Reservoir.* Referring to Fig. 2, let OA be a conduit with uniform characteristics. If the equilibrium chamber at A is very large, we have,

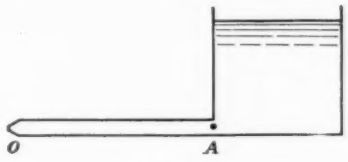

Fig. 2

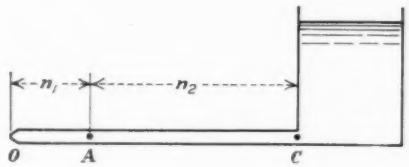

Fig. 3

according to the author's "Théorie Générale," $\alpha \equiv 1$. The fundamental resonance in such a conduit is thus a particular solution of our general theorem. There is double the pressure at O, as several authors have shown.

(*2*) *Resonance of the Odd Harmonics in a Conduit of Uniform Characteristics, Discharging at C From a Very Large Reservoir.* Referring to Fig. 3, let OA be an element of the conduit of uniform characteristics. The half period for OA is $n_1 = 1$; the half-period of AC is n_2. Since there is no discontinuity at A, we know from the author's "Théorie Générale" that the series for α reduces to a single coefficient $a_1 = 1$, with $a_2 = a_3 =$ etc. $= 0$. The series thus reduces to $\alpha_n = (F_{n-n_2})/F_n$.

In all cases where n_2 is an even multiple of n_1, F_{n-n_2} will be equal to F_n, equally at even and at odd epochs. For this case $\alpha = 1$ at every instant and there is resonance. It is seen at once that the condition of n_2 being an even multiple of n_1 gives resonance for all odd harmonics. This fact has been known since the time of the experiments conducted at Toulouse by Camichel, Eydoux, and Gariel.

It is seen at once that no other solution is suitable, since if n_2 is not an even multiple of n_1, $F_{n-n_2} \neq F_n$ and $\alpha \neq 1$. In particular, the even harmonics do not give a solution, a fact which has also been verified experimentally.

(*3*) *Generalization of the Preceding Case for Conduits Having Multiple Characteristics.* If we develop the function α_n, we see that there is at least one general solution of the problem for the case of conduits having multiple characteristics. This is when n_2, n_3, n_4, etc., are all even multiples of n_1. This is true, whatever the nature and the number of the discontinuities.

If we put α_n in the form

$$\alpha_n = A[(F_{N-2N2})/F_n] + B(F_{n-n_2})/F_n$$

it is readily seen that whenever the coefficient B of the odd terms is zero there will be a solution.

The method of procedure is thus completely outlined; in each particular case α_n is expanded in a series and the laws which govern the even and the odd coefficients are studied.

(*a*) *Case of a Single Discontinuity at A.* In the case of a single discontinuity, illustrated by Fig. 4, the series of Equation [15] becomes, as is shown in the author's "Théorie Générale,"

$$\alpha_n = r_1 + s_1 s_2 (F_{n-n_2}/F_n) + s_1 s_2 r_2 (F_{n-2n_2}/F_n) \ldots\ldots [16]$$

in which we assume that n_2 is a multiple of n_1. The symbols r and s denote the coefficients of reflection and of transmission, defined by de Sparre, Löwy, and the author, and whose properties are perfectly known. One particular property is that $s + r = 1$. For these conditions we find after carrying out all the calculations that $A = 0$ and $B = 1$. The conclusion is drawn anew. There is resonance if n_2 is an even multiple of n_1. Only odd harmonics are therefore possible for a conduit having a discontinuity at the point A.

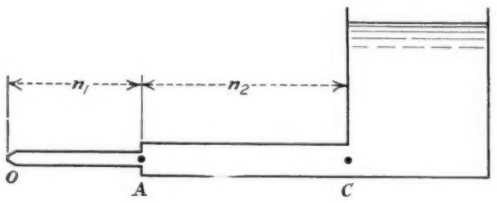

FIG. 4

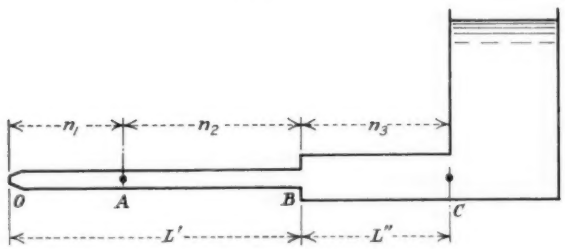

FIG. 5

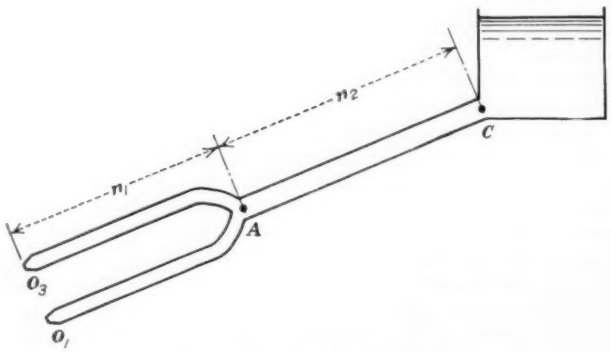

FIG. 6

(*b*) *Conduit With a Single Discontinuity at the Point B.* Referring to Fig. 5, a conduit of this type was used at the Toulouse Laboratory by Camichel. Let us study it from the theoretical point of view. At Toulouse the relation $L'/a' = 2L''/a''$ was true. Consider the point A, such that $n_1 = n_2 = n_3$, and let us ask whether it is possible in this conduit to obtain the third harmonic, as was actually observed by Camichel at Toulouse.

We find on page 107 of the author's "Théorie Générale" formula [90], giving the value of α_n for the case of two successive discontinuities, which it is suitable to use here. Let s_1, s_1', r_1, and r_1' be the coefficients of transmission and of reflection. Since there is no variation of section at point A, we have $s_1 = s_1' = 1$, and $r_1 = 0$. On developing formula [90] it is easily found that the coefficient $B = 0$. Hence $\alpha \equiv 1$, and the third harmonic can be established for the conduit under consideration.

Can the fifth harmonic also be obtained, as Camichel was able to observe? Evidently yes, since this is a particular case of the general theorem given herein by the author, where n_2, n_3, ... are even multiples of n_1.

Therefore, it appears that there is close agreement between the various observations made by Camichel and the theorems proved by the author.

We have been able to analyze by similar methods the case of conduits closed at their upper end.

(*4*) *Case of Synchronized Parallel (Twin) Conduits.* Referring to Fig. 6, the author has shown in his "Théorie Générale," as well as in an article in the *Revue Générale de l'Hydraulique*, that the function α_n, for the case of parallel conduits, geometrically identical, whose gates are operated in synchronism, is given by the expression

$$\alpha_n = r_1 - s_1 + 2s_1s_2(F_{n-n_2}/F_n) + 2s_1s_2r_2(F_{n-2n_2}/F_n) + 2s_1s_2r_2^2(F_{n-3n_2}/F_n) + \ldots\ldots\ldots [17]$$

Let O_1 and O_3 be the two synchronized gates, A the point where the principal conduit is subdivided upstream, n_1 and n_2 the half periods for O_1A (O_3A) and AC, respectively. Assume that n_2 is an integral multiple of n_1. We can write

$$F_{1-2kn1} = F_{1-(2k+2)n1} = F_{1-(2k+4)n1} = \text{etc.} = F_1$$

and

$$F_{1-(2k+1)n1} = F_{1-(2k+3)n1} = \text{etc.}\ldots\ldots\ldots = F_{1-n1}$$

These are the conditions at the lower end of the conduit O_1A if there is to be resonance. Since the conduits are synchronized, these conditions are also true for O_3A. It is easily shown that this results in the series of Equation [17] giving $\alpha_n = 1$, if n_2 is an even multiple of n_1. The odd harmonics are possible in parallel conduits under the conditions given above.

2—RESONANCE OF THE FUNDAMENTAL IN CONDUITS HAVING MULTIPLE CHARACTERISTICS

The author has shown[4] that when the function of integration $F(t)$ possesses certain properties of symmetry, properties which appear to have been realized in the course of experiments by Camichel, we have constantly at the gate

$$v_i = 0$$

But this same condition at the limits is realized after the time of complete closure in the course of the periodic phenomena. On the other hand we know that we may easily realize resonance phenomena which give at the base of the conduit pressure surges of sinusoidal form, in every respect analogous to periodic curves. Therefore, there is no cause for surprise that in these cases the resonance of the fundamental in a conduit of variable characteristics should have the same period, named "apparent," as the periodic phenomena. The identity of the conditions at the limits involves, as can be easily shown, the identity of the analytic formulas.

Camichel and Foch have shown by the experimental method that this property is, moreover, general, and that the fundamental is always in resonance with the apparent period of the conduit. Foch, in particular, in the course of resonance tests, obtained surges at the gate which did not obey at all the law of symmetry given above for the function $F(t)$, yet whose period was equal to the apparent period. The latter should therefore be a characteristic of the conduit, independent of the manner of development of the fundamental or of any other initial condition, as it arises from the final formulas themselves, which contain only the quantities L, a, and the section S of the conduit.

We may in fact ask ourselves with some reason if, with respect to the resonance of harmonics, a sector of a conduit of variable section can vibrate the same if a discontinuity occurs between the

[4] See articles by the author in *La Houille Blanche*, May-June and July-August, 1936.

node and the loop just as the fundamental vibrates in a conduit having discontinuities. Our theory of harmonics could then be generalized.

From the theoretical point of view, since periodic sinusoidal movements are identical with resonances of the same type, it will suffice to recall very briefly the theory we have developed at length, both in our "Notes à l'Académie des Sciences" of Paris and in the review *La Houille Blanche* for the case of two conduits of different sections.

The method of attack which the author followed was inspired by a work by Foch on conduits furnished with air chambers. We write down the surge at the gate in the form

$$H - H_0 = A \sin mt \quad \ldots\ldots\ldots\ldots\ldots\ldots [18]$$

where $m = 2\pi/\theta$, and θ is the apparent period of the conduit, to be determined.

In a similar manner we have at the discontinuity (wye)

$$H_1 - H_{10} = F[t - (L_1/a_1)] + F[t + (L_1/a_1)] = G(t) - G[t - (2L_2/a_2)]$$

where L_1, L_2, and a_1, a_2 refer to the two branches 1 and 2 of the conduit. We have further

$$G(t) = -\tfrac{1}{2}B \cos(mt + \phi) \quad \ldots\ldots\ldots\ldots\ldots [19]$$

Here B and ϕ are two constants easily determined.

Now we write the equations for the velocities at the point of discontinuity in the various branches, assuming sections S_1 and S_2. Application of the equation of conservation of discharge leads to the following relations:

For a variation of section

$$\tan mL_1/a_1 = \mu' \cot (mL_2/a_2) \quad \ldots\ldots\ldots\ldots [20]$$

where $\mu' = a_1S_2/a_2S_1$.

For a wye, with branch 1 discharging into 2 and 3

$$\tan mL_1/a_1 = \mu' \cot (mL_2/a_2) + \mu'' \cot (mL_3/a_3) \quad \ldots [21]$$

where $\mu'' = a_1S_3/a_2S_1$.

From Equations [20] and [21] is found the value of the apparent period θ for the conduit. With θ known, the problem of the distribution of the surges will be completely determined for the case of sinusoidal movements.

3—DISTRIBUTION OF THE PRESSURES ALONG A CONDUIT HAVING MULTIPLE CHARACTERISTICS, IN CONNECTION WITH THE RESONANCE OF THE FUNDAMENTAL OR OF THE HARMONICS

Camichel, investigating experimentally the distribution of the fundamental along a conduit of constant section, noticed that the maximum pressure at the upper third of the conduit also reached the value $2H_0$. The author has always thought that this law did not have the generality given it by Camichel, otherwise few inclined conduits could have resisted without injury the resonance of the fundamental. In examples taken from practice the author has found, quite on the contrary, distributions differing greatly from those indicated by Camichel.

The author gives for this fact the following general explanation: In all that has been said so far (with the exception of the case where we have expressly assumed for simplicity that the law of surges was sinusoidal), we have not had to make any assumption regarding the form of the curve $F(t)$, except in connection with the values of $F(t)$ at even and odd epochs. The problem thus retains a great degree of freedom.

It is easily understood that as the pressure at the gate, as well as the pressure at any other point, is always a function of $F(t)$ and of $f(t)$, at small intervals of time apart, there will be a close relationship between the curve of surges at the gate and the distribution of surges along the conduit. (This is an essential property of the integral function $F(t)$, which is used in the graphical method.)

But Camichel carried out his experiments on resonances with a turning cock which caused very abrupt opening and shutting of the discharge (hydraulic check valve); therefore, there is nothing astonishing in the fact that his recording apparatus, placed at the bottom of the conduit, should register a "notched curve" corresponding to a dangerous distribution of surges along the conduit. Some calculated examples will confirm this point of view.

Resonance of the Fundamental

(*1*) *Resonance of the Fundamental in a Conduit of Uniform Characteristic; Curve Having the "Notched Form."* Let us assume that

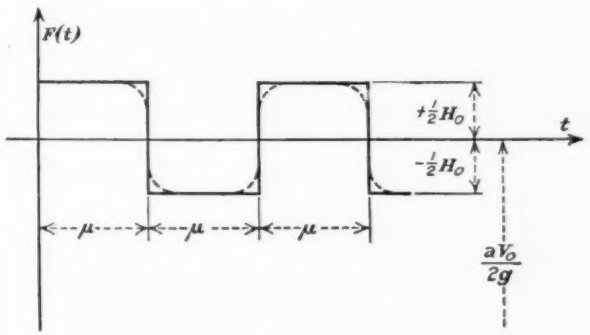

Fig. 7

the function $F(t)$ is a "notched" function, represented by Fig. 7; also, that it satisfies the conditions

$$F_{2n} = (av_0/2g) + \tfrac{1}{2} H_0$$

$$F_{2n-1} = (av_0/2g) - \tfrac{1}{2}H_0$$

It is seen immediately that

$$H - H_0 = F(t) - F[t - (2L/a)]$$

is also a notched curve. A very simple graphical construction will give the curve of surges as a function of time at a point of any abscissa whatever: $x = L/3, L/2, 2L/3$, etc. We verify in fact that the doubling of the pressure ($2H_0$) occurs as far as the immediate neighborhood of the top of the conduit (as Camichel observed in his conduit at Toulouse), because very little of the corners of the notches is rounded.

It is evident that resonances causing the formation of notched curves are very dangerous for inclined conduits. Luckily the majority of curves observed for pressure conduits are of the sinusoidal type and less dangerous, as we will see.

(*2*) *Resonance of the Fundamental in a Conduit of Uniform Characteristic; Curve Having Sinusoidal Form.* If we assume that

$$F(t) = \tfrac{1}{2}A \sin(2\pi t/\theta) + (av_0/2g) \quad \ldots\ldots\ldots [22]$$

we have clearly at any point of abscissa x

$$H_x - H_0 = A \sin(\pi/2)[1 - (x/L)] \cos\left(\frac{2\pi}{\theta} t - \frac{\pi}{2}\right) \quad [23]$$

In front of the gate we find

$$H - H_0 = A \cos\left(\frac{2\pi}{\theta} t - \frac{\pi}{2}\right) = A \sin \frac{2\pi}{\theta} t \quad \ldots\ldots [24]$$

The movement is exactly determined, at any instant and at any

point. One can always calculate the velocity corresponding to a given H_x by using

$$v = v_0 - \frac{g}{a}\left[F\left(t - \frac{x}{a}\right) + F\left(t - \frac{2L - x}{a}\right)\right]$$

It is found, on substituting for $F(t)$ its sinusoidal form, that when the pressures are maximum, they are so for the full length of the conduit and the velocities are zero. This property is general. Indeed, because of the differential equation

$$\frac{\partial v}{\partial x} = \frac{g}{a^2}\frac{\partial H}{\partial t}$$

when $\frac{\partial H}{\partial t} = 0$ (H minimum or maximum), $\frac{\partial v}{\partial x} = 0$, and the velocity is the same at this instant at every point in the conduit. It cannot be other than zero, since it is zero at the loops.

(3) *The Fundamental in Conduits Having Multiple Characteristics.* We will study only the case where the curve is of sinusoidal form. It will be sufficient here to take again the problem of periodic movements, assuming that the maximum pressure rise at the bottom of the conduit is

$$\left.\begin{aligned} H_{max} - H_0 &= A \sin(mt) = H_0 \\ H_{max} &= 2H_0 \end{aligned}\right\} \quad \ldots\ldots [25]$$

The surge at the point of discontinuity, as has been shown by the author in his article in *La Houille Blanche*, will be

$$H_1 - H_{10} = H_0 \cos(mL_1/a_1) \quad \ldots\ldots [26]$$

where $m = \frac{2\pi}{\theta}$. Knowing the extreme surges at two points in the conduit, it is not difficult to calculate them for any other point.

(4) *Case of Parallel Conduits, and the Case of the Equilibrium Chamber.* These two cases have been treated in detail by the author in his article in *La Houille Blanche.* All the developments are valid, with the condition we recall that there is double the pressure at the bottom of the conduit.

We remember that the pressure rise at the base of an equilibrium chamber is given by

$$H_1 - H_{10} = H_0 \sin\frac{\pi}{2}\frac{\epsilon}{1+\epsilon} \quad \ldots\ldots [27]$$

where ϵ is given by the formula

$$\epsilon = \frac{2/\pi}{\frac{\mu'}{(\pi/2)(L_2a_1/L_1a_2)} + \mu'' \cot\frac{\pi}{2}\frac{L_3a_1}{L_1a_3}} \quad \ldots\ldots [28]$$

where $\mu' = S_2a_1/S_1a_2$; $\mu'' = S_3a_1/S_1a_3$. This last formula, however, is no longer valid when the cotangent appearing in the denominator tends to ∞. For such a case we assume

$$(\pi/2)(L_3a_1/L_1a_3) = \pi(1 - \epsilon') \quad \ldots\ldots [29]$$

where ϵ' is assumed small; ϵ is then the root of an equation of the second degree

$$-\frac{2L_1a_2}{L_2a_1}\mu'\epsilon^2 + \left[2 + \mu'' - \frac{2L_1a_2}{L_2a_1}\mu'\epsilon'\right]\epsilon + 2\epsilon' = 0 \quad [30]$$

Case of Odd Harmonics in a Conduit—Distribution of Pressures Along the Conduit

Whatever be the form of the function $F(t)$, we have always

$$H_x - H_{x0} = F\left(t - \frac{x}{a}\right) - F[t - (2L/a) + (x/a)]$$

Let us assume that the function $F(t)$ has a period $4L/pa$, p being an integer, and that we have

$$F(t) = F[t - (4L/pa)], \text{ and } F(t) = -F[t - (2L/pa)] + (av_0/g)$$

(If the conduit is not uniform, we will assume that it is possible to substitute for any segment the expression $4L_i/p'a_i = 4L/pa$.)

The case $p = 1$ corresponds to the fundamental, already studied. To supplement this we shall consider only the odd values of p which give us the odd harmonics of the conduit.

At the point whose abscissa is $x_1 = L/p$, we have

$$H_{x1} - H_{x10} = F[t - (L/pa)] - F\{t - (L/pa) - [(2p-2)L/pa]\} \quad \ldots\ldots [31]$$

This quantity is identically zero for $p = 3, 5, 7, \ldots\ldots$ Thus, there is always a loop at the point with abscissa $x_1 = L/p$, if p is odd.

Let us study the point with abscissa $x_2 = 2L/p$. We have

$$H_{x2} - H_{x20} = F[t - (2L/pa)] - F[t - (2L/a) + (2L/pa)] \quad [32]$$

If in front of the gate we have

$$H - H_0 = \delta$$

and it may be shown that at the point with abscissa $x_2 = 2L/p$ we will have at the same instant

$$H_{x2} - H_{x20} = -\delta$$

If the pressure at the gate oscillates between H_0 and $-H_0$, it will oscillate at the point with abscissa x_2 between $-H_0$ and H_0 (a fact already known, ever since Camichel's studies, for the third harmonic).

The velocity is always given for a point at abscissa x by

$$v_x = -(g/a)[F\{t - (x/a)\} + F\{t + (x/a) - (2L/a)\}]$$

It can be shown without difficulty that at the point having abscissa x_2 the velocity is constantly zero. There is a node at these points. The analysis may be continued for the points whose abscissas are $x_3 = 3L/pa$, $x_4 = 4L/pa$, etc. In particular, at the point with abscissa x_4 the pressure is always identical and in phase with that prevailing at the right of the gate.

The Function $F(t)$ Is of Sinusoidal Form. The proof given in the preceding paragraph is quite general, and assumes solely that the function $F(t)$ is periodic. Let us suppose in addition that it is sinusoidal, which will often be true in practice, or a satisfactory approximation. It may be shown that the pressure and the velocity at any point are given by

$$\left.\begin{aligned} H_x - H_0 &= A \sin\frac{p\pi}{2}\left(1 - \frac{x}{L}\right)\cos p\left(\frac{2\pi}{\theta}t - \frac{\pi}{2}\right) \\ v_x &= -(g/a)A \cos\frac{p\pi}{2}\left(1 - \frac{x}{L}\right)\sin p\left(\frac{2\pi}{\theta}t - \frac{\pi}{2}\right) \end{aligned}\right\} \quad [33]$$

where $A = H_0$ in the case of movements of resonance. There is a maximum every time that

$$p\left(\frac{2\pi}{\theta}t - \frac{\pi}{2}\right) = k\pi$$

We have under these conditions

$$H_x - H_0 = \pm H_0 \sin p\frac{\pi}{2}\left(1 - \frac{x}{L}\right)$$

a relation which tells us how the maxima are distributed along the line.

The case $p = 1$ corresponds to the resonance of the fundamental in a conduit with uniform characteristics. The curve of distribution of pressures along the conduit is sinusoidal, and no more linear, as in the case of a linear movement of the gate.

It may be shown that there is a loop of the system

for $p = 3$, at the points $x = L$ and $x = L/3$;

for $p = 5$, at the points $x = L$, $x = \frac{3}{5}L$, and $x = \frac{1}{5}L$;

for $p = 7$, at the points $x = L$, $x = 5L/7$, $x = 3L/7$, and $x = L/7$

and so on.

At intermediate points there are "knots," nodes with $v = 0$. We do not lay stress on these calculations which are elementary.

4—CONCLUSIONS

Resonances and periodic movements obey simple laws which are not without analogies between themselves. The author's study which appeared in *La Houille Blanche*, together with this present paper, forms a complete whole.

The principal results arrived at in this paper are found to be verified in a remarkable manner by the experiments of Camichel, Eydoux, and Gariel, de Sparre, Boucher, Neeser, and Foch. These experiments have served as constant guides in the author's studies.

The author's aim has not been entirely theoretical. He has been induced to undertake his investigations by his obligation to calculate for certain practical cases the boundary curve of the surge pressures along the conduit.

With the exception of the case of resonance of the fundamental automatic check-valve type, realized by Camichel, and the resonance of the harmonics of higher order, which are moreover difficult to obtain, the cases of resonance in a conduit of uniform slope, although advisable to avoid, nevertheless cannot in general cause its rupture. Certain special cases, such as conduits with projecting points, equilibrium chambers, and branches can, on the contrary, be subject to dangerous surges. The theory enables us to study these cases.

It will be observed that the author's theory of periodic movements and of resonances, applied to the study of equilibrium chambers, furnishes us with a theory complementary to that developed in the author's "Théorie Générale." It is sometimes useful to know the values obtained by the second method. Further, it may be mentioned that the author's theory has several points of contact with the theory of sound waves developed by Constantinescu.

The author concludes this study by stating the hope that experimental research in this domain will supplement to completion the work of Camichel, Eydoux, Gariel, and Neeser.

Typical Analysis of Water Hammer in a Pumping Plant of the Colorado River Aqueduct

By R. M. PEABODY,[1] LOS ANGELES, CALIF.

This paper presents a method of analysis of surge conditions in a pumping system by arithmetical integration and is an extension of the work done by Professor Knapp at the California Institute of Technology. The analysis utilizes the step-by-step method, includes the complete characteristics of the pumping equipment, and determines their effect upon surge conditions. The valve characteristics are also included, and this is the first presentation of such a method of analysis.

THE COLORADO River Aqueduct carries water from the Colorado River to the cities of The Metropolitan Water District of Southern California. Diversion from the river is from the reservoir formed by Parker Dam, about one hundred and fifty miles below Boulder Dam. From the point of diversion to the terminal reservoir at Cajalco, near Riverside, California, the length of the main aqueduct is 242 miles. To cross the intervening high levels in the desert area five pumping plants are required with a total lift of 1617 feet. The lifts in the various plants range from 144 to 440 feet. The aqueduct is constructed for a carrying capacity of 1600 second feet. Ultimately there will be nine 200 second foot motor-driven pumps in each plant. The present installation is three such pumps per plant. Power is obtained from Boulder Dam over a long transmission line. The delivery lines are from 800 to 2000 ft in length and are steel pipes 10 ft in diameter. Three pumps are connected to each pipe through 6-ft diameter pipes which converge a short distance from the plant. The design of these delivery lines required a careful study of the operating conditions, particularly with reference to water hammer.

The pumping system discussed in this paper consists essentially of a short inlet pipe leading from an open reservoir to the pump intake, a motor-driven centrifugal pump, a shutoff valve at the discharge of the pump, and a delivery pipe to an open reservoir at the top of the pump lift. Under normal pumping conditions the pressure throughout this system is steady. Starting a pump, shutting down a pump, failure of the power supply, or failure of certain parts of the apparatus to function properly will initiate a series of transient pressure variations in the system and give rise to more or less severe water hammer. It is the purpose of this paper to give a practical method for determining the pressure variations in such a system.

Operation of the System

A typical pumping system is shown in Fig. 1. It represents, with some simplifications, one of the pumping plants of the Colorado River Aqueduct now under construction by The Metropolitan Water District of Southern California.

In normal operation, the pump is started, brought up to speed, and the motor synchronized with the pump discharge valve closed except for a small by-pass. If the delivery pipe is empty, it is filled through the by-pass. With the pump at normal speed, and the delivery pipe filled, the pressure on the pump side of the valve is practically the shutoff pressure developed by the pump plus the inlet head, and the pressure on the delivery side of the valve is the static head from the upper reservoir. The discharge valve is then slowly opened and the pump discharges against the net head from inlet reservoir to discharge reservoir, plus the head due to friction losses in the system. In taking a pump out of service, the discharge valve is first closed slowly, the power supply to the motor is then disconnected, and the pump and motor decelerate to rest. In normal starting and stopping operations the discharge valve is moved slowly, the velocity in the delivery pipe changes slowly, and the resulting pressure variations are small.

Conditions Producing Water Hammer

There are a number of possible operating conditions which will produce rapid variation of velocity in the delivery pipe, causing fluctuations in pressure or water hammer. The effect of every such condition must be investigated, and the system made safe against failure resulting from accidental faults that are possible, even though only remotely probable.

Certain emergency and accidental conditions which may occur are the following:

1 Power failure due to electrical fault. This condition is certain to occur more or less frequently. The motor circuit breaker is tripped open and the pump discharge valve automatically starts to close.

2 Delay in tripping motor breaker. If a motor is not immediately disconnected from a short circuit, it will act for a

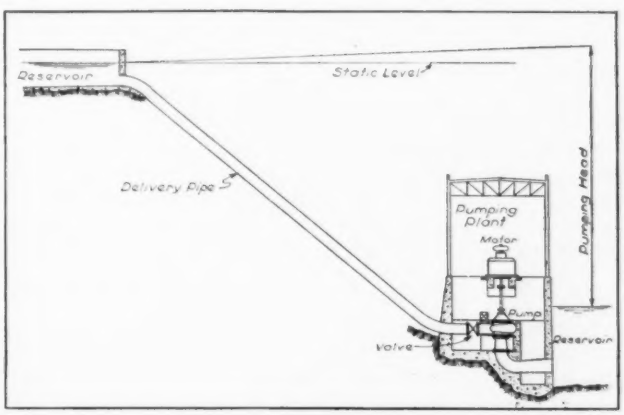

Fig. 1 Typical Pumping System

[1] Senior Engineer, Metropolitan Water District of Southern Calif.

Contributed by the Hydraulics Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., Dec. 6–10, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until March 10, 1989, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

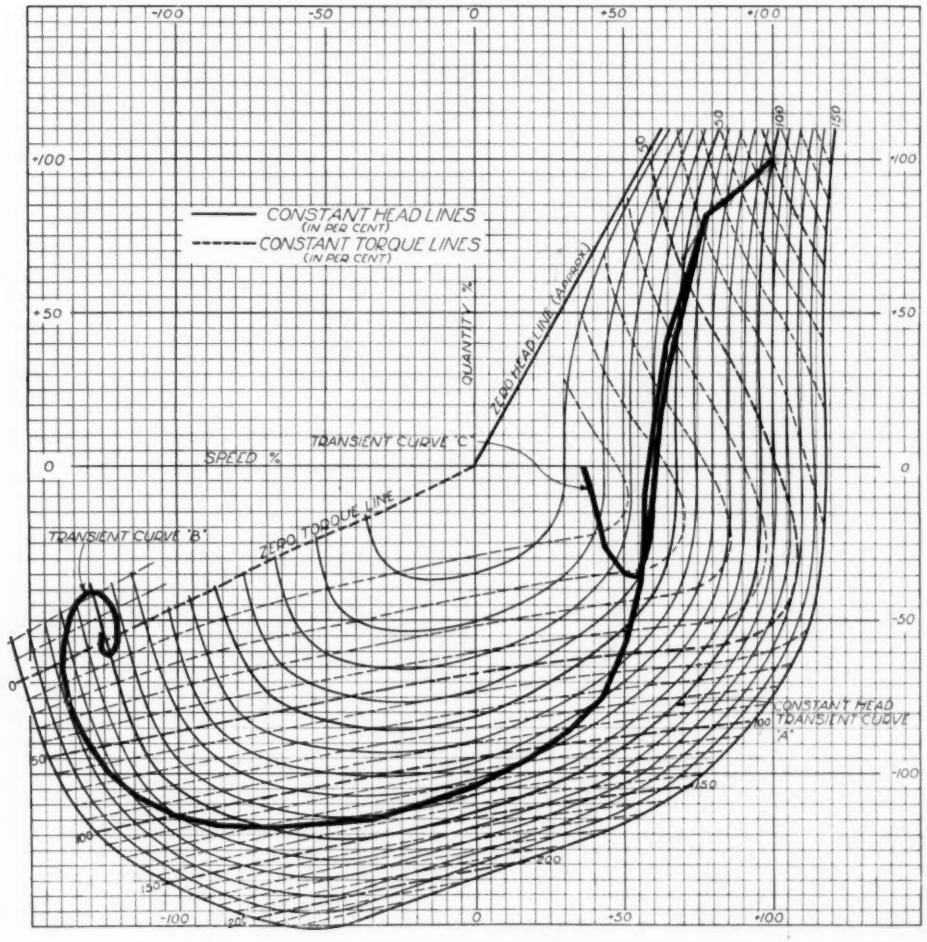

FIG. 2 PUMP CHARACTERISTICS DIAGRAM

short time as a generator, giving additional retarding torque and resulting in more rapid deceleration than normal.

3 Failure of valve to operate when power is shut off. In this case, the flow in the pipe line will reverse; the pump and motor will reverse and attain runaway speed in the reverse direction.

4 Delay in operation of valve. If the operation of the valve, in case of power failure, is delayed until full reverse flow has been established, and the valve then closes rapidly, severe water hammer will result.

5 Failure of shaft coupling. The flywheel effect of the motor is removed, the speed will drop rapidly, and the pump will reverse rotation.

6 Seal-ring seizure. The speed will drop rapidly as in 6, but the pump will not reverse.

All of these conditions, and others, must be investigated. In this paper, however, only two cases will be considered; first, power failure with the valve failing to operate; and second, power failure with the valve automatically closing at a predetermined rate.

POWER FAILURE WITH THE VALVE REMAINING FULLY OPEN

When the power supply is suddenly cut off, the only force driving the pump is the kinetic energy of the rotating parts. If the flywheel effect were large, compared to the pumping energy required, the pump would decelerate slowly. The resulting rate of change of pipe-line velocity would be gradual and the pressure variation would be small. However, the kinetic energy is generally small compared to the pumping energy and the drop in speed is rapid.

The effect of the speed drop in the first small time interval after the power is switched off is to reduce the pump discharge and to reduce the velocity in the pipe line. As a result of the sudden drop in pipe-line velocity a wave front of reduced pressure travels up the pipe and is reflected from the open end as a wave front of increased pressure. When this increased pressure reaches the pump, it adds to the pumping head then existing and further reduces the pump discharge. Soon the speed of the pump is reduced to the point where no water can be delivered against the existing head and reverse flow commences, although the pump is still rotating in the pumping direction. The speed now drops still more rapidly, passes through zero, and the pump, acting as a turbine under no load except the inertia of the rotating parts, eventually reaches a runaway speed in the reverse direction.

In analyzing quantitatively such a transient condition, it is necessary to know the head and torque of the pump for all of the variations of speed and discharge that occur during the transient. This information is completely given by a chart such as is shown in Fig. 2. The use of this chart in the study of transient phenomena has been described in a paper[2] by Prof. Robert T. Knapp. This paper gives the methods of obtaining the test data used in the construction of the chart and the method

[2] "Complete Characteristics of Centrifugal Pumps and Their Use in the Prediction of Transient Behavior," by R. T. Knapp, Trans. A.S.M.E., vol. 59, 1937, pp. 683–689.

of plotting the results. The chart gives the pump characteristics for the steady-state conditions corresponding to coordinates of speed and flow. Dr. Knapp's paper supplies experimental verification of the assumption that the instantaneous flow conditions at any point on a path of transient behavior are identical with the flow conditions for the corresponding steady state of operation. The complete characteristics diagram as given in Dr. Knapp's paper shows the pump characteristics throughout the entire field of possible pump operation. For most problems in the study of water hammer, the entire diagram is not needed and consequently in Fig. 2 the entire second quadrant, the first quadrant above the zero-head line, and most of the third quadrant above the zero-torque line are omitted. Also, it has been found more convenient to express the characteristics in percentages of the pump characteristics (flow, speed, head, and torque) at normal rating. The diagram of Fig. 2 is based on actual tests of a scale model of one of the pumps for the Colorado River Aqueduct.

Three transient paths are shown on the diagram. That marked A follows the rated-head line and is for a constant-head transient such as would occur when the power is shut off from a pump without any discharge valve, pumping directly into a large reservoir without an intervening pipe line. The speed-time relation during such a transient can be calculated from the inertia-torque relation of the pumping unit. The transient path marked B is that resulting when the power is shut off from a pump, without a valve, pumping into a reservoir through a fairly long pipe line. Transient path C is for the same condition as B, but with a valve at the pump discharge which closes at such a rate that the pump is prevented from reversing, but holds the maximum pressure rise within reasonable limits.

In determining paths B and C, it is necessary to calculate the variation with time of the head on the pump and pipe line, the discharge, the speed, and the torque. This can be done by taking small intervals of time and, by a method of trial and error, determining changes in the characteristics during the time interval such that the conditions at the beginning and end of the interval will satisfy the pipe-line characteristic equation, the pump characteristic diagram, and the inertia-speed-torque relations of the rotating parts. For transient C, it is also necessary to take into account the pressure drop through the valve. A brief development follows for the pipe-line equation and the inertia-speed-torque relation.

Notation

z = time from start of transient condition, sec
L = length of pump discharge pipe, ft
A = area of pump discharge pipe, sq ft
a = velocity of pressure wave, fps
v = velocity of flow in pipe line or through valve, fps
H = head in ft. H is the head at the lower end of the pipe line at any time, and, if the valve is fully open, or there is no valve in the system, it is equal to the head developed by the pump
H_p = pumping head. With no valve, $H = H_p$
Q = pump discharge, cfs
N = pump speed, rpm
M = pump torque corresponding to a given speed and discharge
H_v = pressure drop across partly open valve, ft
ΔH = pressure rise or drop above or below H, ft
Δv = change in velocity, fps
h = $\Delta H/H_0$
h_p = H_p/H_0
q = Q/Q_0
n = N/N_0
m = M/M_0
h_v = H_v/H_0
R = magnitude of resultant reflected wave arriving at the valve or pump at any time during a transient condition
c = coefficient of pressure drop across the valve

$$H_v = cv^2/2g$$

K = pipe-line constant, $= av_0/2gH_0$
g = acceleration of gravity
ω = angular velocity $= 2\pi N/60$
WR^2 = flywheel effect of rotating parts
I = moment of inertia of rotating parts. $I = WR^2/g$
Subscript $_0$ denotes a value for steady pumping conditions, or just prior to the start of a transient
Subscript z denotes a value at a time z after the start of a transient

The Pipe Line

The pressure variation in the pipe line is developed from the fundamental equation of change of pressure

$$\Delta H = a\,\Delta v/g \quad [1]$$

or, the change in pressure is equal to the change in velocity multiplied by the velocity of the pressure wave divided by the acceleration of gravity. The pressure change is modified by partial and complete reflections of the pressure wave from changes in section of the pipe line, any dead ends in the pipe system, and from the open end at the upper reservoir.

If subscript $_0$ indicates the start of the transient condition and subscripts $_1$, $_2$, $_3$, ..., small successive time intervals after the start of the transient, the following equations hold:

$$\Delta H_1 - \Delta H_0 = (a/g)(v_1 - v_0) + 2R_1 \quad [2]$$

$$\Delta H_2 - \Delta H_1 = (a/g)(v_2 - v_1) + 2R_2 \quad [3]$$

$$\Delta H_3 - \Delta H_2 = (a/g)(v_3 - v_2) + 2R_3 \quad [4]$$

$$\Delta H_z - \Delta H_{z-1} = (a/g)(v_z - v_{z-1}) + 2R_z \quad [5]$$

Adding, and noting that $\Delta H_0 = 0$

$$\Delta H_z = (a/g)(v_z - v_0) + 2(R_1 + R_2 + R_3 + R_z) \quad [6]$$

In the example being considered, the pipe line is assumed uniform, without any dead ends, and the only reflection is the complete reflection from the open reservoir of a wave front leaving the pump at time z, which reaches the pump again in time $z + (2L/a)$ as a wave front of equal magnitude and opposite sign. If the time intervals are equal to $2L/a$, then $R_z = -\Delta H_{z-1}$, and the equation becomes

$$\Delta H_z = (a/g)(v_z - v_0) - 2(\Delta H_1 + \Delta H_2 + \Delta H_3 \ldots + \Delta H_{z-1}) \quad [7]$$

Dividing by H_0 and noting that $v = Q/A$

$$\frac{\Delta H_z}{H_0} = \frac{a}{gH_0}\left(\frac{Q_z}{A} - \frac{Q_0}{A}\right) - 2\left(\frac{\Delta H_1}{H_0} + \frac{\Delta H_2}{H_0} + \frac{\Delta H_3}{H_0} \ldots + \frac{\Delta H_{z-1}}{H_0}\right) \quad [8]$$

and if $h = \Delta H/H_0$ and $q = Q/Q_0$

$$h_z = (aQ_0/gA_0H)(q_z - 1) - 2(h_1 + h_2 + h_3 \ldots + h_{z-1}) \quad [9]$$

or

$$h_z = 2K(q_z - 1) - 2\Sigma h \quad [10]$$

q_z is taken as positive for flow in the pumping direction and negative for reverse flow.

[a] Change from 1/4 intervals to 1/2 intervals.

Data used in Tables 1 and 2

N_0 = 400 rpm
H_0 = 310 ft
Q_0 = 215 cfs
v_0 = 8.21 fps
hp = 8402
L = 2188 ft

a = 2856 fps
$2L/a$ = 1.533 sec
M_0 = 110,318 lb-ft
WR^2 = 465,100 lb-ft²
Δt = 0.383 sec (1/4 interval)
Δt = 0.766 sec (1/2 interval)
K = 1.175

The development just given, except as to notation, follows the one published by R. S. Quick.[3] Friction loss in the pipe line is neglected since it affects the results only slightly, unless it amounts to say, 10 per cent or more of the head.

Inertia Equation

$$M = \frac{WR^2}{g}\frac{d\omega}{dt} \quad [11]$$

or, torque is equal to the moment of inertia of the rotating system multiplied by the angular acceleration.

Let Δt be a small time interval and subscripts 1 and 2 denote values at the beginning and end of the interval.

Then approximately

$$\frac{M_1 + M_2}{2} = \frac{WR^2}{g}\left(\frac{\omega_1 - \omega_2}{\Delta t}\right) = \frac{2\pi WR^2}{60g}\left(\frac{N_1 - N_2}{\Delta t}\right)$$

or

$$N_1 - N_2 = \frac{153.6}{WR^2}(M_1 + M_2)\,\Delta t$$

Let

$$n = N/N_0 \text{ and } m = M/M_0$$

$$n_1 - n_2 = \frac{153.6 M_0}{WR^2 N_0}(m_1 + m_2)\,\Delta t \quad [12]$$

Thus, on a simple pumping system without a valve, for the analysis by successive short time intervals of a transient condition caused by removing the driving power from the pump, the following conditions must be met at the beginning and end of each time interval:

$$h_s = 2K(q_s - 1) - 2\Sigma h \quad [10]$$

$$h_{ps} = F_1(q_s, n_s) \quad [13]$$

$$M_s = F_2(q_s, n_s) \quad [14]$$

$$n_1 - n_2 = \frac{153.6 M_0}{WR^2 N_0}(m_1 + m_2)\,\Delta t \quad [12]$$

Functions [13] and [14] are given by the pump characteristic diagram. The time interval Δt should be made equal to or an even division of the time interval $2L/a$.

Table 1 shows a summary of a part of the calculations for the transient path B of Fig. 2. Fig. 3 is plotted from the data of Table 1 and shows the time history of head, flow, and speed when the pump is suddenly shut down without any valve in the system. It is to be noted from Fig. 3 that reversal of flow takes place considerably in advance of reversal of rotation. With a larger flywheel effect, and other conditions the same, the time between reversals of flow and speed would be larger and the head variation less. In a system with a small flywheel effect and a high value of pipe-line constant K, the speed and flow reverse quickly and, if the pipe line is of considerable length, the head variation is great.

Effect of the Valve

When a valve adjacent to the pump discharge is closed during a transient, the head on the pump at any instant is equal to the head on the pipe-line side of the valve plus or minus the pressure drop across the valve

$$H_p = H \pm H_v \quad [15]$$

[3] "Comparison and Limitations of Various Water-Hammer Theories," by R. S. Quick, *Mechanical Engineering*, vol. 49, May, 1927, pp. 524–530.

The plus sign is used for flow in the pumping direction, and the minus sign for reverse flow.

The head loss in the valve is a function of the position of the closing element of the valve (disk, plug, needle, or flap) and the velocity through the net area of valve opening.

$$H_v = cv^2/2g \quad [16]$$

The coefficient c varies with the valve opening, and for the various types of valves that may be used, little information about it is available.

The valves to be installed with the pumps on the Colorado River Aqueduct are of the rotating-conical-plug type, consisting essentially of a valve body or housing and a conical plug arranged to be rotated within the housing by means of an external oil-pressure-operated hydraulic cylinder. The water passage through the valve plug is circular in cross section and is tapered

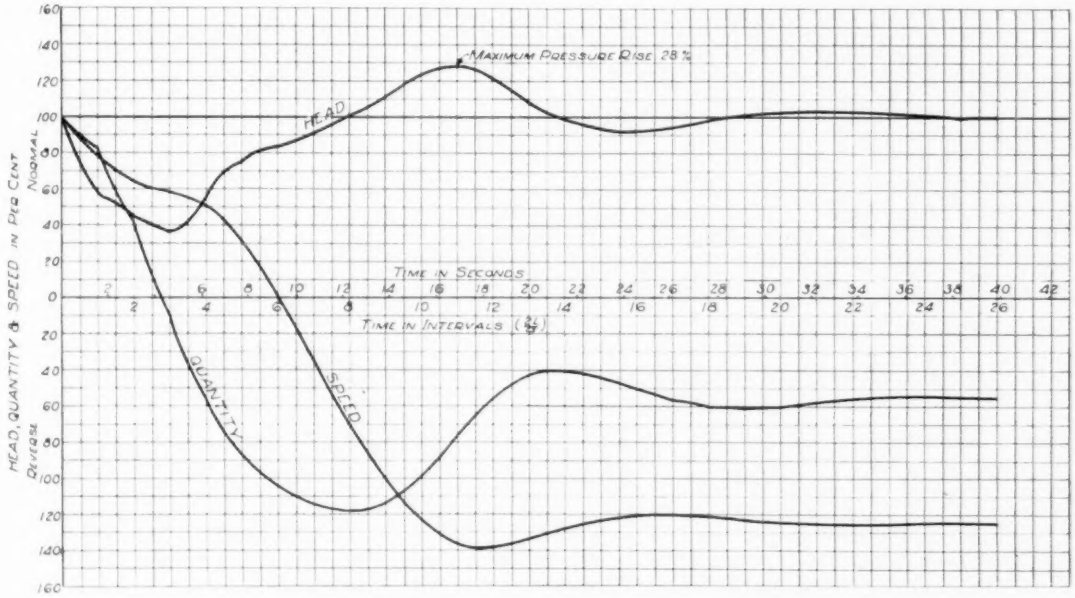

FIG. 3 TIME HISTORY OF TRANSIENT CURVE *B* OF FIG. 2
(Pump shutdown without valve operation.)

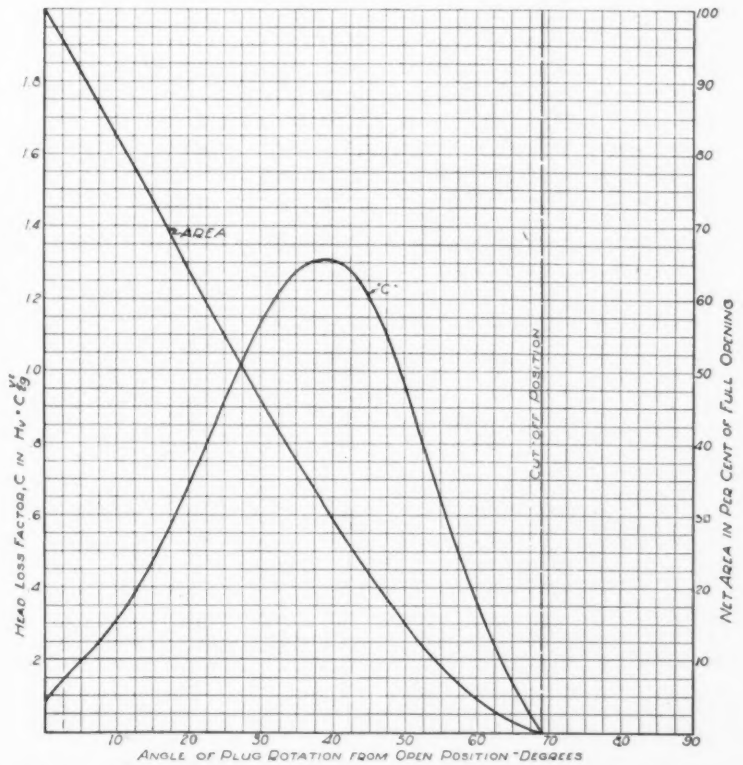

FIG. 4 TYPICAL HEAD-LOSS FACTOR *c* AND NET AREA OF A ROTARY-PLUG VALVE

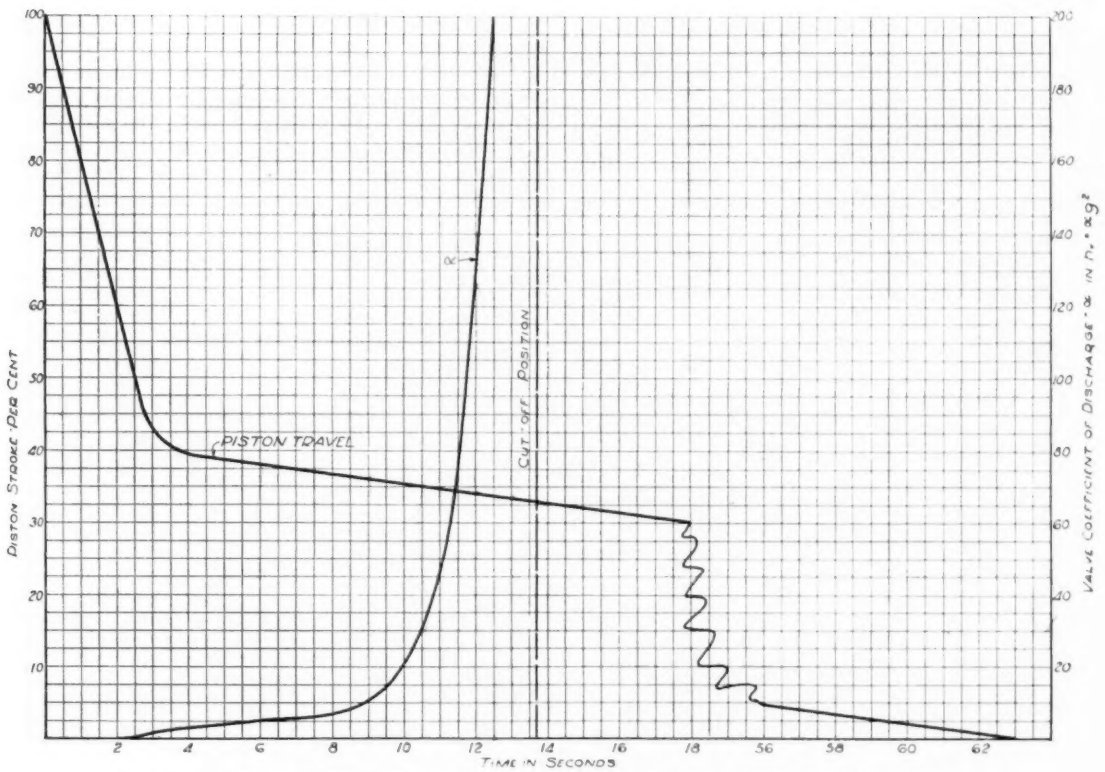

FIG. 5 VARIATION WITH TIME OF PISTON STROKE AND VALVE DISCHARGE COEFFICIENT α

so that when the valve is fully open, the water passage forms part of a smooth gradual increase in diameter from the pump discharge flange to the delivery pipe. The operating control of the hydraulic cylinder is arranged to rotate the plug slowly for the normal operations of starting up the pump or taking it out of service. In case of power failure or other emergency condition which removes the driving power from the pump, a supplementary control is brought into action automatically which rotates the plug rapidly until a considerable throttling effect is developed, after which the rate of rotation of the plug is retarded and the reverse flow through the pump is shut off gradually to reduce the pressure rise in the pipe line. The mechanism for controlling the emergency closing is so arranged that the point in the stroke where the rate changes from rapid to slow can be varied, and the rate of closure before and after this point can also be varied. Once set, the adjustments are locked and cannot readily be changed.

For predetermining the timing of the closing stroke to give minimum pressure rise and prevent, if possible, the reverse rotation of the pump and motor, the throttling characteristic of the valve must be known for all positions of the plug. Experiments have been conducted on valve models both by the

(Pump shutdown with discharge valve closing)

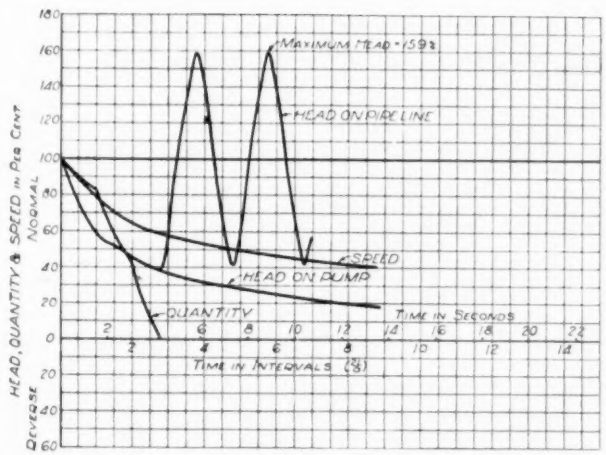

FIG. 7 TIME HISTORY OF TRANSIENT IF VALVE IS CLOSED INSTANTLY ON REVERSAL OF FLOW

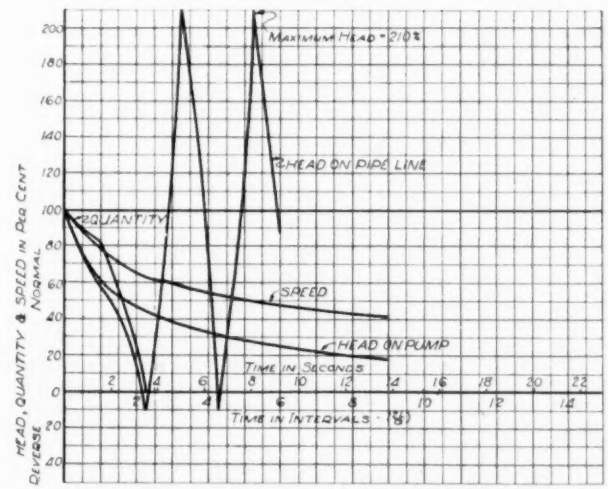

FIG. 8 TIME HISTORY OF TRANSIENT IF VALVE IS CLOSED RAPIDLY FOR ITS FULL STROKE

Metropolitan Water District at the hydraulic machinery laboratory at the California Institute of Technology, and by the valve manufacturers in their own laboratories. Tests have also been made on a scale model of the valve and pump assembled together to determine how the throttling effect of the combination is related to the characteristics of the pump and valve as determined separately.

The variation of the coefficient c in formula [16] for a typical model valve is shown in Fig. 4.

The model-valve experiments show that the head loss can be expressed by a formula of the form

$$H_v = \alpha' Q^2 \quad [17]$$

where α' is constant for each position of the valve plug.

To use this formula in the study of transients, it is more convenient to express the head loss as a ratio to the initial steady pumping head, $h_v = H_v/H_0$ and $q = Q/Q_0$ so that

$$h_v = \alpha' q^2 Q_0^2/H_0$$

or

$$h_v = \alpha q^2$$

where

$$\alpha = \alpha' Q_0^2/H_0 \quad [18]$$

The angular position of the valve plug is a function of the stroke of the piston of the operating cylinder, which for a predetermined program of closing rates is a function of the time from the start of the transient. Fig. 5 shows the variation with time of piston stroke and α as used in the illustrative example given herein.

To include the effect of the pump discharge valve in the study of transient conditions during pump shutdown, the throttling effect of the valve must be considered as affecting the head on the pump.

The head on the pump is given by

$$h_{p_2} = 1 + h_s \pm \alpha q_s^2 \quad [19]$$

The change in the different variables during each small time interval must be adjusted to satisfy Equation [19] as well as Equations [10], [13], [14], and [12]. A portion of the tabulation for calculating transient curve *C* of Fig. 2 is given in Table 2. Fig. 6 is plotted from the values given in Table 2, and shows the variation with time of pipe-line head, pumping head, flow, and speed. Note that for this condition the speed does not reverse, since the valve is closed before the reverse flow can overcome the inertia of the rotating parts.

To illustrate the effect of different valve-closure programs on the pumping system, Fig. 7 has been plotted to show the conditions resulting if the valve could be made to close instantaneously at the instant the flow in the system reverses. Such a condition is only hypothetically possible, but is approximated with some types of check valve.

Fig. 8 shows the condition when the valve starts to close at the same rapid rate as for Fig. 6, but instead of slowing down toward the end of the stroke, continues to close at the same rapid rate.

Conclusion

The behavior of a pumping system during a transient is the result of interaction between the pump, the pipe line, the check or shutoff valve, and, in many cases, also a relief valve, air chamber, or surge suppressor. If the characteristics of each of these elements are known, the conditions during the transient can be quite closely predicted. The formulas for the pipe line, even including branch pipes, changes of section, and dead ends are well supported by experimental verification, as brought out in the previous symposium on water hammer.[4] Little has been published on the reverse-flow characteristics of pumps. It appears quite probable that characteristic diagrams for pumps of a given specific speed will be found similar. However, information on complete pump characteristics is generally available for only a limited range of specific speeds. Reliable data on the loss of head in valves as a function of the valve opening are almost completely lacking.

Analysis by the methods herein outlined involves a great deal of laborious calculation, but approximate simple formulas that are generally applicable are totally lacking.

Much time and labor can be saved and a clearer picture shown of the pressure and discharge by using the graphic method of water-hammer analysis[5] instead of Equation [10] for the pipe line head variation. The pump diagram, the valve characteristic, and the inertia equation must be coordinated with the water hammer diagram. The necessity for step-by-step and trial-and-error calculations is not entirely eliminated, but the work is greatly simplified.

For important installations, the various transients possible of occurrence must all be analyzed and the system constructed to be safe for the most severe conditions reasonably probable. The cases herein used as illustrations represent approximately the condition at one of the pumping plants on the Colorado River Aqueduct. For the purposes of this paper, the effects of compound and branching delivery pipes, the inlet pipes, and other conditions peculiar to those plants have been omitted, and the examples do not accurately represent actual conditions at any of the plants.

The investigations on which this paper is based were made in connection with the pumping plants of the Colorado River Aqueduct of The Metropolitan Water District of Southern California. F. E. Weymouth is general manager and chief engineer of the Metropolitan Water District. The design and construction of the pumping plants are under the direction of J. M. Gaylord, chief electrical engineer.

Condenser-Tube Life as Affected by Design and Mechanical Features of Operation

By A. J. GERMAN,[1] WATERBURY, CONN.

Condenser-tube corrosion is found to occur as a result of many factors which, generally, are of a chemical, electrochemical, and mechanical nature. It is beyond the scope of this paper to cover the field completely; therefore, the paper is limited to those problems associated with mechanical factors affecting condenser-tube life in land and marine condensers operating on the seaboard. In such units, mechanical features of design and operation have proved to be of great importance with associated problems commonly requiring the attention of mechanical engineers rather than chemical or metallurgical engineers before a final solution is achieved.

The details of this discussion indicate a general method of approach to a solution of the problem of inlet-end tube failures, by which local occurrence the type of trouble can usually be recognized.

It should not be overlooked that many tube troubles can be minimized, if not eliminated, by a change in tube alloy (frequently without greater expense) when the mechanical alterations required are too costly or impractical. The author dismisses the choice of material, tube quality, method of production, and details of installation, all of which are of major importance in many cases, and confines his remarks to a consideration of the effect on tubes of turbulence in the circulating water resulting from design or deterioration. He gives also a brief discussion of the possible effects of high temperature on tubes while the unit is off the line.

General Considerations

IT IS known from experience that air in the circulating-water system is detrimental. Tubes carrying an unbroken column of water will last longer than if that column were intermittent. Many theories covering this question are available, but with the admission that air in circulating water is damaging, we need not consider the theoretical aspects.

Figs. 1 and 2 illustrating a ship's propeller indicate the damaging effects of air on metal parts. Relatively rapid corrosion occurs on the vacuum side on the trailing half of the blade, while the working (pressure) side is not appreciably affected. Experience has shown the necessity for streamlining the cap over the shaft nut, as shown in Fig. 2, old-style hemispherical covers having corroded through in as short a time as that required for one trip.

For the sake of brevity, the terms "turbulence" and "cavitation" as used in this paper, imply the presence of damaging air bubbles in the circulating water. The damage brought about by this type of corrosion is usually found at inlet ends of the first-pass tubes, with very little or no evidence of such action at the inlet ends of the second-pass tubes. In unusual cases, the occurrence may be reversed. Generally, trouble will be concentrated in specific zones of the condenser. Such localization of tube deterioration necessarily directs one's attention to the surrounding conditions and brings under consideration the related

[1] Chief Engineer, Scoville Manufacturing Company. Mem. A.S.M.E. Mr. German was educated in marine-engineering schools in Holland and Germany, and after graduation was employed as an engineer on the Holland-American Lines. In September, 1903, he came to the United States and held a position helping to install boilers and engines on battleships and cruisers for the Newport News Shipbuilding and Drydock Company. From this position he went to Providence, R. I., where he was chief operating engineer of the power plant of the Rhode Island Street and Suburban Railroad Company. His next position was with the Hartford Steam Boiler Inspection and Insurance Company as inspector; later he became assistant to F. B. Allen, vice-president. He joined the Scoville Manufacturing Co. in 1912 as chief engineer.

Contributed by the Power Division and presented at the Fall Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held at Providence, R. I., October 5–7, 1938.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

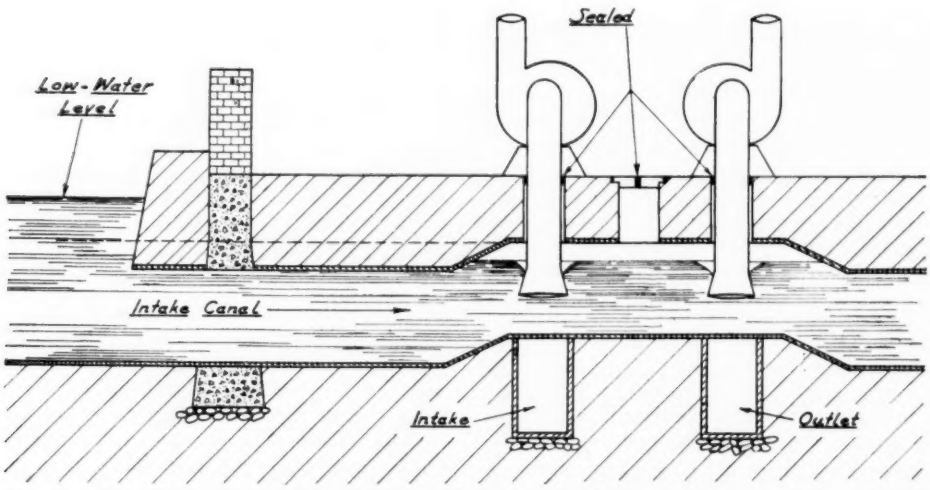

FIG. 3 ONE ARRANGEMENT FOR CONDENSER-WATER SUPPLY WHERE AIR WAS FOUND TO ENTER THE SUCTION BELL EVEN THOUGH THE ROOF OF THE INTAKE CANAL IS LOWER THAN LOW-TIDE LEVEL

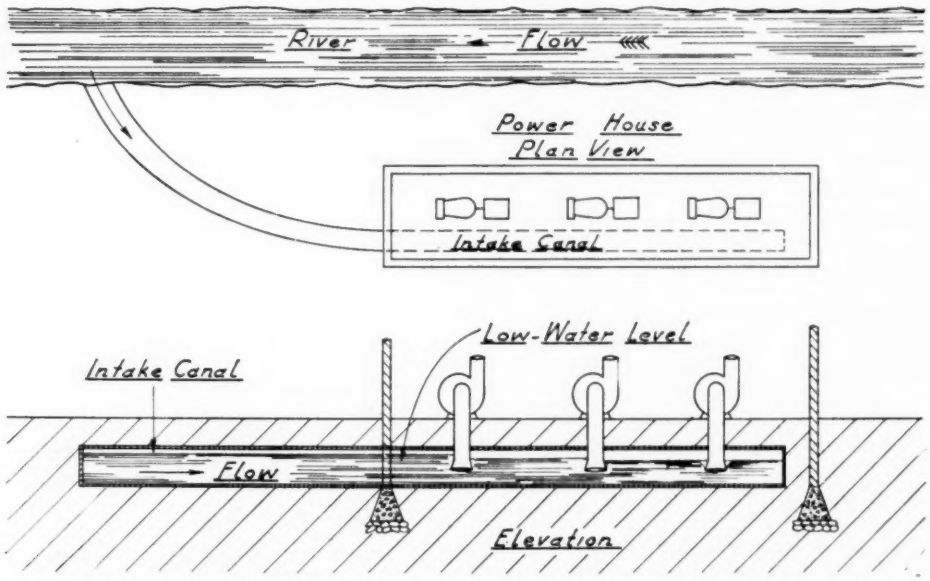

FIG. 4 ARRANGEMENT IN WHICH AIR ENTERS THE CONDENSER CIRCULATING SUPPLY WHEN THE RIVER LEVEL IS LOW AND THE PLANT IS OPERATING AT CAPACITY WITH THE THREE SUPPLY PUMPS ON THE LINE

elements of the installation as the intake screen, suction bell, circulating pump, pump stuffing boxes, valves, piping, inlet and discharge piping, water boxes, ferrules, and the conditions affecting and effected by them. Such effects are in most cases traceable to factors far ahead of the tubes themselves. The correction must be at the source. An inspection to discover the causes of tube corrosion should cover the entire hydraulic cycle, starting at the intake canal.

IMPORTANT MECHANICAL FEATURES OF DESIGN AND OPERATION

Air in the circulating water may be of two types: (*a*) Air entrained mechanically, and (*b*) air released from solution by turbulence at low-pressure areas.

Sources of and Possible Remedies for Entrained Air. The bell at the end of the pump suction pipe may not be submerged sufficiently, particularly at low tide. Such a condition obviously may permit great quantities of free air to enter. Air so introduced cannot be absorbed by the water, which is already saturated, and being carried along with the stream will damage tubes. If the suction bell cannot be lowered, due to distance limitations between the bottom of the pipe and the floor of the intake canal, one or two branches may be run from the suction pipe to act as a secondary suction. This procedure will reduce the flow at the original suction bell and prevent an external cone from forming around it.

Free air has been found to enter at the suction bell even though the roof of the intake canal is lower than low-tide level. Fig. 3 illustrates a case where such a condition was found. A new intake canal crossing over existing intake and discharge canals had been designed. Since all canals would still be below low-tide level, no objection was foreseen. Until there was an especially high tide, which flooded the basement floor because of water entering around the suction pipe of the pump and manhole under the basement floor, no trouble developed. However, in order to prevent any further flooding, the openings at the top of the new intake canal were sealed with the result that air accumulated, as shown in Fig. 3. At quite regular intervals this air accumulation reached a point in the canal where a cone formed around the suc-

tion bell and the air discharged into the circulating-water system. The remedy, of course, was to vent the canal with a pipe, the top of which was a few feet higher than the extreme high-tide level. Tube life was thereby materially improved.

When a power plant is designed with a basement-floor level dangerously close to conventional high tide, the designing of the intake canal calls for extra caution.

Many plants have a number of pumps which obtain their water from one canal. Fig. 4 illustrates a bad condition, as concerns tubes, resulting from such a layout. When the canal was originally built, future additional capacity requirements were considered, but the additional units later installed proved to require a greater capacity than was originally contemplated. The factor of safety on canal size was insufficient. After plant expansion, with low water, capacity load, and all three units on the line, the water level in the canal dropped after each suction pipe, so that air was admitted into the suction pipe farthest away from the main intake end of the canal. The remedy in such a case, when possible, is to extend the canal from the terminal end to the source of supply.

A second source of entrained air in the circulating water is found in circulating-pump stuffing boxes, water-sealed with the seal connected to the discharge chamber of the pump. Since the pressure at this point may be below atmospheric pressure, considerable air may be drawn in through the stuffing box, which is located on the suction side of the pump and always under vacuum. The water for the pump water seal should be supplied from a source with a pressure considerably higher than the pump discharge in quantities sufficient to cause a flow out of the stuffing box. Metal guards can be placed to keep excess water off the room floor.

It is obvious that leaky joints, valves, and pipes, in a system through which water under vacuum is carried, present sources of probable air entrainment.

Air Release From Solution. Under normal conditions sea water contains considerable quantities of dissolved air. Turbulence caused by obstructions to streamline flow may result in the formation of low-pressure areas and the release of this dissolved air from solution. In considering the circulating-water system from strainer to tail pipe, the following paragraphs in this section of the paper are devoted to a discussion of those portions of the equipment which may be important in this respect.

Intake Screen. The purpose of this is to keep out all trash, fish, eels, mussels, and shellfish. The screen is not always effective; failure sometimes resulting in a damaging effect on the tubes. Small shells may become lodged in the tubes and bake on while the condenser is hot or warm while off the line, due to leaking stop valves or entering drains. When the unit is replaced in service, a pit may occur directly adjacent to the shell on the downstream side, even though the circulating water does not carry entrained air. The water velocity passing over the shell, or any other foreign body, will produce a low-pressure area and cavitation directly in back of it. The released air concentrated in this zone does its usual damage. Tube samples with shells still attached, or with their impressions clearly visible, are in the author's possession and show pitting directly back of the shell on the downstream side.

Injection Strainer and Bilge Keel. The preceding paragraph, covering intake screens on stationary power-plant systems, should be supplemented by a brief consideration of injection strainers on board ship. Such injection strainers should be so designed that trash can neither enter nor collect and should be streamlined, as shown in Fig. 5, in order that undue turbulence will not be set up.

The author has observed that the rolling of a ship in heavy water may result in the entrapment of air under the bilge keel. To prevent such entrapment, it has been found advantageous to cut away a section of the bilge keel, as shown in Fig. 6.

Circulating Pumps. Old condensers of both stationary and marine types where tubes have lasted for many years are in existence, while newer installations are troublesome. The better life of old units is certainly not because tubes as now made are inferior; indeed, tube production has greatly improved.

The company with which the author is associated has in operation old pumps driven by reciprocating engines at speeds from 45 rpm to 100 rpm. Modern pumps are now driven at much higher speeds, in some cases by auxiliary turbines, without reduction gear, at speeds approaching 2000 rpm. Such excessive speeds in-

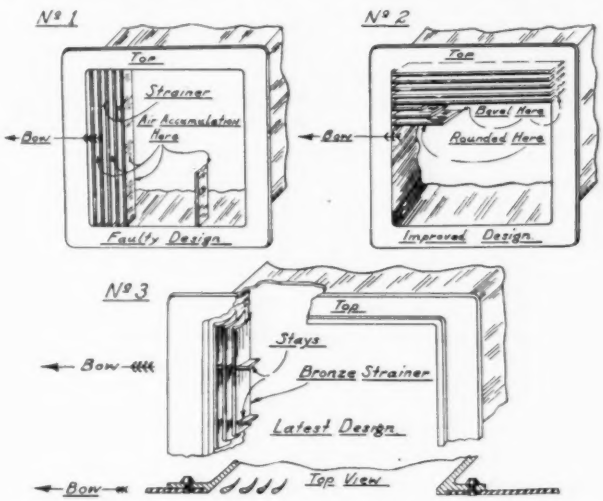

FIG. 5 STREAMLINE INJECTION STRAINERS FOR USE ON SHIPS

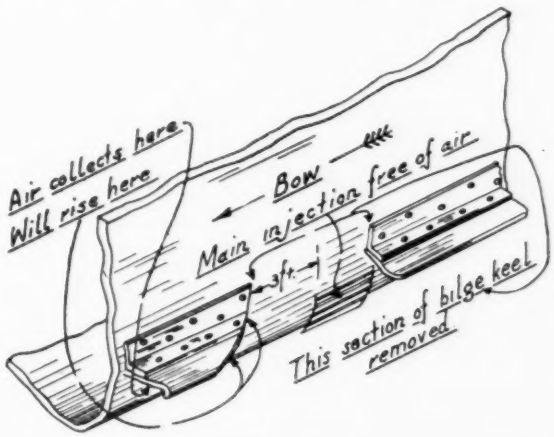

FIG. 6 SECTION OF BILGE KEEL CUT AWAY TO PREVENT AIR ENTRAPMENT

crease cavitation, cause circulating water to enter water boxes and tubes very turbulently, especially when the pumps are located close to the water box, as they frequently are. Some quite recent designs, in fact, have the pump discharge directly secured to the water box and a few have the pump integral with the water box. In such cases little or no liberated air has a chance to return to solution. The effect on tubes in such cases requires no comment.

It would seem advisable to return toward the earlier-type pump, which was larger and slower, but to incorporate improvements in design. While first costs would be greater, the author believes that the additional investment would be good, due to

power-factor correction, increased tube life, and freedom from condensate contamination, which is of increasing importance on modern high-pressure boilers operating at high ratings.

Both wear and misalignment both in impellers and pump casings, as shown in Fig. 7 will increase turbulence and are, therefore, to be avoided. In so far as pump life is concerned, it is desirable to minimize suction lift by placing the pump as near as possible to the water source.

Pump improvements will be reflected by savings on tubes.

Piping Between Pump and Water Box. In many cases, discharge piping is found with very short-sweep fittings, such as elbows and tees, which interfere with streamline flow and set up turbulence. Large divided water-box condensers, with the division plate open or closed, may require two pumps. Both pumps, however, may not be operated at low peak periods, especially with low-temperature circulating water. To provide for such an installation, the piping between pumps and inlet water box may be so designed that the water from either can reach both inlet nozzles. This is done by crossover piping and gate valves. Such design presents many sources of possible air accumulation and tube damage. Since the efficiency of the pumps and the resistance of the two sets of piping may differ, it is not safe to assume that the water supply from either pump is the same as that from the other.

In such condensers with two tail pipes, trouble may result when both tail pipes are in the same discharge canal, one entering at the canal terminal. This latter is apt to find greater resistance to flow and care should be taken that the discharge canal be ample in size, or of such design that the crowding of water at one tail pipe is not possible. If, for example, the water from both tail pipes is caused to flow into a large Y, the center or outlet of which is in line with the center line of the condenser, then the resistance to flow from each tail pipe will be equal.

Discharge piping with large check valves between the pump and the inlet water box, the top or head of which is at a considerably higher elevation than the top of the pipe, should be avoided. Gate valves are also located in such pipe lines. When such valves are in a vertical position with relation to the pipe, their tops may be considerably higher than the pipe top. Such check and gate valves are excellent air chambers, acting similarly to air chambers on pump lines, virtually as shock absorbers. This shock-absorber action is accomplished by having at least half of the chamber filled with air, such air accumulating and rising as circulating water passes through the pipe. Such collections will discharge periodically into the circulating water with the usual damaging effect on the tubes. A pipe connection should be made from the highest point on such valves to the tail pipe of the condenser, which will act as a vacuum pump. A small amount of water should be allowed to by-pass in order to make sure that no such accumulated air will enter the tubes.

Inlet Nozzles. Many inlet nozzles are so designed that flow is interrupted, as shown in Figs. 8*a* and 8*b*. The diameter of the discharge pipe is found to be greater than that of the inlet water box, which should never be the case. The nozzle is flattened, beginning some distance from the water box. Care is

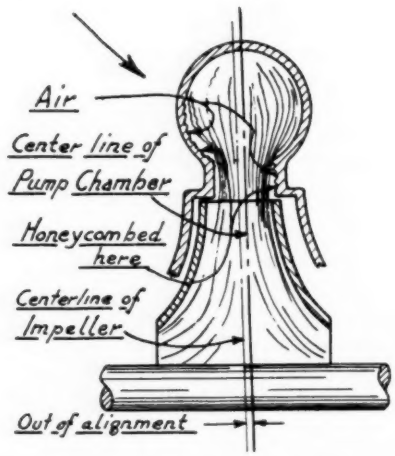

FIG. 7 MISALIGNMENT OF PUMP IMPELLERS WILL INCREASE TURBULENCE AND CAUSE CAVITATION

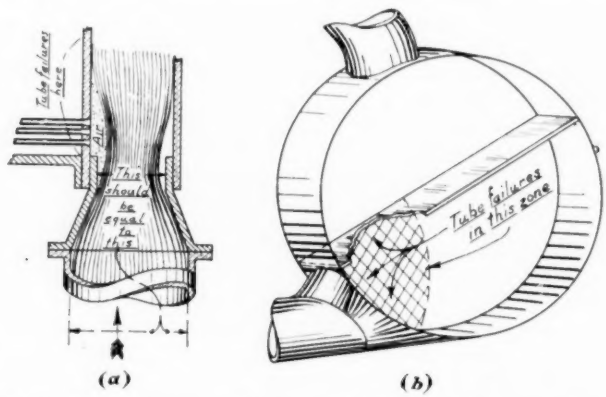

FIG. 8 INLET NOZZLES IN WHICH THE WATER FLOW IS INTERRUPTED

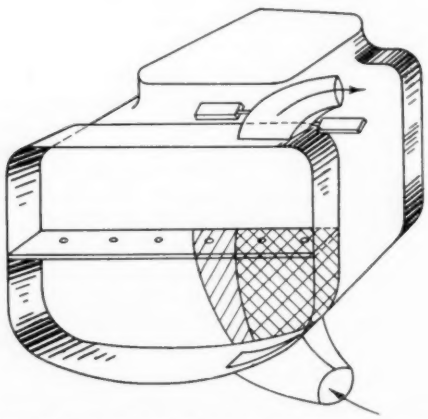

FIG. 9 CASE WHERE TOO GREAT A SPACE EXISTS BETWEEN THE INLET NOZZLE AND THE TUBE-SHEET FACE

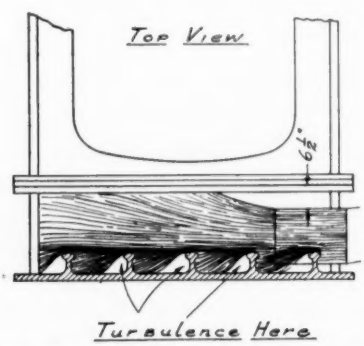

FIG. 10 IMPROPER ARRANGEMENT OF REINFORCING RIBS IN THE WATER-BOX HEAD SHOWN IN FIG. 9

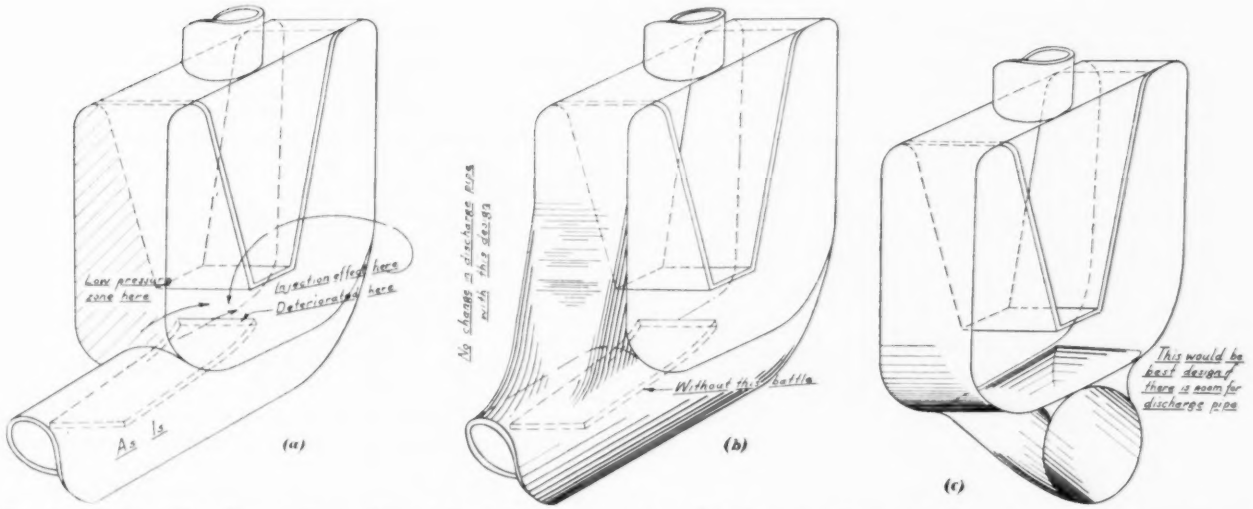

FIG. 11 A WATER-BOX DESIGN WHICH CAUSED TUBE DETERIORATION AND TWO PROPOSED DESIGNS TO ELIMINATE SUCH DETERIORATION

taken, however, to make up for this by lengthening the opening at the water box, so that its area is equal to that of the pipe area. Again referring to Fig. 8, it is seen that as water enters the water box its flow is tapered. This causes a low-pressure zone at the tube sheet in line with and on the side of the nozzle. The greater the entering water velocity, the smaller the amount of water which will pass through the zone described, which, in turn, affects tube life in that zone.

Figs. 9 and 10 illustrate a case where a space of $6^1/_2$ in. was found between the inlet nozzle and the tube-sheet face. Tubes in the low-pressure zone deteriorated rapidly. It was proved that through part of this tube bank (the shaded area), there was even a reverse flow of water, indicating that the inlet-water-box pressure in the indicated area was less than the pressure of the reverse-flow water box. This condition was further checked by temperature measurement at the outlet nozzle, which showed a difference in temperature of 6 C in various layers of outgoing water before mixing had been completed.

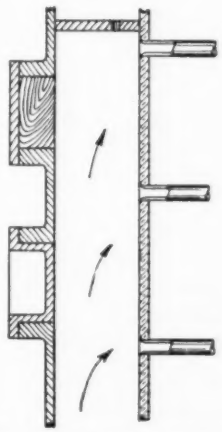

FIG. 12 WOOD-FILLED AND RECESSED INSPECTION DOORS WHICH WILL ELIMINATE WATER-BOX TURBULENCE

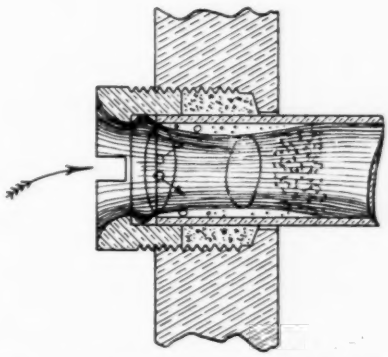

FIG. 13 CONVENTIONAL FERRULE AT THE INLET END OF A CONDENSER TUBE

Water Boxes. The author's discussion of water-box design can best be handled by a treatment of specific cases.

Fig. 10 shows a water box as well as an injection nozzle. Undoubtedly, the design of the water-box head was a contributory factor to general tube deterioration. It will be noted that reinforcing ribs were shaped like rails but were integral with the head, also that their position relative to the flow of water was at right angles. Low-pressure zones were created on the downstream sides of these reinforcements as the water struck and passed over them. The side of the ribs facing the flow and near the inlet was found to be free of corrosion. The downstream sides, however, could be cut with a pocketknife. All were affected likewise. The sides of the remaining ribs facing the flow were affected by corrosion progressing from the inlet onward.

The entire inner surface of the water box should be as smooth as possible and any necessary reinforcings should be external.

Figs. 11*a*, 11*b*, and 11*c* illustrate the effect of another water-box design on tube life. It is believed that the designer's object was to have some low-temperature circulating water pass through the upper tube rows for rapid condensation and also to have a certain percentage of the second-pass water flow through the bottom of the condenser in order to increase the condensate temperature. The condensers are on twin-screw sister ships operating under similar conditions. The condensers on one ship experienced tube trouble. The general design of the troublesome condensers is shown in Fig. 11*a*. It will be noted that the circulating water enters at one side of the water box which has an enlargement at the bottom, coming considerably below the condenser shell; this to permit easier flow to the first-pass section farthest away from the inlet. To divide the water equally between the two halves of the first pass, a horizontal baffle plate was cast integral with the inlet nozzle as a part of the water-box casting. Tube failures occurred at the upper section of that half of the first pass near the inlet circulation. The circulating water seeking the path of least resistance, resisted a change of direction of flow causing the greatest percentage to pass by the first half of the first pass and enter the half farther away from the inlet. This caused a low-pressure zone at the upper half of the first pass near the inlet, with tube failures resulting.

Reverse flow was found in the affected section of the first pass. It should be noted that inlet piping to the water box could not be seen without removing the floor plates. Upon demonstration of this evidence and submission of the recommendations shown in Figs. 11*b* and 11*c*, it was argued that the theory seemed correct but for the fact that the duplicate sister ship did not experience

similar tube failure. It later developed that the sister-ship's water-box inlet was located at the bottom and center, giving uniform distribution of circulating water and no low-pressure zone. In the second vessel tube deterioration was uniform over the entire first pass.

Much has been done to improve steam distribution with gratifying results. Circulating-water distribution is equally as important and should not be overlooked.

Inspection Doors. Practically all inspection doors are so designed that a large recess is found between the door and the main body of the water box. This causes turbulence. Such recesses should be filled with wood or replaced with doors of special design, as shown in Fig. 12.

Ferrules. With high water velocity and tubes installed with ferrules extending into the water-box inlet end, tube corrosion may be found even if the circulating water enters the water box smoothly. The conventional ferrule, with bell entrance and counterbore—to permit the tube to fit snugly against this counterbore shoulder—was designed to bring about smoother flow. Many who install tubes with this type ferrule have the opinion that a

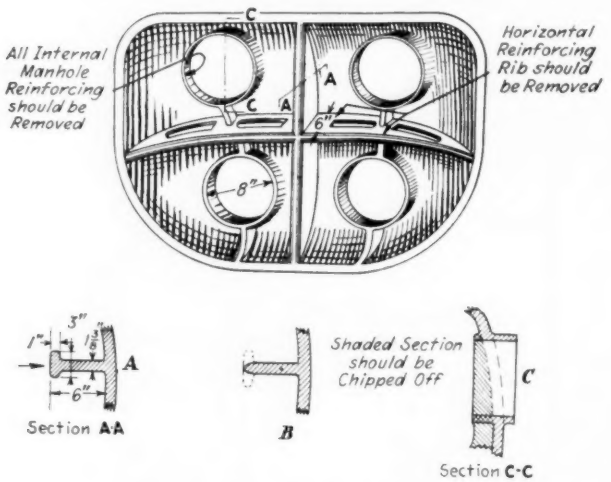

FIG. 14 COMBINATION REVERSE-FLOW WATER BOX AND HEAD

space must be provided between the end of the tube and the shoulder of the counterbore in order to have room for tube expansion.

Fig. 13 shows the conventional tube installation described. Note the clearance between the counterbore shoulder and tube end; this clearance has been found to be as much as $^3/_8$ in. Such practice requires that the ferrules extend farther into the water box (which will be shown to be detrimental), but disregards the fact that the counterbore shoulder and the tube inlet end should be in permanent close contact. All expansion and contraction of tubes installed in this way should be provided for at the outlet end. The use of a fiber packing ring in conjunction with the ferrule at the inlet end and a metallic packing with as little fiber as possible at the outlet end will accomplish this. That there are other methods allowing for expansion, such as shell expansion joints, floating heads, and a predetermined bow in the tubes when rolled at both ends, should be mentioned.

The clearance between the tube end and the ferrule counterbore shoulder forms a pocket which is ideal for causing turbulence in the water just before it enters the tube. The tube-entrance area is considerably smaller than the pocket area, causing the flow of water to assume a curvature, as shown in Fig. 13. A low-pressure zone begins to form at the tube end, which zone will vary in length, depending upon the water velocity or the length of space between the tube end and the counterbore shoulder. Air liberated in such recesses will obviously act destructively on tube ends, although it may return to solution on its way through the tube and cause no further damage. If ferrules of the type under consideration are examined after service, they frequently are found badly corroded just back of the counterbore shoulder.

Long ferrules have been used on the theory that corrosion might be absorbed by the ferrule itself. Extending well into the water box, such ferrules have in some cases been helpful. The author disagrees with the general theory of this practice, because the farther the ferrules extend into the water box, the greater will be the turbulence caused.

If ferrules must be used, there is a type that does not extend into the water box and makes no break in the inside diameter of the ferrule and tube; hence, uninterrupted flow results, reducing turbulence at the tube entrance.

The foregoing consideration of ferrules, as affecting inlet-end corrosion, permits a question as to why inlet-end corrosion also occurs where tubes are rolled into the tube sheet without ferrules. Such corrosion is found, but it should be remembered that water

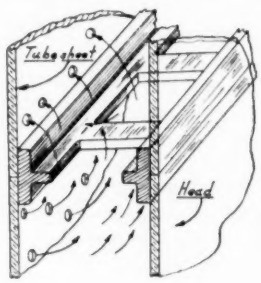

FIG. 15 REVERSE-FLOW WATER BOX WITH REINFORCING PLATE IN THE CENTER

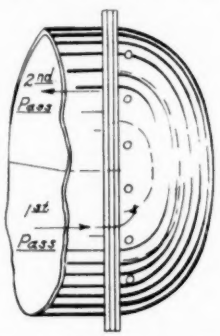

FIG. 16 IDEAL REVERSE-FLOW WATER BOX WITH TEST HOLES DRILLED AS SHOWN

may be turbulent before it reaches the tube, due to factors discussed earlier.

Failures of Second-Pass Tubes. Mention was made that occasionally condensers are found where tube failures occur in the second pass. Such troubles ordinarily result from faulty design of the reverse-flow water box, such as shown in Fig. 14. It will be noted that the water box and head are integral. This in itself would be ideal, if there were curvature instead of the conventional flat head and if there were a much larger cross-sectional area at the center; that is, between the first-pass outlet and second-pass entrance. Such ideal design, however, as in the case under consideration, is spoiled by reinforcing ribs running from left to right of the water box and at its center, since they interfere with free flow. Although four openings are provided in these reinforcings, it is apparent that water will reach the second-pass tubes in a turbulent condition. Further, the edge of the reinforcing is rail-shaped, as shown by cross section *A-A*. In addition, the designer found it necessary to extend cylinders, such as in inspection openings, into the water box, making still more turbulence. This is shown by section *C-C*. Six such condensers have come to the author's attention. The importance of having the reverse-flow water box free from obstructions to water flow is again indicated.

One reverse-flow combined water box and head was found to have been designed with a factor of safety of over 20. A calculation showed that all internal reinforcing could have been omitted with perfect safety.

Fig. 15 shows another common type of reverse-flow water box.

Again the reinforcing is placed between the tube sheet and water-box head and might be termed a division plate with an opening. The entire reinforcing is one casting, shaped like an angle iron, and bolted to the tube sheet and water-box head. Above such reinforcings low-pressure zones occur in which dissolved air accumulates, discharging at intervals into the second-pass tubes.

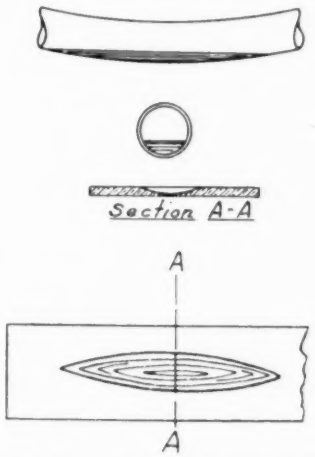

FIG. 17 CORROSIVE ACTION OF CONCENTRATING SALT WATER AND AIR ON A SAGGING CONDENSER TUBE WHEN THE CONDENSER IS OFF THE LINE

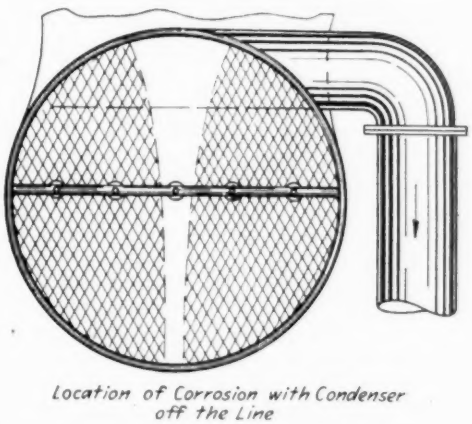

FIG. 18 CONDENSER IN WHICH CORROSIVE ACTION OF THE TYPE SHOWN IN FIG. 17 WAS FOUND

The tops of such cast-iron reinforcings are frequently found to be corroded. In a few cases the section between the tube sheet and head has disappeared, while the bottom of the reinforcing, where solid water contacts, was found sound. Stud bolts, instead of cast-iron reinforcings as described, are preferable. It is consistently noted that where there are such cast-iron reinforcings in the reverse-flow water box, tube trouble is experienced.

Fig. 16 shows what the author believes to be the most nearly perfect design for reverse-flow water boxes. It is to be noted that six openings from the bottom to the top were drilled in the side of the water box for test holes. When a colored liquid is forced into the lowest opening it will be seen to discharge from the highest opening, though not visible in the second and third openings from the top down. This indicates that, in this type of combined water box and head, turbulence is at its minimum.

OFF-THE-LINE CORROSION

Condensers are found where tubes sag between tube sheets and support plates. When such units are drained water will remain in the sagging sections. If turbine throttle and gate valves do not entirely prohibit the passage of steam the condenser will become hot and act in effect as an evaporator.

Fig. 17 illustrates the corrosive action of concentrating salt water and air entering through the turbine labyrinth packing as evaporation proceeds with ultimate penetration centrally, as at section *A-A*. This type of trouble was encountered in a plant having condensers of the type shown in Fig. 18. In this case failures were limited to those tubes above the bottom of the tail pipe. All other tubes remained full of water. To avoid this trouble condensers should be kept cool (not above room temperature) while off the line.

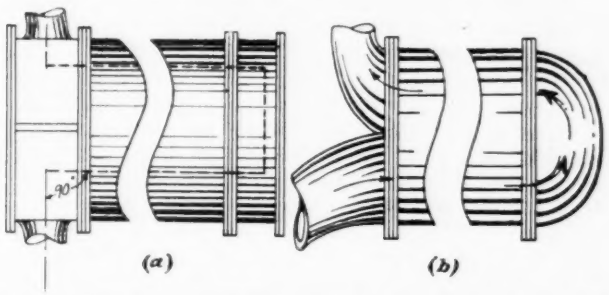

FIG. 19 TWO DESIGNS OF CONDENSER WATER BOXES, ONE (*a*) OF THE CONVENTIONAL TYPE AND ONE (*b*) IDEAL FROM A CIRCULATING-SYSTEM POINT OF VIEW

CONCLUSION

Fig. 19 illustrates two condensers; (*a*) one of the conventional design and (*b*) one ideal from a circulating-system point of view. It will be noted that in the conventional design water must make a 90-deg turn at the inlet water box, with low-pressure zones on each side of the nozzle, and an accumulation of air under the division plate. In the reverse-flow water box two 90-deg angle changes are necessary, one on leaving the first pass and one on entering the second pass. It will be noted in Fig. 19*b* that the entrance to the first-pass tubes is streamlined. There is no division plate. Provision is made for entrance of water without unnecessary turbulence. The reverse flow existing was explained earlier.

The author is of the opinion that with all conditions, except design, the same on both condensers, the tubes in the layout, as proposed in Fig. 19*b*, would last much longer than in the conventional-type two-pass condenser.

Discussion

H.N. BOETCHER.[2] Condenser-tube deterioration is one of those complicated problems which defy solution by one formula, for the simple reason that the number of factors entering into them is too large. Mr. German's paper considers one side which, at least in stationary plants, is associated closely with the tendency toward the use of higher water velocities in condensers, which in turn has resulted in shorter tube life in many cases. Lack of knowledge with regard to the potential decrease of tube life has apparently caused a condition in which a proper balance between first and maintenance costs does not always exist anymore. In some of these cases, a review of the circulating-water system on the basis of Mr. German's suggestions, with corresponding changes, may result in definite savings. In view of the extensive flood-protection work carried on in many localities, special attention should be given also to the case mentioned by

[2] Assistant to Superintendent of Steam Stations, Consolidated Gas, Electric Light, and Power Co., Baltimore, Md. Mem. A.S.M.E.

him in which sealing of the floor outlets of an inlet tunnel resulted in forming air pockets, with detrimental results.

As Mr. German's paper is based on practical experiences rather than experimental or analytical work, it may seem amiss to question his use of certain terms. On the other hand, the fact that a few authors use these terms in accordance with their own definitions has caused a condition which makes one wish for an A.S.M.E. or A.E.C.—or some other alphabetic—Committee on Technical Terms and Definitions with complete authority to fix these terms. Mr. German uses the terms cavitation and turbulence in a way which does not agree with the definitions accepted by hydraulic engineers and other workers in similar fields. Cavitation certainly is encountered in the case of propellers and pump impellers.

Air, however, is a retarding, and not an accelerating factor in this type of destruction. Turbulence is a type of flow which may be associated with, but does not cause release of air. Air dissolved in circulating water is released by general decrease in pressure below atmospheric pressure—which, though not mentioned by Mr. German, is the principal source of air of this type in many condensers—or by local decrease in pressure as caused by obstructions. In this latter case, it may be accompanied by turbulent flow.

The type of attack to which Mr. German refers is the "air-impingement" which appears to be a combination of corrosion of clean metal surfaces and a scouring action by rapid water flow which removes the products of corrosion almost immediately. The corroded surfaces usually have relatively smooth, metallically clean contours, as opposed to the pitted appearance of surfaces attacked by cavitation. The attack depends on the presence of air at high water velocities as caused by local conditions or by general design. It has been found also all along the inner surfaces of tubes when velocities are sufficiently high.

Mr. German's paper justly emphasizes the importance of designing and operating equipment connected with condensers for low air infiltration and for smooth flow. This is a field to which little hydraulic engineering has been applied so far. However, experience shows that the content of free and dissolved air in circulating water is so high even under the best conditions that relatively quick tube deterioration occurs when the water velocity is above the critical point at which turbulent flow begins. As it is impractical to reduce the air content of the water entering the system by artificial means, uniformly moderate velocities in the tubes should be used unless the tubes are made of an alloy with high resistance to air-impingement attack.

Author's Closure

The author agrees with Mr. Boetcher that a definite standardization of engineering terms is a useful project. Where "turbulence" was referred to in the paper the author pointed out the low-pressure zone caused by pressure drop, but referred to differential pressure and not necessarily lower than "atmospheric." With this one qualification it is believed that the author and Mr. Boetcher are in agreement.

Condenser Performance With Reduced Cooling Surface

By J. H. HARLOW,[1] and R. A. BOWMAN,[2] PHILADELPHIA, PA.

The authors discuss changes made in two condensers of 50,000 sq ft heat-absorbing surface, which changes provided steam lanes in the tube nests in an attempt to increase the effectiveness of the condenser surface. The heat-absorbing surface in the first condenser was reduced 20 per cent, while that in the second condenser was reduced 30 per cent. The authors present drawings showing the changes made, and explain the reasons for making them. Performance data on both condensers, before and after the changes were made, are presented in both graphical and tabular form.

AT THE Philadelphia Electric Company's Delaware Station there are six Westinghouse, two-pass surface condensers each of which originally contained 50,000 sq ft of heat-absorbing surface comprising approximately 9100 No. 18 gage tubes of 1 in. outside diameter. These condensers each serve one 30,000-kw unit and went into service during the period from 1920 to 1924. During the early portion of their life, they were operated almost continuously, but with the subsequent installation of the Richmond Steam Station and Conowingo Hydroelectric Station, they have been mainly in peak service for the last ten years. Each condenser is provided with two Le Blanc air pumps, one of which is a spare, and two circulating pumps each rated at 37,500 gpm. The normal practice is to operate with one circulating pump in service, the other being in reserve. Cooling water is obtained from the Delaware River adjacent to which the station has been built. In 1931, provision was made for chlorinating the circulating water, and, with the exception of those periods when the river-water bacteriological demand has exceeded the capacity of the chlorination equipment, all of the water used for cooling in the condensers of this plant has been treated by this equipment for the prevention of slime and scale. In general, it may be said, that these condensers have been maintained in a satisfactory condition by following this process.

About two years ago, when from two to four hundred tubes which had developed leaks had been removed or plugged in each condenser and when there was evidence to indicate that the rate of failure could be expected to increase, it was decided to begin a gradual schedule of complete retubing whereby one or two condensers would be retubed each year. It is worthy of note that each of these condensers had had a service life of over 55,000 operating hours up until the time of retubing and that all of the tubes were somewhat roughened on the inside caused by pitting.

On discussing the retubing problem with the manufacturer, it was suggested that, during the retubing process, some of the tubes be omitted and that, in this manner, provision be made for steam lanes in the tube nest. As a result of progress in condenser design since these condensers were installed some 14 to 18 years ago, it had been learned that the effectiveness of condenser surface could be considerably improved by providing free access for the steam to the cooling surface. One of several ways of doing this was by providing lanes through the tubes, and the construction of these particular condensers was such that laning could be applied merely by leaving out the proper tubes. The manufacturer made a study of the tube arrangement and suggested a pattern to be followed while replacing the tubes in the condenser.

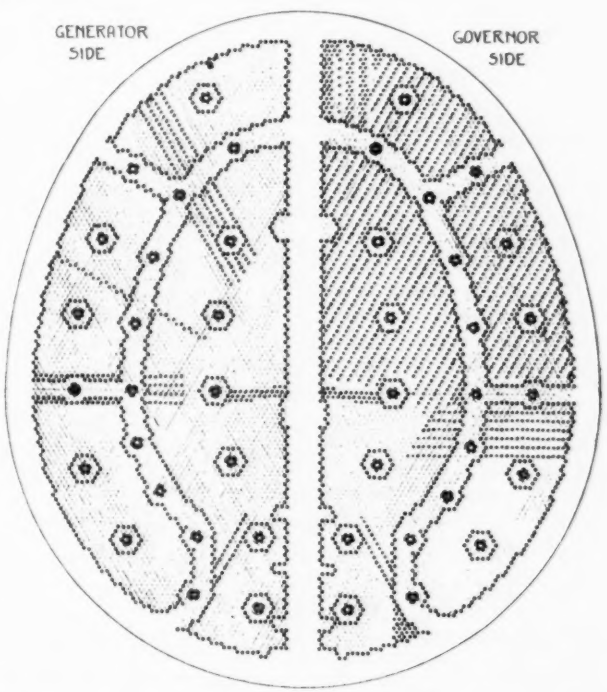

FIG. 1 TUBE ARRANGEMENT OF CONDENSER NO. 5, WITH 20 PER CENT OF TUBES OMITTED

It was concluded, therefore, to try out this scheme on No. 5 condenser which happened to be the first one scheduled for retubing. The tubes in this condenser were replaced during September, 1936, according to the pattern shown in Fig. 1. As a result, the surface in this condenser was reduced by 20 per cent or from 50,000 sq ft to 40,000 sq ft. It will be noted that the lanes were chiefly on the side of the condenser toward the turbine throttle. This was because it was felt that the velocity of the

He is the author of several technical papers.

Contributed by the Power Division and presented at the Fall Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in Providence, R. I., October 5–7, 1938.

NOTE: Statements and opinions advanced by authors are to be understood as individual expressions of their authors, and not those of the Society.

steam exhausting from the last-stage wheel of the turbine would tend to carry it across the exhaust connection so that the greatest burden would be on that portion of the condenser away from the turbine throttle. Therefore, more surface was allowed to remain where the loading was expected to be greatest. Further, if the laning did help the steam to enter the tube nest, it was felt that probably laning on the throttle side would tend to increase the amount of steam condensed on this side and thus evenly divide

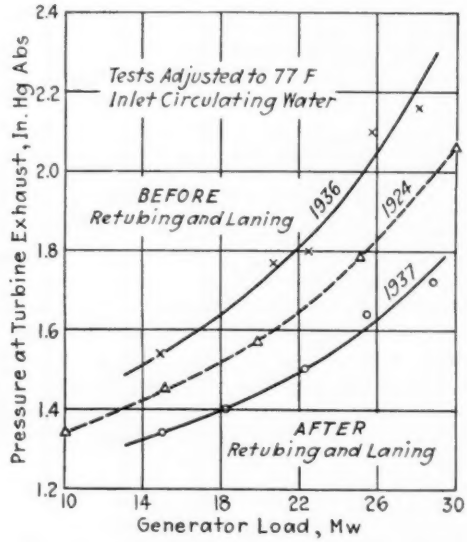

FIG. 2 PERFORMANCE DATA FROM CONDENSER NO. 5

the burden on all of the surface. It should also be realized that this was the first condenser to be retubed and a 20 per cent reduction in surface seemed to be a no inconsiderable change for a first attempt. In addition to opening up the tube bundle in order to provide better access for the steam, a small baffle was inserted to shield the air offtake connection at the center of the condenser. An inspection of Fig. 1 will reveal the location of this baffle where a small number of tubes were omitted in a symmetrical pattern on both sides of the vertical center line and slightly more than half way down from the top.

Two types of performance data, before and after retubing, were obtained to show the change in performance resulting from the alterations. The first is shown in Fig. 2 which presents the results of tests which were run on No. 5 condenser just before and just after the new tubes with laning were installed. This figure shows the relation between generator load and turbine exhaust pressure. One curve shows the condenser performance before retubing and the other after retubing. All of the tests were run under warm-circulating-water conditions and all were adjusted for comparison to the same inlet-water temperature, namely, 77 F. This temperature was selected due to the fact that it was about the average of the inlet temperatures experienced while the tests were in progress. In no case was the departure more than a few degrees, so that the required adjustment was small. The improvement in vacuum, as shown by these tests, was very substantial varying from about 0.15 in. Hg at the lower loads to over 0.40 in. at the higher loads.

Such a substantial gain as that indicated by the tests which were made just before and just after retubing caused some speculation as to whether or not all of this gain could be attributed to the laning. In order to answer this question, the record was searched and some tests were discovered which had been run in 1924 within a few months after the condensers were originally installed. The dashed curve in Fig. 2 shows the results of these early tests adjusted to 77 F inlet circulating water. This curve leads to two interesting conclusions: First, it appears that about one half of the total gain from retubing and laning resulted from the laning, the other half being the result of substituting new tubes for the old ones; and, second, it appears that the effect of the roughness on the water side of the old tubes was to reduce the vacuum as much as 0.20 in. Hg at the heavier loads and higher circulating-water temperatures when compared with new smooth surface, even though the rough surface appeared to be clean and had been subject to chlorination for several years.

A second type of comparison between the before-and-after performance is provided by the daily check of condenser operation. Fig. 3 shows the results of such a check which was made on No. 5 condenser and shows the experience for the year previous to retubing and laning and for the subsequent year. A very substantial improvement as a result of the changes can be noted as shown by the figure. Attention is called to the fact that values shown above the zero line show performance which is poorer than standard and that values below the zero line show performance which is better than standard.

These results, obviously, were very gratifying, for, in addition to reducing the cost of the retubing job, an improvement in vacuum was obtained.

The second condenser to be retubed was No. 3. The results on No. 5 had proved so satisfactory that the manufacturer suggested that the laning idea be carried still further and that the surface in this condenser be reduced by 30 per cent instead of 20 per cent. This would mean reinstalling only 35,000 sq ft of cooling surface instead of the 40,000 sq ft as replaced in No. 5 condenser. In obtaining this increased reduction in surface, it

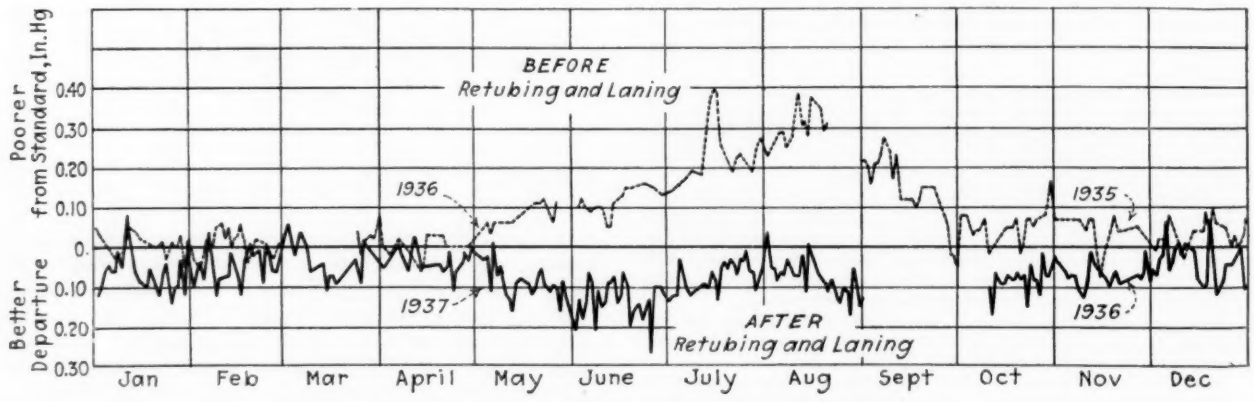

FIG. 3 DAILY CHECK OF PERFORMANCE OF CONDENSER NO. 5

was proposed to provide laning on both the throttle and the generator sides of the condenser in a balanced pattern as shown by Fig. 4. In this pattern, it will be noted that, in addition to the more balanced arrangement, a somewhat different scheme of laning was suggested from that employed for No. 5 condenser. In those zones, where tubes were not replaced in No. 5, they were omitted in every other row, thus making certain portions of the condenser more open for the passage of steam. In the case of No. 3 condenser, however, the proposed lanes through the tube bundle were more definite and wider and several open paths were provided through which the steam could penetrate deeply into the tube bundle. A baffle similar to that installed in No. 5 condenser was also to be provided. During April and May, 1937, No. 3 condenser was retubed as suggested.

Tests similar to those run on No. 5 were also run on No. 3 condenser. The tests immediately before and after on No. 3, however, were made during a period of low circulating-water inlet temperature. An analysis of the tests later, when the heat-transfer rates were being computed, developed that this was somewhat unfortunate, due to the fact that the increase in volume of the noncondensable gases, occasioned by the lower inlet temperature and consequent higher vacuum apparently resulted in somewhat overloading the air-removal equipment. The gain obtained is shown in Fig. 5, wherein all of the test points have been adjusted to 43 F circulating water, and is in the order of

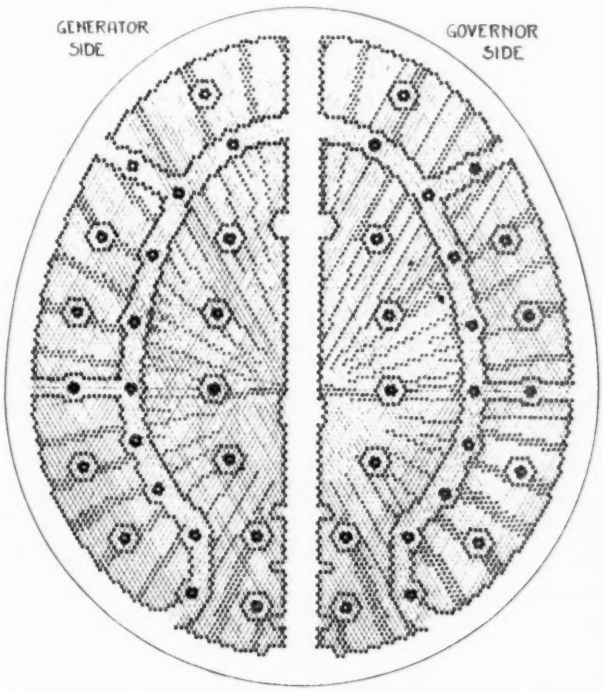

FIG. 4 TUBE ARRANGEMENT OF CONDENSER NO. 3, WITH 30 PER CENT OF TUBES OMITTED

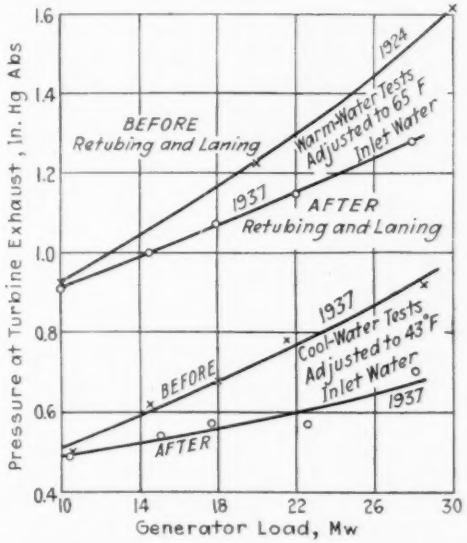

FIG. 5 PERFORMANCE DATA FROM CONDENSER NO. 3

0.25 in. Hg at the higher loads and trails off to a small value at low load. In order to obtain a comparison of before-and-after performance under warm-water conditions, it was necessary to refer to the results of a group of tests which had been made on this machine about two years after the original condenser was put into service. The results obtained from these early tests, together with the results obtained from tests run with warm water subsequent to retubing, all of which were adjusted to 65 F circulating-water temperature, are also shown in Fig. 5. The gain as indicated by this comparison is about the same as indicated by the comparison which was obtained on No. 5 condenser between the early tests and the test after retubing. Fig. 6, which is a plot of the daily check of the performance of No. 3 condenser for the year before and the year after retubing, indicates that the gain, throughout the year, was of similar mag-

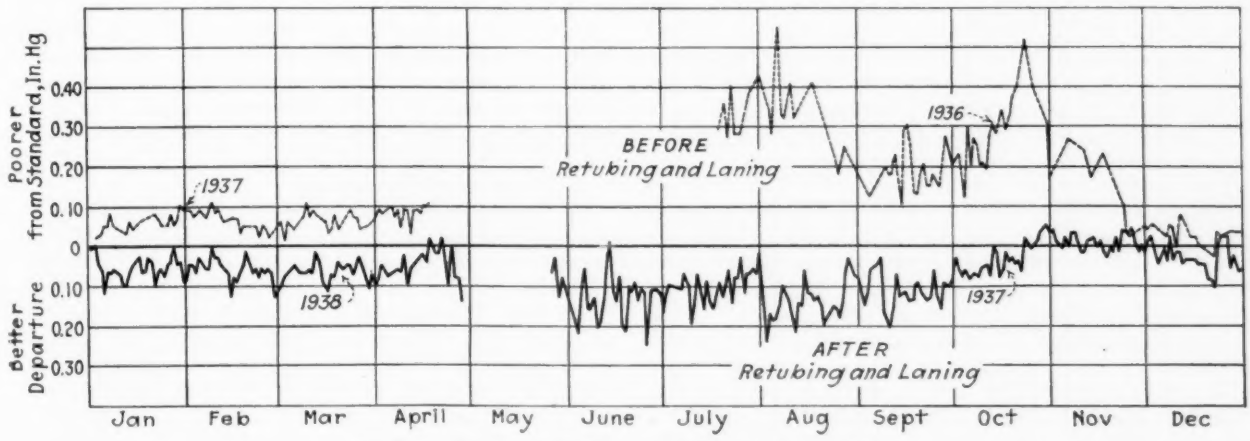

FIG. 6 DAILY CHECK OF PERFORMANCE OF CONDENSER NO. 3

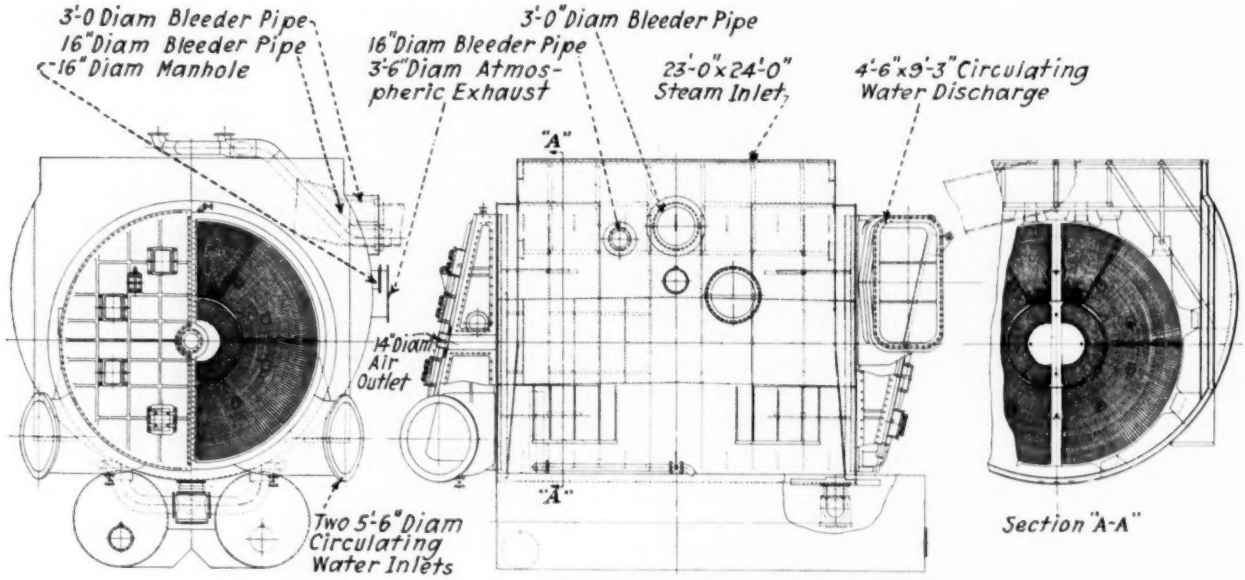

FIG. 7 CONDENSER DESIGNED SO THAT ALL THE TUBE SURFACE WILL BE SUPPLIED WITH STEAM CLOSE TO EXHAUST PRESSURE

nitude to that obtained on No. 5 condenser, as shown in Fig. 3.

Since retubing No. 3 condenser two more of the Delaware Station condensers have been retubed following the scheme used for No. 3, and with similar results.

The improved performance obtained on these condensers after the removal of tubes results from the application of modern design principles to old apparatus, and it would seem to be of interest to review briefly the developments in condenser design leading up to the present ideas on the subject.

The early condensers were no more than tubes placed in a shell and cooled by water so that steam would condense on them. The vacuum was usually limited by the air-removal pump, and the prime mover, a reciprocating engine, could not profitably utilize a high vacuum anyway so little thought was given to condenser efficiency. However, with the development of the turbine with its ability to use high vacua to good effect, and the improvement of air-removal technique, the necessity of improving condenser performance was evident.

The most obvious point of attack was the lowering of the pressure drop of the steam so that the steam would reach all the surface at the highest possible pressure and temperature. One solution was the radial-flow type of condenser of which those at Delaware Station are examples. In this type, steam is admitted all around the periphery of the bundle to reduce the velocity, and the length of flow path is limited to the radius of the circular tube bank. However, at the time the units for the Delaware Station were built, the tubes were still crowded into the shell.

In the design of the condenser under discussion, the steam may be considered to flow from the periphery to the air-removal chamber along a great many paths in parallel. The pressure at the air offtake is the same for all paths while the pressure on the periphery varies in an unpredictable manner due to the irregularities of flow from the turbine. The pressure difference available for moving the steam through the tube bank for any individual path is then the difference between the pressure which happens to exist at the start of the path and the air-removal-chamber pressure.

The pressure gradient, or rate of change of pressure with distance at any point along a path, is roughly proportional to the square of the steam velocity and to some function of the tube spacing. The amount of steam flowing at any point along a path is equal to that entering the path minus that condensed between the entrance to the path and the point. It can be shown that just enough steam will enter a path that the summation of the gradient multiplied by unit length will equal the pressure differential existing for that path. It is possible that along some paths this amount of steam will be less than can be condensed, and in this case there will be surface toward the inside of the bank which is not supplied with steam. Conversely, there will be other paths which will allow steam to pass into the air chamber and the vacuum existing in the chamber is largely determined by this steam and the characteristics of the air pump.

Since the time the condensers in question were built, the technique of arc welding has been developed; hence, today practically all condenser shells are fabricated, whereas, formerly they were cast. The resulting reduction in shell cost has encouraged the manufacturer to be more liberal in using large shells and it has been found that the extra space has paid well for itself. The tubes can now be placed on large centers with a still further reduction in pressure drop. What is more important, they can be given a very large pitch at the outside of the bank and a smaller one at the center in conjunction with a change in the air baffle to localize the air removal to the center of the bundle.

By so doing a substantial over-all flow resistance is maintained, but a large percentage of it is concentrated near the center of the bank. This means that there must be flow practically to the center of the bank to satisfy the available pressure differential and, in spite of flow inequalities and nonuniform condensing capacity, very nearly all of the surface will be supplied with steam at close to exhaust pressure.

Fig. 7 shows an example of a condenser built along these lines. It will be noticed that the main portion of the tubes are set on radial lines so that there is a gradual decrease in pitch toward the center. On the periphery, there is very little resistance to steam flow. The center group of tubes is set on a rather close triangular pitch so as to give a comparatively high resistance which assures an ample supply of steam through all the main tube bank; since lack of flow in the closely pitched center section along any path would practically eliminate the pressure drop over it and with paths in parallel this is an impossible condition.

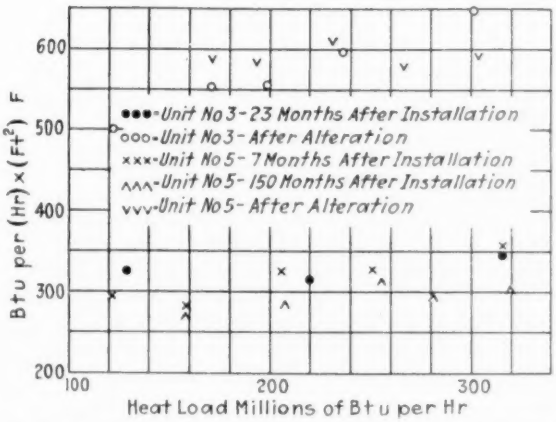

FIG. 8 HEAT-TRANSFER RATES FOR CONDENSERS NOS. 3 AND 5

The essential difference between the condenser shown in Fig. 7, and the original units at the Delaware Station is the fact that the former has a generous tube spacing near the periphery and a tight spacing near the center, while the latter is tight over the entire area. It is obviously impractical to change the tube pitch of the old unit to bring it into conformity with the modern one, but nearly the same result may be obtained by leaving out alternate rows of tubes as was done on No. 5 condenser or by introducing narrow lanes as on No. 3 condenser. Actually, the pitch on the subject condensers was not excessively close ($1^1/_2$ in.) and it seems reasonable to say that the improvement is due to introducing a nonuniform pitch more than to the increased average pitch.

In order to get a comparison of the heat-transfer rate after the changes were made, with that obtained by the same units in their original condition, the results of the tests shown in Figs. 2 and 5, together with data from some additional tests which were made shortly after the condensers were installed, have been calculated and listed in Tables Nos. 1 and 2. These rates are also given in the form of curves in Fig. 8. No data are given for tests made at water temperatures below 50 F, because the heat-transfer rates given in these cases are not consistent in that they decrease very rapidly as the load and water temperature are reduced. This indicates that the limitation on the vacuum under cool-water conditions is not heat-transfer rate, but the capacity of the air-removal pump to handle the existing leakage.

In comparing the rates after the change with the original ones,

it should be remembered that the improvement is not due wholly to increased utilization of the tube surface although that does account for most of it. Fortunately, the pumps supplying cooling water to these units have steep characteristics so that about the same amount of water is circulated now as was circulated before. As a result, the water velocity was increased in inverse ratio to the reduction of number of tubes and some of the rate increase must be credited to this increased water velocity. It might be mentioned here that if the increased resistance had caused a substantial reduction in the amount of water flowing, the increased rise in water temperature would have counteracted to some extent the effect of the higher rate on the vacuum.

It might be argued, and reasonably enough, that the gain obtained was not so much the result of laning as the result of the fact that new clean surface was substituted for the old worn out tubes. Undoubtedly a considerable gain resulted because of the new tubes, but there are several reasons as follows, for believing that a large portion of the improvement was the result of the laning:

1 The condenser surface on the water side, before retubing, although rough, appeared to be in good condition being free of slime as a result of several years of the chlorine treatment.

2 Several of these condensers were pickled with ferrocyanide and okite on the steam side a year or so before retubing, but after several years of chlorination, without showing any improvement in vacuum.

3 No. 5 condenser has been in operation for about two years since it was retubed and is still showing about the same improvement over the original installation as it did shortly after retubing. The tubes in No. 5 condenser are still smooth, however, and several years of operation will be required before a measure of the effect of roughness with the reduced surface can be obtained.

4 The heat-transfer rates on No. 5 condenser, as calculated from tests made shortly after the original installation, although somewhat higher, check closely with heat-transfer rates computed from the tests made just prior to retubing, as will be seen from Table 2.

5 As indicated in Figs. 2 and 5, a substantial improvement was shown between the early warm-water tests and the warm-water tests made shortly after retubing, in which comparison it should be expected that the tubes were in similar condition for both sets of tests.

Further Experiments in the Planing of Hardwoods

By E. M. DAVIS,[1] MADISON, WIS.

This paper is supplementary to a previous one,[2] and gives results of further experiments in the planing of hardwoods.

Results are given in tabular and graph form showing the percentage of defective pieces obtained in planing samples of twenty-two woods with six different cutting angles; seven woods with unjointed knives and with four different amounts of jointing; and sixteen woods with four different depths of cut.

ONE COULD probably devote a lifetime of study to the planing of wood without exhausting all the possibilities of the subject. About a year ago the writer presented a paper[2] describing tests recently made at the Forest Products Laboratory at three moisture contents (6, 12, and 20 per cent), two different feed and speed combinations (36 fpm at 3600 rpm and 54 fpm at 5400 rpm), and four different cutting angles (15, 20, 25, and 30 deg). Since then further experiments have been made, and this paper may be considered a continuation of the previous one. It introduces two additional cutting angles (5 and 10 deg), and presents some data on the effect of depth of cut and amount of jointing.

The machine used was a 30-in. cabinet planer of strictly modern type. This point needs to be emphasized because there are many types of planers and related machines, such as molders, planer-matchers, jointers, and flooring machines. Some of these are more flexible than the cabinet planer, some are more highly specialized for certain types of work, and each of them has its own characteristics and limitations. These machines are so similar in the type of cutter head used that it is assumed that the results obtained with one parallel the results obtained with another. However, there is no definite proof that this is so.

Judging the Quality of Planing

The "planability" of woods may be judged in several ways, all valid but all different. Recent European researches, for instance, lay great emphasis on power consumption as an index to ease of cutting. Frequently large production plants are interested in the rate at which dulling of knives occurs with different woods. When machining studies were begun at the Forest Products Laboratory about three years ago, preliminary contacts with woodworkers indicated that the quality of surface is nearly always the most important consideration in this country. For this reason and because it was necessary to limit the scope of the work, quality of surface has been used in these tests as a measure of planability.

Needless to say a mechanical method of measuring the smoothness or quality of a planed surface is desirable to eliminate the factor of personal judgment if for no other reason. Numerous devices have been made both here and abroad; some of them, according to report, can measure irregularities of a millionth of an inch in metal. Unfortunately, as far as the writer knows, no wholly practical method of measuring minute irregularities in wood has yet been developed.

One factor in the quality of a planed surface obviously is the number of knife cuts per inch. Certain German investigators consider from 16 to 25 cuts per inch necessary to a good finish, which is somewhat higher than recommendations of our own manufacturers of woodworking machinery. In this study knives were jointed lightly but often, while feed and speed were adjusted to give about thirty marks per inch. Knife marks were so uniformly good that for all practical purposes they could be ignored as a variable and this was done. Knife marks are important but they are relatively easy to control. They are always present although they may be quite obscure at times. On the other hand, planing defects may or may not be present. When present they tend to overshadow the knife marks in importance unless the latter are bad. In this paper the quality of planing is judged wholly by the planing defects. It is recognized, of course, that they are not the whole problem.

Quality of surface was judged by visual inspection. Each test piece was examined after planing for any chip marks, raised grain, fuzzy grain, or chipped grain that might have developed during the process. Any piece might contain none or possibly all of these defects, which were graded according to whether they were present in a slight or pronounced degree. As a check on the accuracy of this method it was found that a definite relationship existed between these grades and the amount of sanding necessary to eliminate the defects; the poorer the grade the more sanding. It was also found that the frequency of occurrence of a given defect in different woods gives an indication of its degree; for instance, if wood *A* has twice as many occurrences of chipped grain as wood *B*, the degree of chipped grain in *A* will average more serious than in *B*. For the purpose of this paper it was decided to combine all grades and base the tables on percentage of defective pieces. This largely eliminates the personal judgment of the grader as to just what grade should be assigned a given piece, and it eliminates a large amount of detail that only leads to the same conclusions.

A close inspection plus the fact that even a single chip mark, for instance, was enough to class a piece as defective explains in part why some of the defect figures in the tables that follow may seem high. Also, when planing with so many different cutting angles, for instance, some of the angles are not at all favorable, and this shows up in the results.

Selection of Test Material

In tests dealing with the machining of wood it often seems that the job is more than half done when the test material is properly prepared. Preparation includes selection, sizing, and condition-

[1] Senior Wood Technologist, Forest Products Laboratory, Forest Service, U. S. Department of Agriculture, Madison, Wis. The laboratory is maintained in cooperation with the University of Wisconsin.

[2] "Experiments in the Planing of Hardwoods," by E. M. Davis, Trans. A.S.M.E., vol. 60, January, 1938, paper WDI-60-1, pp. 45–49.

Presented at a joint meeting of the Wood Industries Division of The American Society of Mechanical Engineers, and the Cost and Production Division of the Southern Furniture Manufacturers' Association at High Point, N. C., September 21–23, 1938.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until March 10, 1939, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ing to uniform moisture content. The size chosen was 1 in. × 4 in. × 3 ft, a convenient size to handle, and, since it contains one board foot, a convenient unit of measure. The moisture content was 6 per cent, which is logical because hardwood lumber for exacting use is usually well kiln dried.

It is possible to find hand-picked samples that will prove almost anything. For example, one could prove that yellow poplar is heavier than white oak by comparing the heaviest poplar with the lightest oak. This illustrates the necessity of basing all tests on samples that are representative in quality and adequate in number, because of the fact that wood is so extremely variable.

No two pieces of wood are just alike. They vary in many respects, such as rate of growth, angle of grain, and, most important of all from the woodworking standpoint, they vary in specific gravity or density. This is the best single indication of strength properties and hardness. Hardness in turn is related to power consumption and rate of dulling of tools, and so, indirectly, the specific gravity of any test sample tells considerable about certain machining properties.

The heaviest pieces usually have about twice the density of the lightest pieces in the very same wood. For example, 1000 pieces of yellow poplar ranged from 0.28 to 0.62 in specific gravity, and 1300 pieces of white oak ranged from 0.38 to 0.80. The hardness increases as the $2^1/_4$ power of the specific gravity, so that a piece of wood that is twice as heavy as another will have nearly five times the hardness. Obviously specific gravity is a factor that deserves serious consideration in selection of samples. White oak, one of the heavier common woods, has on the average only 1.4 times the specific gravity of poplar, which is one of the lighter of the common woods. This illustrates the fact that there is often a greater difference between the extreme samples of any wood than there is between average samples of different woods.

When specific-gravity figures are graphed in a frequency curve, approximately 90 per cent of all samples are concentrated in about the middle half of the total range in specific gravity. This leaves, in round figures, 5 per cent of all samples spread over one fourth of the range at the light end and another 5 per cent covering about one fourth at the heavy end of the distribution. When a woodworker complains of difficulty with some wood it is often found that his complaint is really based on a small proportion of extremely light or extremely heavy pieces. Such pieces are frequently trouble makers because they depart so widely from the normal. They would in all probability give misleading results in test material where the number of samples is relatively small. Consequently all test samples were chosen from the 90 per cent of the pieces that lie in the middle half of the specific-gravity range.

The number of rings per inch also has some influence on the quality of the planed surface, at least in the ring-porous woods, like oak. Consequently 5 per cent of the pieces at each extreme were excluded. In other words, as far as rings per inch and specific gravity are concerned, the samples represent the log run with the freak pieces out. The angle that the rings make with the surface is another factor to be considered, since edge-grain and flat-grain lumber machine differently in some respects. Edge-grain or quartered lumber is usually a small part of the whole even in woods that recognize quartered grades, like oak, gum, poplar, or sycamore. In other hardwoods quartered boards are usually accidents. Only clear flat-grain pieces were used in the tests.

In brief, the test samples conformed to the following specification: Size, 1 in. × 4 in. × 3 ft; moisture content, 6 per cent; specific gravity, from the middle half of the range; number of rings per inch, from the middle half of the range; angle of grain, flat; number of samples, 50 per species; quality, clear.

Effect of Cutting Angles on Quality of Planing

The cutting angle appears to be the factor that more than any other affects the quality of the planed surface. To name the best cutting angle for a given wood under given conditions is difficult because of the number of factors involved.

Before discussing cutting angles in detail some definition of terms is desirable. The terms illustrated in Fig. 1 are generally accepted and have been used in this paper.

Knives 1 and 2 are held in the cutter head at a 30-deg angle with reference to the radius, and the clearance bevel *c* is the same for both, 40 deg. The cutting angle *a* is the angle between the face of the cutter and the radius. With a knife, like 1, that has only the clearance bevel, the cutting angle and the knife angle, or angle at which the knife is held in the head, are identical. Varying this latter angle is, of course, one way of changing the cutting angle, but it means changing cutter heads, which is quite a job in a cabinet planer. A more common way of changing the cutting angle is by the use of knives beveled on two sides, like knife 2, which has a cutting bevel or back bevel *b*. The

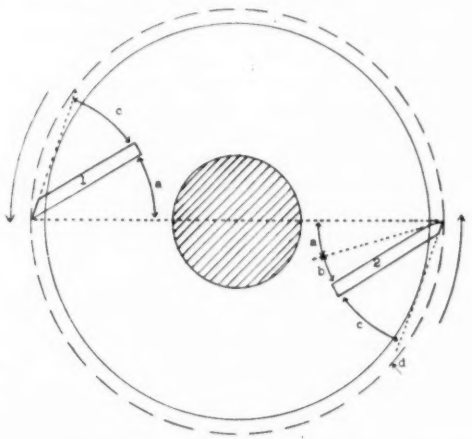

Fig. 1 Terms Used in Connection With Planer Knives (*a*, Cutting angle; *b*, cutting bevel; *c*, clearance bevel; *d*, cutting circle.)

planer used has a knife angle of 30 deg. By means of back bevels the other cutting angles used in this study, 25, 20, 15, 10, and 5 deg, were obtained. At each angle the samples were planed on one side at 36 fpm feed and 3600 rpm, then planed on the other side at 54 fpm feed and 5400 rpm. Figures used here are averages of these two feed-speed combinations.

Table 1 shows the scope of cutting-angle tests that have been

FIGS. 2 TO 6 EFFECT OF CUTTING ANGLES ON QUALITY OF PLANING

made so far. These tests cannot be considered complete until the blank spaces are filled in as a minimum. It will probably be desirable to include a somewhat wider range of cutting angles and possibly a few more woods as well.

It was hoped that data on six cutting angles would reveal a consistent trend for each wood, a definite optimum with results becoming increasingly poorer as cutting angles departed from the optimum in either direction. Most of them do show a definite trend in spite of minor inconsistencies. Table 1 is rather large, except for reference purposes, and graphs have been prepared that tell the story more plainly for the fourteen woods on which data for all six cutting angles are available.

In Fig. 2 willow makes a bad start with nearly 70 per cent of defective pieces at a 5-deg cutting angle, but improves steadily until 20 deg is reached when the trend reverses sharply. Cottonwood not only starts badly but gets steadily worse until the 25-deg angle is reached, after which some improvement is made. The cottonwood curve fails to show that the optimum has been found. Possibly a 0 or a 35-deg cutting angle would give better results than any of the angles actually used. It is interesting to note that although willow and cottonwood start close together the curves cross twice. Yellow poplar is not so much influenced by cutting angles as the other woods; results fall within a relatively narrow range, except for the 30-deg angle. Taking each of the four woods shown in Fig. 2 at its best cutting angle, magnolia makes much the best showing, and yet at 20 deg it is slightly more defective than the willow. For magnolia, as for cottonwood, it is possible that the best cutting angle was not among those used so far. The testing of cutting angles at 5-deg intervals should serve to locate the optimum angle approximately, provided that enough angles are tried.

Fig. 3 shows the results for sycamore, red gum, black gum, and soft maple. These woods agree much better in their general trend than do the preceding four which are also diffuse porous. The optimum appears to lie between 5 and 15 deg for sycamore and red gum, and 5 and 20 deg for soft maple. The black gum is not wholly consistent, but even here there is a certain wider range where better results obtain than at the extremes.

Three ring-porous woods, elm, hackberry, and pecan, are shown in Fig. 4. Definite optimums appear; for elm at 15 deg, and even there the results were none too good; for hackberry, which showed the widest variation from best to poorest of any wood, at 20 deg; and for pecan, which is not entirely consistent, around 25 deg. The angles at both extremes appear to be definitely bad for all three.

An interesting contrast appears in Fig. 5, which gives the results for three more ring-porous woods, red oak, ash, and white oak. The ash runs along without being greatly affected until the optimum is reached at 25 deg. Between 25 and 30 deg it takes a decided turn for the worse. The oaks, on the other hand, show a big improvement from 5 to 10 deg and are little changed at 15 and 20 deg, but much poorer results are obtained if the knife angle is increased to 25 and 30 deg. In two distinct respects the oaks showed up better than any other wood: (1) The optimums were slightly better than the nearest rival, pecan; (2) the range within which good results were obtained was much wider than for other woods.

In Fig. 6 the effect of cutting angles on the occurrence of the different planing defects is shown. Taking all defects into account there is little to choose between 10, 15, and 20 deg although the 10-deg angle is slightly the best of the three. Some of the samples had more than one kind of planing defect, which explains why each point in the all-defects curve is somewhat lower in numerical value than the sum of the four points directly below that represent the individual defects. Fuzzy grain takes a slightly inconsistent course; it is not greatly affected, but the general trend indicates poorer results at each extreme. Raised grain improves consistently as the cutting angle increases from 5 to 15 deg and gets somewhat worse beyond 20 deg. Cutting angles have a great deal more effect on chip marks than on any other defect, increasing from an occurrence of 5 per cent with a 5-deg cutting angle to 40 per cent with a 30-deg cutting angle. Chipped grain, in general the least common of the defects, increases slightly with increased cutting angles.

Effect of Jointing on Quality of Planing

To joint or not to joint is the subject of many a woodshop debate. Some foremen maintain that one-knife finish is good enough, that one knife does all the cutting anyway, and that jointing is therefore a waste of time. Others insist that each knife can and should be made to do its share of the work, that better finish is obtained in that way, and that jointing is necessary to bring this about. The answer to the problem, as to many other woodworking problems, appears that "it all depends." It depends, for instance, upon the requirements of the job, it depends upon the kind of machine being used, and it depends, not least, upon the skill of the operator. No one answer will hold true under all the varying conditions found in the trade. This paper gives the results of a series of jointing tests

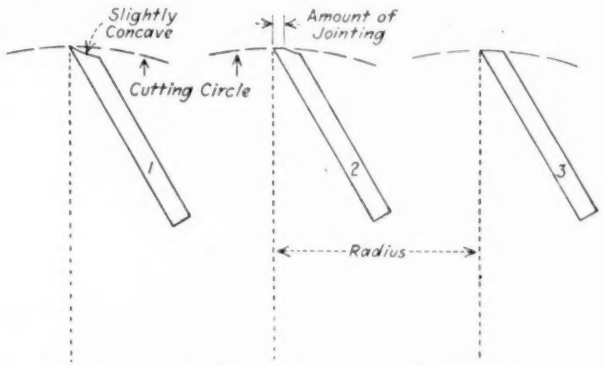

Fig. 7 Effect of Jointing Planer Knives

made with a 30-in. cabinet planer, a 20-deg cutting angle, a feed of 36 fpm, and a speed of 3600 rpm making a cut of $^1/_{16}$ in. Seven important hardwoods were tested at a moisture content of 6 per cent.

In the newly ground knife, like 1 in Fig. 7, the sharp cutting edge, has only a fine line of contact with the cutting circle, and there is ample clearance. But it is not possible to grind so that all the knives project exactly the same amount. A slight projection by one knife beyond the others causes that knife to do more than its share of the work. This often results in a one-knife finish, that is, a finish that shows only one knife mark for each revolution of the head. The first jointing is done to equal-

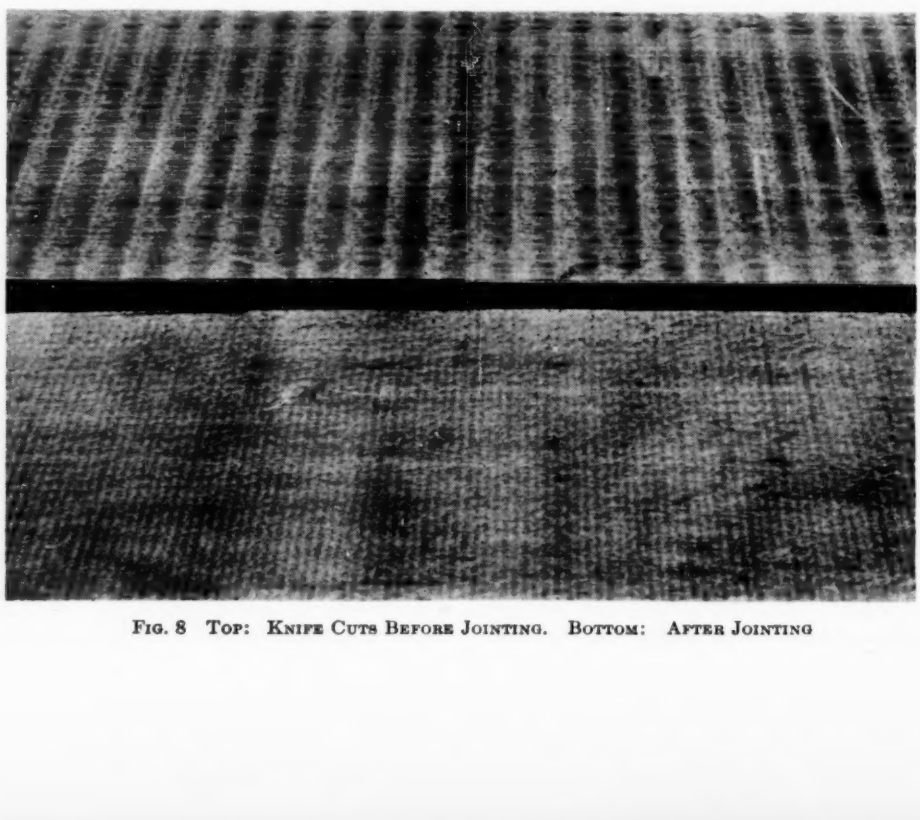

Fig. 8 Top: Knife Cuts Before Jointing. Bottom: After Jointing

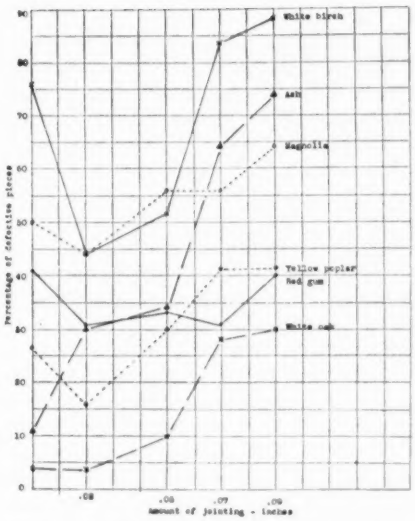

FIG. 9 EFFECT OF AMOUNT OF JOINTING ON QUALITY OF PLANING

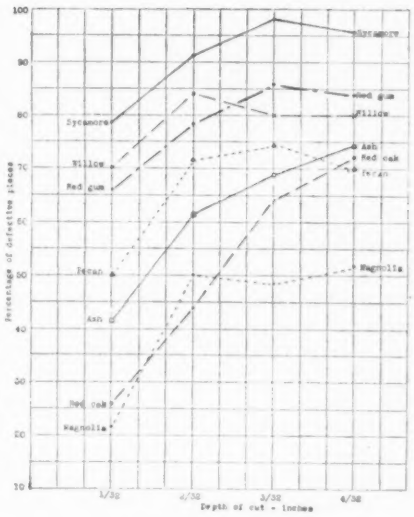

FIG. 10 EFFECT OF DEPTH OF CUT ON QUALITY OF PLANING

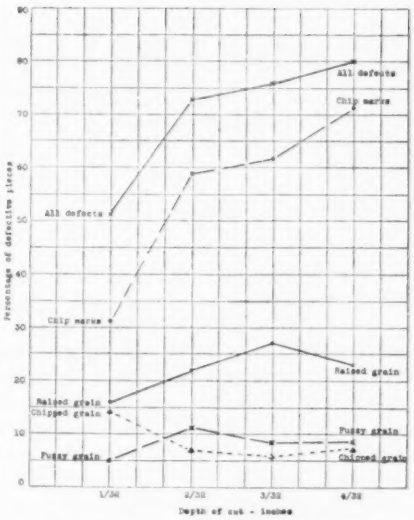

FIG. 11 EFFECT OF DEPTH OF CUT ON QUALITY OF PLANING

ize the projection of all knives and insure that each one makes its own cut in every revolution. Fig. 8 contrasts the finish before and after jointing. The same feed and speed were used with both samples, of course, and both are hard maple.

Whenever the knives become dull or nicked, jointing is again resorted to from time to time as a sharpening process. Repeated jointings gradually generate a pronounced "heel" which has no clearance because it conforms to the cutting circle. See 2 Fig. 7. Theoretically, it may be possible to joint until the entire knife end conforms to the cutting circle, as in 3. However, when an amount of heel about like that at 2 was developed a halt was called because of mechanical difficulties and because the data already obtained told the story. In practice the poorer quality of the work would probably have caused the operator to grind off most of the heel long before the condition shown at 2 was reached. A secondary effect of jointing is to produce a thicker, stronger cutting edge that offers more resistance to nicking.

Because of the knife marks the planed surface is not strictly plane but consists of a series of ripples the width of which from crest to crest is governed by the rate of speed and feed of the machine. The wider the ripples the deeper they inevitably are and the more work is necessary to prepare the surface for any fine finish. It is probably immaterial whether the ripples represent one-knife or four-knife finish provided their spacing is the same. In either case the number of marks per inch will depend upon the potentialities of the machine used and upon the requirements of the job. A finish that is wholly satisfactory for boxes may be entirely inadequate for corestock. However, the tests described here were concerned primarily with high-grade finish and were made on a machine designed for such work.

A publication of the Forest Products Research Laboratory of England gives some figures that are of interest in this connection. For a four-knife cutter head of about a 5-in. cutting circle at 3600 rpm and a feed of 30 fpm the depth of the ripples is given as 0.0000364 in. It further states that a projection of 0.0006 in. in one of the four knives removes the ripple marks of the other three. These figures seem almost insignificantly small, yet such knife marks are plainly visible to the naked eye and corresponding revolution marks can be easily felt with the finger.

The conclusion to be drawn from Table 2 is to joint the knives, but joint lightly.

The first run was made with knives that had just been ground in the machine but not jointed. For the second run the knives were jointed lightly but enough to touch the full length of each blade. Measurements made with a small steel scale and a hand lens near each end and at the middle of each blade show the joint to vary only slightly from an average width of 0.02 in. The average width of the jointed portion of the blade was increased to 0.05, 0.07, and 0.09 in. in the third, fourth, and fifth runs, respectively, as shown in Table 2.

Table 2 is based upon the occurrence of chip marks, chipped grain, raised grain, and fuzzy grain. On this basis the unjointed knives as a rule give substantially poorer results than do knives that were lightly jointed. When knife marks, as well as these defects, are taken into account every piece planed with unjointed knives may be considered defective because at this feed and speed one-knife finishing gives about eight marks per inch which requires considerable sanding in itself even if the piece is otherwise perfect. The jointed knives, on the other hand, give satisfactory knife marks regardless of the amount of joint. As the amount of

joint is increased, however, the quality of the planing becomes poorer. These data are shown graphically in Fig. 9, except that red oak, which follows white oak closely, is omitted.

Chip marks were the commonest defect. Chipped grain was also common with the unjointed knives. Fuzzy grain was occasionally found, particularly when heavily jointed knives were used.

Effect of Depth of Cut on Quality of Planing

The depth of the cut that is made by the planer may have a decided influence on the quality of the surface that results. There are, of course, many times when conditions leave the operator little choice in this matter. Again conditions sometimes make a preliminary roughing cut desirable and this permits some leeway in varying the depths of the subsequent cuts.

Table 3 shows the result of tests made at depths of cut of $^1/_{32}$, $^2/_{32}$, $^3/_{32}$, and $^4/_{32}$ in. Except that the shallowest cut is the best without exception, the different woods tell somewhat different stories. Some, like ash, beech, and the oaks, are greatly affected by depth of cut, while others, like elm, sycamore, and willow, run along in a relatively uniform way without much regard to this factor. On the average, the shallower the cut the better the results; however, the shallowest cut is much the best of the four, and there is relatively little to choose between the other three. Burning of knives, which often results from extremely shallow cuts, did not occur. A run of 2400 linear feet of mixed hardwoods 4 in. wide on a 30-in. cabinet planer is one thing, and an all-day run at much higher feed and speed with a molder, for instance, is a different proposition, and results would not necessarily be identical. The behavior of seven typical woods at different depths of cut is shown in Fig. 10.

The influence of depth of cut on the individual defects is shown in Fig. 11. There is a rapid increase in all defects between $^1/_{32}$ and $^2/_{32}$ in. with a gradual increase up to $^4/_{32}$ in. Chip marks closely follow this trend, in fact they are so much more common than other defects that they largely govern the trend for all defects. Raised grain shows a steady increase in occurrence up to $^3/_{32}$ in., but drops slightly at $^4/_{32}$ in. Chipped grain, contrary to the general trend, is worst at the shallowest cut and about the same in succeeding cuts. Data obtained in this test fail to indicate that depth of cut has any appreciable influence on fuzzy grain.

Obsolescence in Woodworking Machinery

By PAUL T. NORTON, JR.,[1] BLACKSBURG, VA.

The author discusses the economic aspects of obsolescence of production machinery in general and its relation to cost accounting.

With respect to the woodworking industry, index figures for recent years are given of machinery purchases for comparison with figures for orders for metal-working machinery.

The author then points out the danger to an industry as a whole of the use of obsolete equipment and continues with a discussion of the problem in its relation to profits and governmental depreciation regulations. Finally there is considered the subject of unamortized values in studies of machine replacements.

OBSOLESCENCE in machinery is in some ways similar to premature old age in human beings. If both human beings and machinery are considered merely from the standpoint of earning power, in each case there is a normal productive period and, in an increasing number of cases, this productive period ends before the actual physical life comes to an end. In the case of both human beings and machinery, it is often possible to extend the productive period through rehabilitation, but it should be remembered that in both cases the premature loss of earning power is generally caused by changes in methods to which neither the human beings nor the machinery are readily adaptable.

There is also a certain similarity between the methods which may be used to eliminate the serious economic losses due to premature old age in human beings and to obsolescence in machinery. From a purely economic standpoint there is no loss through either premature old age in human beings or through obsolescence in machinery, provided both have sufficient earning power during their productive lives to take care of their physical lives. In the case of human beings the attempt is being made to solve the problem through old-age pensions. In the case of machinery there is no economic loss, no matter how short the economically productive life may be, provided the machinery has had sufficient earning power during its economically productive period to enable it to pay back both its ordinary operating expenses and also the money invested in it plus a proper return on the investment. If this has been accomplished, the obsolete machine can be scrapped without any economic loss whatever, even though from a purely physical standpoint the machine may be just as good as it ever was. If such a machine is scrapped, or otherwise displaced, before it has reached the end of the life that was previously estimated as its economically productive period, there will almost certainly be an apparent or book loss. This apparent loss seems to be due to premature displacement, but it actually represents a charge which should have been distributed over the real economically productive period of the machine. If there had been no error in the previous estimate of productive life, all necessary charges would have been made against the machine during its real economically productive period, and there would be neither a real economic loss nor even an apparent or book loss when the machine is displaced. The economy study, which is made in order to determine whether a machine should be replaced by a more modern one, should be based on the realizable value of the present machine and should disregard completely any accounting adjustment that may be necessary because of a difference between the book value and realizable value of the present machine. The problem of unamortized value will be discussed again at greater length later in this paper.

There is no excuse for neglecting the serious economic problem caused by obsolescence of machinery and other physical assets. Theoretically the problem is easy to solve. All that is necessary is to determine the economic life of the proposed asset and then to write off the first cost of the asset from its earnings during the economic life. The real difficulty is that it is almost impossible to predetermine the economic life of an asset, but that is no reason for not making as accurate an estimate as is possible. Factors of safety are customary in both engineering and business estimates, and it would seem desirable also to use a factor of safety in making future life estimates.

Definition of Obsolescence

The Committee on Reserves for Rehabilitation of the Machinery and Allied Products Institute has adopted the following definition of obsolescence:

> Obsolescence is the loss in value of an asset brought about by exhaustion of raw materials, or the development of another asset that will better do the same thing or replace the product, before the original estimate of the life of the asset has elapsed and the cost has been recovered through depreciation; extraordinary depreciation of an asset resulting from the development of new processes or inventions.

The first part of this definition is rather unusual in that it makes obsolescence depend upon whether the original cost has been recovered through depreciation charges. This part of the definition does suggest one important point, namely, that management's willingness to replace a present machine with a more modern one depends to a large extent upon whether the investment in the present machine has been recovered through depreciation charges. As previously explained from a purely economic standpoint this should not be the case, but it is certainly true that management is faced with a serious practical problem in making replacements which involve large accounting adjustments due to unamortized book values. No matter what one's concept of obsolescence may be, it is certainly true that obsolescence presents no real problem whatever in cases where the investment has been fully recovered through depreciation charges before the machine is displaced.

Extent of Obsolescence in Woodworking Machinery

It does not seem possible to obtain definite figures, but apparently most persons who have studied the problem feel that there is even more obsolescence in woodworking machinery than in most other kinds of machinery used in the manufacturing industries. Studies have been made which give at least a rough idea of the amount of obsolescence in metal-working machinery.

[1] Professor of Industrial Engineering, Virginia Polytechnic Institute. Mem. A.S.M.E.

Presented at a joint meeting of the Wood Industries Division of The American Society of Mechanical Engineers and the Cost and Production Division of the Southern Furniture Manufacturers' Association at High Point, North Carolina, September 21–23, 1938.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until March 10, 1939, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of the author, and not those of the Society.

There are also indexes which show something about the trend in the production of both machine tools and woodworking machinery. Perhaps it may be possible to form some sort of opinion with regard to the extent of obsolescence in woodworking machinery by comparing these three series.

The *American Machinist* made extensive studies of obsolescence in metal-working machinery in 1925, 1930, and 1935. These studies indicated that 44 per cent of metal-working machinery in the United States was over ten years old in 1925, 48 per cent in 1930, and 65 per cent in 1935. There is, of course, no direct relationship between age and obsolescence of machinery, but the figures just quoted do seem to indicate that there is a large amount of obsolescence in metal-working machinery, and that the condition became progressively worse during the decade between 1925 and 1935. No one familiar with the low rate of manufacture of such machinery during the years 1931 to 1934, inclusive, would be surprised at these figures, but many persons will doubtless be surprised to learn that it has been estimated that on July 1, 1937, metal-working machines over ten years old still made up 61 per cent of the total of all metal-working machinery, in spite of the much greater activity in the machine-tool industry between January 1, 1935, and July 1, 1937. It would require many years of great activity in the machine-tool industry to bring the average age of metal-working machinery back to the 1925 figure.

The machine-tool index gives dollar values of orders received and is based on 1926 shipments as 100 per cent. The index was 131.2 for 1928, 155.8 for 1929, and then dropped rapidly, being 70.9 for 1930, 41.0 for 1931, and 19.6 for 1932. It then started to climb, but was only 27.1 in 1933 and 46.2 in 1934. No wonder 65 per cent of metal-working machinery was found to be over ten years old at the beginning of 1935. The last three years have told an entirely different story. The index increased to 86.0 in 1935, to 136.6 in 1936, and to 186.9 in 1937. An unusually large percentage of these machines have been exported during the last two or three years, but the domestic orders alone would have brought the index up to 108.4 for 1936 and to 129.1 for 1937.

There is also an index for woodworking machinery but it tells a very different story during the last several years. This index gives shipments and is based on the average shipments during 1922, 1923, and 1924 as 100. This index fell to 3.2 in March, 1933, averaged only 8.4 for the year 1934, 13.8 for 1935, 24.3 for 1936, and 30.1 for 1937. To make the woodworking-machinery and machine-tool figures more comparable it seems desirable to translate the woodworking-machinery figures to a percentage of orders received in 1926 and also to use only the domestic orders for machine tools, as it seems probable that the export shipments of woodworking machinery were much less important during the last few years than was the case with machine tools. Table 1 shows the indexes with these changes.

TABLE 1 INDEXES OF MACHINERY ORDERS RECEIVED

Average for year	Woodworking machinery	Domestic machine tools
1934	16.0	36.7
1935	21.9	64.9
1936	33.6	108.4
1937	38.5	129.1

These figures are offered for what they may be worth and with no claim that they prove anything with regard to obsolescence in woodworking machinery. They do seem to indicate quite clearly, however, that during recent years the purchases of new woodworking machinery have been much less in comparison with the middle 1920's than has been the case with the domestic purchases of new machine tools.

There may easily be some reasons other than a comparatively large degree of obsolescence for what on its face would seem to be an unsatisfactory situation with respect to the equipment of the woodworking industries. In the middle 1920's large quantities of woodworking machinery were being purchased for use in factories producing wood bodies for automobiles. The woodworking industries have lost practically all of that important outlet for their productive facilities, as well as other outlets which were less important than automobile bodies but did require in the aggregate a large amount of woodworking machinery.

The great peaks and valleys in the production curves of manufacturing of all types of machinery are due primarily to the fact that the users of machinery are actively in the market for new machinery only when there is an active demand for their own products. In 1937 there was an active demand for most products which require machine tools for their production, while there does not seem to have been as active a demand for the products of the wood industries which use the bulk of woodworking machinery.

Even if it could be shown that the comparatively small production of woodworking machinery in recent years was due merely to a general decrease in the demand for wood products, and did not mean that woodworking machinery was much more obsolete than other types of machinery, there would be little cause for satisfaction on the part of the owners of the woodworking plants that are still able to operate. How soon will there be further inroads by other raw materials into those fields which are still largely supplied by the woodworking industries? The history of this country is full of examples of raw materials which have been in a large measure supplanted by other raw materials, principally because the older industries did not avail themselves of the machines and productive methods which inventive genius had made available. Some of these industries have now taken advantage of these newer methods and are regaining their former positions of importance. What will be the answer of the woodworking industries to this challenge?

Some Economic Results of Obsolescence of Machinery

Most engineers are familiar with important industries which neglected to make adequate depreciation charges and were unable to replace equipment when it became obsolete. For years individual concerns in these industries had seemed to be profitable and had paid satisfactory dividends to their stockholders, but a large part of these dividends were paid from apparent profits and not from real profits. These companies were living on their capital. What is more, both the company and the stockholders paid taxes to the federal government on apparent profits which were not really profits at all. The corporation paid these taxes on the entire amount of these apparent but unreal profits; the stockholders paid individual income taxes on that part of these apparent profits which were paid to them in dividends. As long as corporation taxes were small and in those cases where ample reserves were retained by the corporation, the tax part of the problem was not such a serious one. With present high corporation and individual taxes and with the bringing of pressure upon corporations to pay out a large part of their book profits, the situation becomes serious indeed.

From the standpoint of corporation taxes which may be levied on book profits which are not real profits, because depreciation charges have been inadequate, the situation just described has become somewhat less serious because of the recent modification of the penalty tax upon undistributed book profits, although the normal tax is now so high as to make it very costly if any of the taxable profits are not real profits. From the standpoint of the ultimate solvency of the corporation and its ability to replace obsolete equipment, the situation is still just as dangerous in cases where corporations distribute part of their capital as dividends out of apparent but unreal profits. These dividends are

apt to be spent by the stockholders (at least that part which is left after income taxes have taken what is really a capital levy) and it is not an easy matter for such corporations to get this money back from their stockholders, or indeed to obtain from anyone the funds which may be needed for machine replacements.

Recent Changes in Depreciation Regulations

Even though the penalties of the Revenue Act of 1936 have been modified considerably, Treasury Decision 4422, under which so many depreciation rates have been drastically reduced, is still in force. It is probable that there have been many cases where the present depreciation regulations have resulted in the disallowance by the federal government of adequate depreciation charges, and it should be remembered that every dollar of real depreciation which is disallowed means exactly one dollar of taxable but unreal profits. On the other hand, those who so vehemently condemn Treasury Decision 4422 should remember that there is nothing in the new regulations which will prevent the owner of depreciating assets from getting the depreciation which he considers proper, including a reasonable allowance for obsolescence, provided his rates are based upon a replacement policy which actually replaces the assets when they become obsolete. But it is no longer possible for one to depreciate at a rate of say ten per cent when he uses the assets for from fifteen to twenty years. How can anyone expect the government to allow a high depreciation rate if the actual life is so much greater than the life which is equivalent to the depreciation rate which is claimed?

One of the reasons why so many owners of machinery object to the new depreciation regulations is that most of these persons do not have adequate records with which to satisfy the Bureau of Internal Revenue that their depreciation claims are reasonable. These persons would do well to reconcile themselves to the fact that they will not be able to obtain adequate depreciation charges for tax purposes unless they do have adequate records, which means that in most cases they must keep individual records of their principal items of machinery instead of attempting to use a flat depreciation rate on a large group of machinery with different life expectancies. Many of the recent decreases in depreciation rates have been due to excessively large depreciation charges in previous years and in such cases there is nothing that the owner of the machinery can do about the matter now, except perhaps in some cases to go back to years still open and reduce the depreciation charges on those returns so as to make it possible to charge additional depreciation in the future. But even if it is reasonable for future depreciation charges on present equipment to be reduced because of excessive depreciation charges in the past, these lower rates should not be accepted without careful examination in the case of machinery which may be purchased in the future. The only safe procedure is to maintain adequate records of individual machines and to make the best possible estimates of the future life of each machine. If this is done, and if replacements are actually made when the estimated lives come to an end, there is no reason whatever why the present depreciation regulations should prevent any owner of machinery from obtaining adequate depreciation charges on his tax return.

Properly administered, the new depreciation regulations should hurt no one, but there is serious danger that the present tendency to reduce depreciation rates may in future years greatly increase the loss due to obsolescence of machinery, because there will be a tendency for obsolete and practically worthless equipment to be carried at high book values at the time such equipment would ordinarily be replaced. No company cares to write off large amounts when replacing equipment. In fact in many cases it is impossible for a company to do so and at the same time maintain its credit rating and appearance of solvency. But continuing to use obsolete equipment under these conditions will not solve the problem. Competitive conditions in an industry or between industries make it necessary for a company to have modern methods and modern equipment if it is to sell its products at a profit.

Unamortized Values in Replacement Studies

It has often been claimed that, in making a study to determine whether a machine should be replaced, any unamortized value of the present machine should be charged in some way against the proposed machine. Most of the best-known replacement formulas do this in one way or another, but it is heartening to note that in a survey made some years ago a large majority of the companies replying to a questionnaire stated that they would not think of charging this unamortized value against the future, but instead would charge it against profit and loss or surplus. It is probable that in most cases these companies were not so much interested in economic theory as in the competitive disadvantage that would result if they charged into their future costs an item which their competitors would not have to worry about if these competitors did not have to consider such unamortized values. Whatever the reason, these companies certainly gave the correct answer, both practically and theoretically.

Any difference between the book value and the realizable value of replaced equipment represents additional depreciation which actually occurred in the past during the life of the replaced equipment and which should have been charged as a part of the cost of the products of the replaced equipment. The fact that it may not have been so charged does not alter the fact that the depreciation actually occurred in the past. What is more, this depreciation would undoubtedly have been charged in the past if the estimate of the life of the replaced equipment had been correct. To attempt to charge this past cost against the future is just as unthinkable as to charge any past loss against the cost of some specific future product, when making a cost estimate for the purpose of setting the price at which this future product would be sold.

But this apparent loss, which seems to occur when there is a difference between the book value and the realizable value of a replaced machine may not be a real loss at all. The replaced machine may in reality have been so profitable that it would have shown a real profit even if the actual depreciation had been charged against it during its life. But no matter whether the machine was profitable or unprofitable, the profit or loss occurred in the past and there is no justification whatever for attempting to charge even a real loss against the operations of the future.

To show further the absurdity of the argument that any difference between book value and realizable value should be charged against the proposed machine, let it be supposed that this new machine in turn is replaced before it has had an opportunity, at the depreciation rate used, to pay back its own loss in value plus that remaining from the previous machine. This might continue indefinitely and eventually some machine might have to bear such heavy fixed charges as to make it impossible for its owners to compete with others who had simply written off such differences between book values and realizable values when these differences became apparent.

It is possible that some persons, who charge unamortized values of present machines against proposed machines in making replacement studies, would not actually make such charges on the books if the replacements were actually made. But there is certainly no logic in that attitude. The replacement study should be based on the assumption that the replacement will be made if the results of the study, including both the tangible and intangible factors, indicate that the replacement would be profitable. In making the study the present equipment should be put

in at its realizable value and depreciation and other charges assessed against the present equipment on that basis. If, however, the study indicates that the replacement would not be profitable, the present equipment need not necessarily be written down on the books to its realizable value. The very fact that the replacement has been shown not to be advisable proves that the present machine is not obsolete and therefore realizable value for some other purpose is not a relevant factor. However, the fact that consideration has been given to the replacement indicates that the equipment is probably nearing the end of its economic life, and it would therefore seem desirable to make a new estimate of future life and to set a new depreciation rate accordingly.

Conclusion

It would seem from the foregoing discussion that the problem of possible obsolescence of his woodworking machinery is one of the most important problems which the owner of a woodworking factory must face.

While no definite figures are apparently available, there are strong indications that there is an excessive amount of obsolescence of equipment in woodworking factories; a condition which may cause the woodworking industries to lose some of their present markets to industries using other raw materials.

Under present high federal tax rates and depreciation regulations, a company which does not replace equipment when it is really obsolete is quite likely to pay taxes on apparent profits which are not really profits at all, and also is likely to find it difficult to obtain the necessary funds when it is finally evident to everyone that replacements should be made.

Replacement studies should be based on values as they will be if the replacement is made, and any difference between book values and realizable values of present machinery should be disregarded completely when making such studies. Book values are apt to be much too high in industries with a large amount of obsolescence, and this condition is apt to become worse under present depreciation regulations. Much of the present obsolete equipment was to a large extent written off the books under the previous more lenient depreciation regulations. In the future an owner of depreciating assets will not be able to secure approval of adequate depreciation claims unless these claims are based on proper records and a reasonably definite replacement policy. On the other hand, there is no reason whatever why depreciation allowances under the present regulations should not be adequate, provided the owner of depreciating assets does his part by keeping proper records and by replacing assets which he considers to be obsolete.

The Mechanical Characteristics of Rubber

By F. L. HAUSHALTER,[1] AKRON, OHIO

The author presents some of the characteristics of rubber in which engineers may be interested from a design standpoint, without going into detail on every phase of the subject which might affect design. He points out that there is a vast amount of data still to be collected, especially to establish accuracy on some points that seem to be in doubt. He suggests that to obtain data accurately, it will be necessary to conduct tests in rooms where humidity and temperature are closely controlled. The author presents data showing that moduli of elasticity and the creep of shear and torsion springs are decidedly affected by temperature. Presented graphically are curves showing load-deflection, shear, and torsion characteristics of various rubber specimens including compression pads, rubber shear sandwiches, and torsion springs.

TO TREAT a subject as large as this is a tremendous task, and the author, therefore, plans only to go into phases which may add something to what has already been published, and into others, which may seem to need further clarification.

When considering rubber as an engineering material we should bear in mind that it is a vegetable product which on being coagulated from the sap of a tree becomes a closely packed mass of rubber globules or hydrocarbons separated by their adsorption film of protein, coming together with some precipitated protein and other serum substances, trapped between the particles during coagulation and drying. We should also remember that the carbon atoms of the rubber molecule lay in zigzag linkages of various lengths which straighten out when stretched, perhaps with free rotation at the points of the single bonds, for the molecule of the rubber hydrocarbon has the formula $(C_5H_8)_x$, x varying perhaps from 500 to 3000, with one double bond for every C_5H_8 group. The resistance to slippage of the molecule depends on the orientation of the linkages and on the value of the molecular cohesion, as measured by the Van der Waals forces.

Sulphur mixed with rubber mechanically combines with it chemically as a solution, at the application of heat, and even at room temperatures. The change, known as vulcanization, is not a simple chemical phenomenon, for the rate of combination increases with concentration of sulphur, and for initial concentration of sulphur the rate of combination remains constant until most of the sulphur is consumed. The rate of combination is also influenced greatly by the presence of accelerating substances, acting as catalysts.

Vulcanization greatly reduces the slippage or creep in the molecular structure of the rubber. Evidence indicates that bridges of sulphur tenaciously join together the molecular structure with an attending stiffening action. Vulcanization is undoubtedly an establishment of cross bonds, perhaps crystalline in character, between long chain fiber molecules, both chemical and mechanical in nature.

When rubber, either raw or vulcanized, is stretched it becomes warm, and when stretched even small amounts the heat generated increases sharply above 70 per cent extension. The mechanical work done on the rubber when it is stretched is only a small percentage of the total latent heat. Hence, the heat generated is something more than friction; it may be potential energy, stored by strain of an assembly of oriented single molecules, and when the rubber is stretched there is an evolution of thermal energy corresponding to a heat of crystallization. Likewise, rubber stretched to a given percentage, on being heated, contracts.

There is a tight packing of the rubber molecules as rubber is stretched, because there is a slight increase in density and a very appreciable increase in apparent hardness. The change of durometer hardness with stretch for two rubbers, one a vulcanized pure gum of durometer 40 and the other a carbon-black reinforced stock of durometer 65, is shown in Fig. 1. This closing up of the structure greatly reduces the susceptibility of the rubber to attack from oxygen, its deadly enemy. The greatest vulnerability of rubber to oxygen or ozone is just at the point of change of hardness; the effect then rapidly diminishes as the hardness increases. It has also been found that the susceptibility of vulcanized pure gum to tearing is greatest at from 50 to 150 per cent elongation.

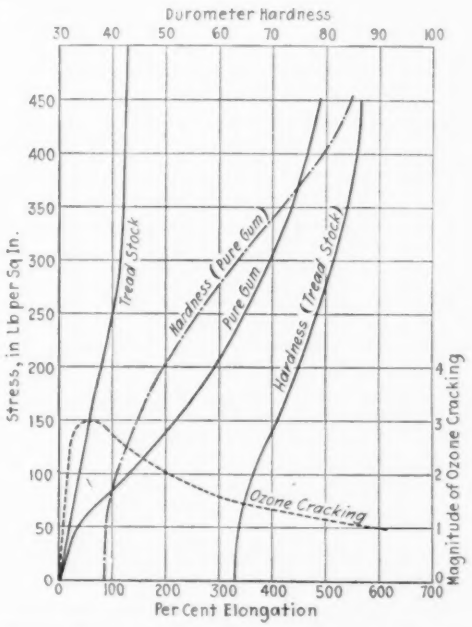

FIG. 1 STRESS-STRAIN RELATIONS AND CHANGE IN DUROMETER HARDNESS WITH STRETCHING OF TWO RUBBERS, ONE A VULCANIZED PURE GUM WITH A DUROMETER OF 40 AND THE OTHER A CARBON-BLACK REINFORCED STOCK OF DUROMETER 65

Fig. 1 also shows typical stress-strain curves for the rubbers mentioned in the preceding paragraph when tested in one-directional tension. Rubber tested in tension in one direction is in compression in the other two planes. A highly valued piece of work by Sheppard and Clapson (1)[2] showed a direct relation between compressive force and equivalent two-way tensile forces. Hollow spheres of rubber were inflated with gas pressure and elongation measurements taken in two directions at right angles

[1] Development Engineer, B. F. Goodrich Co.

Contributed by the Rubber and Plastics Committee of the Process Industries Division, and presented at the Fall Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held at Providence, R. I., October 5–7, 1938.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their autnor.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

to each other. The compressive force was computed from the gas pressure, and the degree of compression in the rubber computed from the reduction in wall thickness of the rubber. A continuous tension-compression curve was obtained in this manner for rubber up to a compression of 97.4 per cent. Fig. 2 shows the results of the work of Sheppard and Clapson (1) plotted with tension and compression to the same scale. For a stock of the cold-cured pure-gum variety of toy balloon, which had a tensile strength of only 570 lb per sq in. at 700 per cent elongation at break, the compressive load at 97.4 per cent compression went to 13,000 lb per sq in. of original cross-sectional area. There is a point of inflection in the tension curve but none in the compression curve.

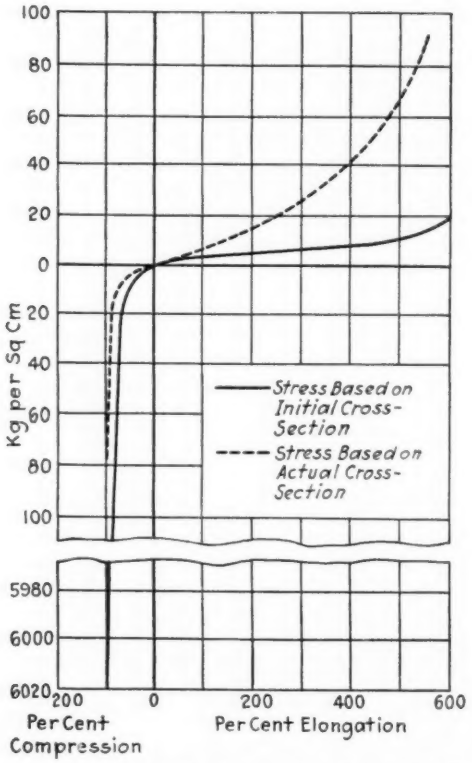

FIG. 2 CONTINUOUS TENSION-COMPRESSION CURVE FOR PURE-GUM RUBBER

Rubber is used but little in tension by engineers, although there is no good reason for not using it more extensively now that rubber can be bonded securely to metal. Rubber can be used safely in tensions up to 30 to 40 lb per sq in. and when working in this region of elongation the load-deflection curves for stocks with a high rubber content is very close to a straight line, meaning that the modulus of elasticity is very nearly a constant within this range. For a pure-gum vulcanizate of about 40 durometer, the modulus of elasticity is about 180.

Rubber has been used longest by engineers in compression, as buffers, shock absorbers, and bumpers of various types. A great number of data have been collected on compression rubber, some of the most noteworthy being by Birkitt and Drakeley (2) and J. Morrison (3). Their work gives us a basis for design of compression-rubber parts. Birkitt and Drakeley (2) investigated the influence of various lubricants on the load-deflection characteristics of compression-rubber disks of the same dimensions and recipe. The result of this work is shown in Fig. 3. What the author wishes to emphasize is that up to 20 per cent compression the curves obtained by using on the loading plates lubricants of soap, glycerine, oildag, and vaseline, practically coincide. It is the author's experience that compression rubber as a load-carrying member should be limited to 20 per cent compression under normal loading. The author wishes to amplify this fact later, but the chief reason is to keep the creep or drift in the rubber to a reasonable figure. Too often compression pads have been used under loads which very badly distorted the rubber, and the rubber took on excessive creep in a short time.

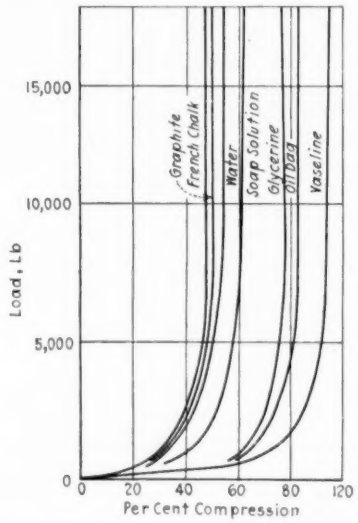

FIG. 3 INFLUENCE OF VARIOUS LUBRICANTS ON THE LOAD-DEFLECTION CHARACTERISTICS OF LIKE RUBBER DISKS

Birkitt and Drakeley (2) showed that vaseline is perhaps the best lubricant to use in investigating the laws of compression rubber. Vaseline was placed on the rubber and loading plates just prior to making the tests so that swelling and softening of the rubber would not influence the results. Using disks of various areas, from 2.4 sq in. up to 5.6 sq in. of the same thickness and compound, the rubber being a pure-gum stock of about 40 durometer, they obtained the results shown in Fig. 4. Note that even up to 30 per cent compression all the curves closely coincide. The thickness of all disks was only 0.12 in. If we figure the modulus of elasticity E from this curve as closely as

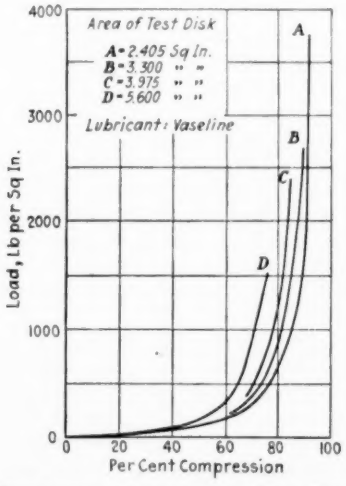

FIG. 4 LOAD-DEFLECTION CHARACTERISTICS OF RUBBER DISKS OF VARIOUS AREAS BUT THE SAME THICKNESS AND COMPOSITION, USING VASELINE AS LUBRICANT

possible, we obtain 188, which is very nearly three times the shear modulus for a stock of 40-durometer hardness.

Birkitt and Drakeley (2) also used vaseline in testing disks of the same recipe as used in the previous test, the thickness varying from 0.157 in. to 0.880 in. The area of the test piece was 2.405 sq in. Fig. 5 shows these results graphically, and Table 1 gives the actual figures obtained. The values at 41.7 lb per sq in. load for all disks lie very close to the curve drawn. If we take the average value of percentage compression at 41.7 lb per sq in., we get a modulus of elasticity of 198, which is only 5.3 per cent greater than obtained on the disks of the same thickness but with different areas.

TABLE 1 EFFECT OF VASELINE ON COMPRESSION DISKS OF VARIOUS THICKNESSES

Thickness of disk, in.	Compression, per cent, at loads in lb per sq in. of			
	41.7	417	1668	2930
0.157	23.2	55.4	72.6	80.2
0.360	19.7	56.2	70.0	74.5
0.466	21.4	62.2	75.2	80.6
0.607	21.5	61.1	74.2	77.5
0.752	20.3	61.1	74.6	78.5
0.880	20.6	62.6	76.4	80.0
Avg	21.1	59.8	73.8	78.6

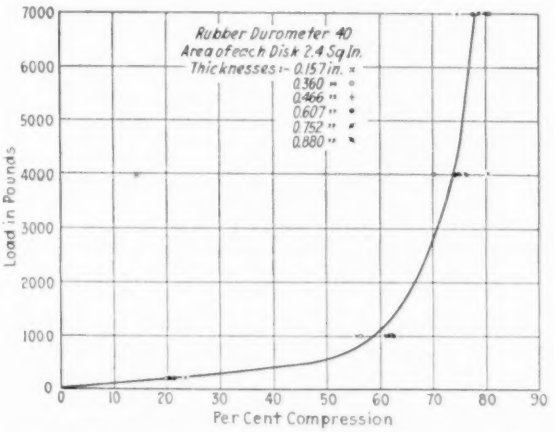

FIG. 5 EFFECT OF VASELINE IN COMPRESSION LOADING OF RUBBER DISKS, USING SMOOTH PLATES

Therefore, it appears from the foregoing that the modulus of elasticity in compression is three times the shear modulus where lubricated surfaces are used and the loading plates are smooth. Morrison (3) later confirmed the work of Birkitt and Drakeley (2) with the disks shown in Table 2. Fig. 6 shows the results of the tests without the use of a lubricant, the plates being serrated by grooves 1/16 in. deep. The rubber was of the same recipe in each case and had a durometer hardness of 55. Fig. 7 shows the results on the same size samples tested between smooth plates lubricated with vaseline. The vaseline drew the curves closely together and, with the exception of curve *A*, the curves almost coincide up to 20 per cent compression. Taking a mean value for the compression of curves *B*, *C*, *D*, and *E*, we obtain a value for *E* of 340, which is equivalent to a durometer hardness of about 57 according to our latest data on modulus of elasticity. Morrison's durometer may have read 2 points lower than the author's.

Morrison (3) took a test piece of this same rubber, 5 in. long, 1 in. wide, and 1/8 in. thick, and obtained a stress-strain curve in tension. The curve was straight up to 40 per cent elongation and within this range the modulus of elasticity in tension was 320 as compared to 340 for the compression value. This checks very closely with three times the modulus of elasticity in shear for rubber of 55 durometer.

TABLE 2 DIMENSIONS OF DISKS USED BY MORRISON (3)[a]

Curve[b]	Disk dimensions: Outside diam., in.	Inside diam., in.	Thickness, in.	Width, in.	Ratio of thickness to width
A	6 3/16	3 3/4	1	1.28	0.780
B	5 1/4	2 1/2	1	1.38	0.725
C	6	2	2	2.00	1.000
D	5	1	3	2.00	1.500
E	4 1/8	1	5 7/8	1.49	3.940

The author believes that the following conclusion can now be reached: The difference between the load-compression curves, with and without the use of vaseline as a lubricant, can be attributed to the high coefficient of friction between rubber and unlubricated plates.

This conclusion is further supported by tests on sponge-rubber disks. Load-compression tests made on 1, 2, 4, 6, 9, and 14 disks in a stack are shown graphically in Fig. 8. The disks were of medium sponge rubber with a cut edge, and were 3 in. outside diameter, 1 in. inside diameter, ⅜ in. and ¼ in. thick. Up to 25 per cent compression the points all fall very nearly on the same line. The air cells collapse and there is very little consequent distortion of the rubber.

Assuming that the coefficient of friction is the factor which destroys the ratio of 3 to 1 between the modulus of elasticity in compression and that in shear, is there a straight-line relationship of any quantity between these two moduli? The author has found that such a relationship exists if certain proportions of effective width to height are maintained and deflections limited to 15 to 20 per cent of original height. This relationship is based on empirical data. The practical application to be found in such data is that compression rubber, to be used as a load-carrying member, should have its deflection limited to 15 to 20 per cent of the original height in order to stay within reasonable values of creep in the structure. All compression-rubber slabs, disks, or cylinders, whether bonded to metal end plates or not, which the author has investigated, and where the ratio of thickness to effective width of rubber is equal to 1 or a little less, the load-compression curve is practically a straight line up to 20 per cent deflection. Under these conditions it has been found that the modulus of elasticity in compression is very close to 6.5 times the modulus of rigidity or shear.

What really happens is that the high frictional engagement between the rubber and loading plate, in not permitting the rubber to slip, causes a considerable proportion of the loading force to be dissipated as a force at right angles to the direction of load application. One has only to view a compression-loading test to be convinced of this.

Effective width is defined as the width of the maximum cross section of rubber. For a 1-in. cube this would be 1 in. For a rectangle 3 × 1 in., the value would still be 1 in. For a perforated slab the distance between holes would be the effective width; for a hollow cylinder it would be the wall thickness of the cylinder, and for a solid cylinder it would be the diameter.

The factor 6.5 holds remarkably well for a vast number of sizes and shapes of rubber articles used as compression members. If we call E the theoretical modulus of elasticity in compression and E_c the modulus in compression calculated empirically by means of the 6.5 factor, Table 3 shows values of each for a number of articles of various dimensions which have ratios of thickness to effective width of 1.0 or more. It is interesting to observe that article No. 1 of this table is one of the disks loaded by Morrison (3) between grooved steel plates. Up to 15 per cent compression, the curve was practically a straight line.

NOTE: T/W = ratio of thickness to width.

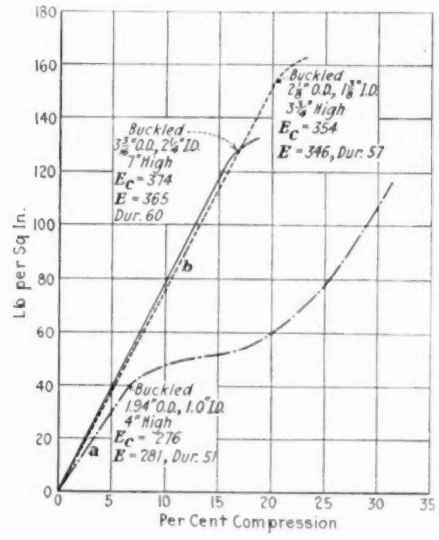

FIG. 9 LOAD-DEFLECTION CHARACTERISTICS OF RUBBER CYLINDERS LOADED AS COLUMNS

Smith has shown elsewhere (4) loading curves for various sizes of disks of various hardnesses. All of the disks, which have a ratio of thickness to effective width of 1.0 or more, can be calculated for modulus of elasticity in compression with the 6.5 factor with reasonable accuracy, as shown in Table 4. These values hold true for compressions up to 15 and 20 per cent of the original thickness. The only other curve in Smith's figure (4), which has a ratio of thickness to width of more than 1.0, does not seem to lend itself to this method of calculation. Beside the durometer hardness of 70 there is a question mark.

In loading rubber cylinders, one must maintain certain proportions of width to height and cross-sectional area in order not to get into trouble from collapse of the member when used as a column, especially when the member is to be subjected to lateral forces as well as vertical. Fig. 9 shows tests on 3 cylinders and their point of collapse. To determine what these proportions should be might well be worth the effort of an ambitious author who wishes to make a mathematical treatise of rubber cylinders, for rubber cylinders do afford a simple means of isolating machines where compliancy in both vertical and horizontal planes is desired.

Loading curves for 1-in. cubes are shown in Fig. 10 up to 30 per cent compression. The curves are practically straight up to 20 per cent compression.

Loading curves for rubber cylinders, listed as articles Nos. 8, 17, and 18 in Table 3, are shown in Fig. 11. These curves are straight lines up to 15 per cent compression.

Fig. 12 shows the cross section of a round ring type of rubber part which has been used in England for a great many years as buffers and as auxiliary springs on railroad cars and locomotives, known as Spencer-Moulton rubber springs. Holes in the steel plate tie in the rubber rings on each side. Adding together the cross-sectional area of the rings we find that the factor 6.5 applied even for this design.

In Fig. 13 is shown the effect of thickness on the compression curves of airplane shock-absorber disks. The curves for thickness of 1 in., $1\frac{1}{2}$ in., and $2\frac{1}{2}$ in. coincide up to about 25 per cent compression, indicating that where a ratio of thickness to effective width of approximately 1.0 or more is maintained the modulus of elasticity can be determined quite accurately. The factor 6.5 also applies for this case, up to the limit of recommended compression loading. Airplane shock-absorber disks for years were used at loadings up to 50 per cent compression of the rubber. High permanent set took place in these disks in the landing gears and they had to be replaced at frequent intervals. For load-carrying members, 20 per cent should be the limit for normal-load operation, exceeding this only on peak loads, for which dependence rubber is an ideal material.

Fig. 14 shows a loading curve for a cylinder of Neoprene designed to support a load of 1100 lb, also one for a rubber slab designed to support a load of 16,000 lb. The curves are straight lines in the working range. There seems to be no difference between the modulus of elasticity of Neoprene and that of natural rubber of the same durometer hardness. The rubber slab consisted of two steel plates with rubber bonded between them. A great number of holes through the slab allowed compliancy. One curve is for the first loading and the lower one for the fifth loading. This is characteristic of all compression-loading tests, but in this case the effect is somewhat exaggerated due to the network construction. Furthermore, the straight portion of the curves do not pass through the origin. This is undoubtedly due to lack of uniformity in the thickness of the slab, giving a greater apparent deflection near the origin.

In an effort to develop a formula for compression slabs of various sizes, thicknesses, and hardnesses, the author had tests

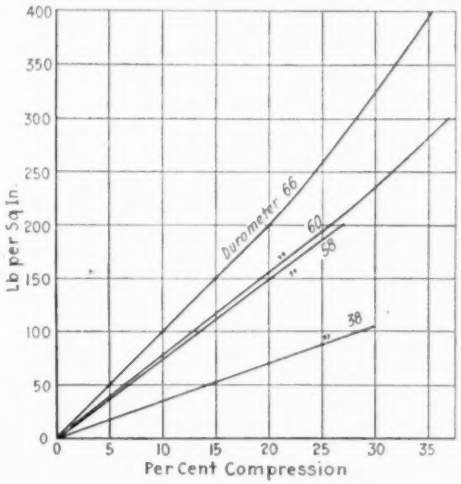

Fig. 10 Compression Loading on 1-In. Rubber Cubes

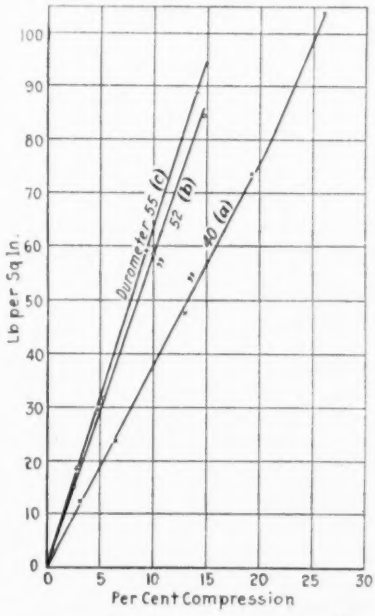

Fig. 11 Compression Loading on the Rubber Cylinders Listed as Articles Nos. 8, 17, and 18 in Table 3

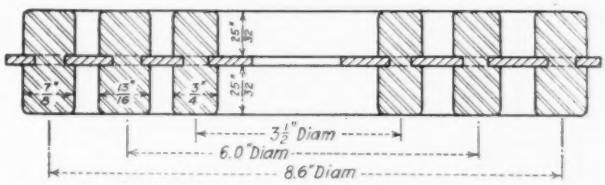

Fig. 12 Spencer-Moulten Circular Rubber Disks for Railroad-Equipment Buffers
(Durometer hardness = 62, E_c = 396 and E = 394.)

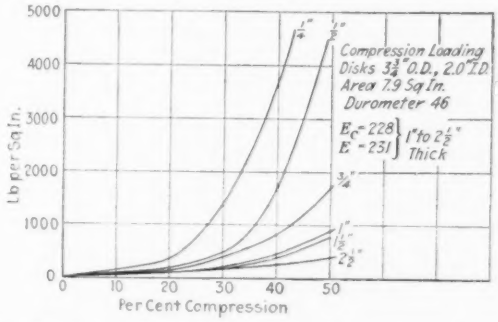

Fig. 13 Effect of Thickness on the Compression Curves of Airplane Shock-Absorber Disks

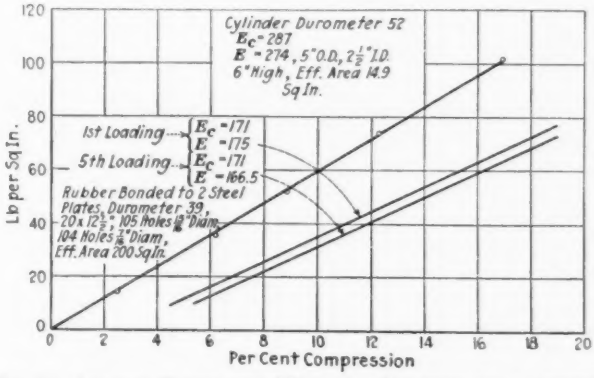

Fig. 14 Loading Curve for a Neoprene Cylinder and a Rubber Slab

conducted on slabs of the following sizes: 1 × 1 in., 2 × 2 in., 4 × 4 in., 6 × 6 in., 8 × 8 in., and 10 × 10 in., in thicknesses of 1/4, 1/2, 3/4, and 1 in., and hardnesses of 34, 40, 50, 60, and 71 durometer. The author has tabulated these data and to date can find no formula which will satisfactorily apply to them as a whole. Even the loading results on the 1-in. cubes of the various hardnesses, as shown in Fig. 15, seem to follow no definite formula beyond 20 per cent compression. It is possible that a nomographic chart can be constructed in order to make use of these data within liberal limits of accuracy.

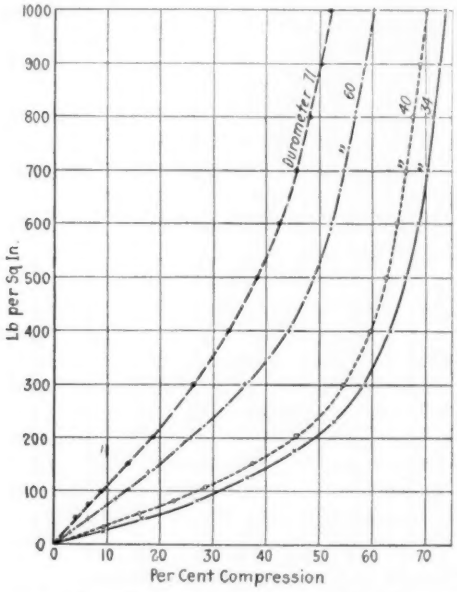

FIG. 15 HIGH COMPRESSION LOADING ON 1-IN. RUBBER CUBES

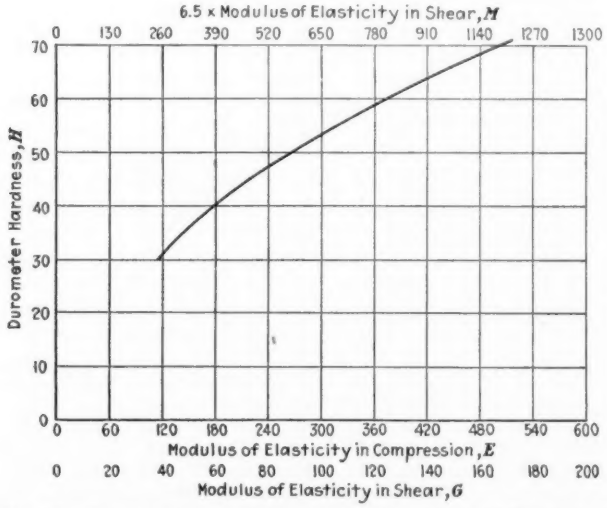

FIG. 16 RELATION OF THE MODULUS OF ELASTICITY OF RUBBER IN SHEAR TO THE DUROMETER HARDNESS

The design of shear-type rubber mountings has been quite thoroughly covered in work already published. A formula which holds reasonably well for plain shear sandwiches placed back to back, given an initial lateral compression, and loaded in vertical shear, is

$$d = WT/AG$$

where d = deflection, in.; W = load, lb; T = initial thickness of rubber in one sandwich, in.; A = area of two shear surfaces, sq in.; and G = modulus of elasticity in shear, lb per sq in.

The relation of modulus of elasticity in shear and durometer hardness is shown in Fig. 16. The data from which this curve was drawn are shown graphically in Fig. 17. The lateral compression placed on the rubber initially was 50 lb per sq in. An examination of these curves shows them to be straight lines up to 20 per cent deflection for the 60-durometer rubber and up to 40 per cent for the very soft rubbers. These data were taken after the mountings had been deflected to 1 in. deflection four times successively in order to work the rubber structure sufficiently to make it more representative of service conditions. Such preliminary loading not only loosens up the structure but removes some of the permanent set in the rubber.

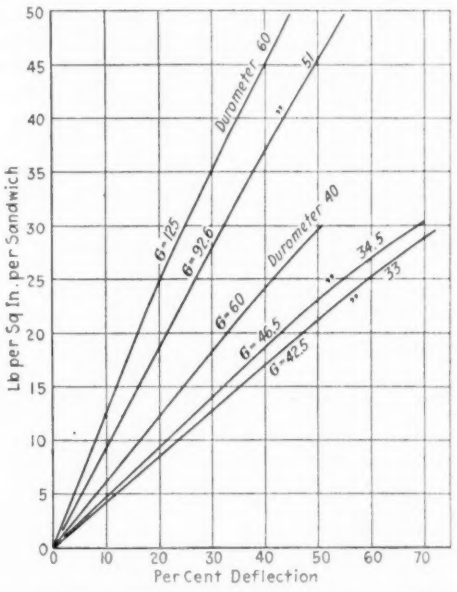

FIG. 17 VERTICAL SHEAR ON TWO 10 × 5-IN. × 1-IN-THICK RUBBER SANDWICHES
(Initial lateral compression of 50 lb per sq in. was used.)

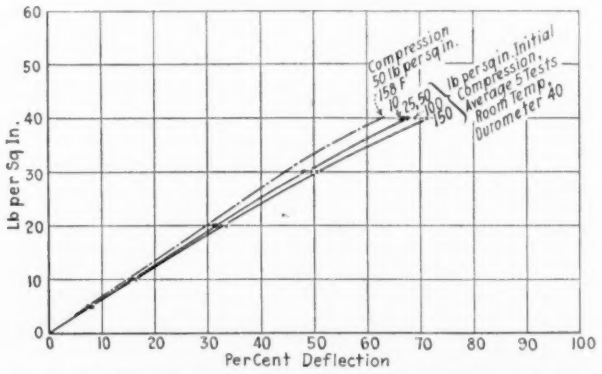

FIG. 18 EFFECT OF LATERAL PRESSURE ON SHEAR-LOADING CHARACTERISTICS OF 10 × 5-IN. × 1-IN-THICK RUBBER SANDWICHES

When the foregoing formula is used it should be noted that T is the initial thickness of rubber. It has been found that the degree of lateral compression placed on the rubber, within certain limits, does not materially affect the shear characteristics when the percentage deflection in shear is based on the original thickness of rubber. Tests made on 10 × 5-in. × 1-in-thick sandwiches, a size chosen by the Electric Railway Presidents' Conference Committee for their pioneer research in the develop-

ment of rubber springs for street-railway trucks, at initial lateral compressions of 10, 25, 50, 100, and 150 lb per sq in. showed insignificant changes in the shear loading curves when deflection was figured on the original 1-in. thickness of rubber, but when corrections for actual thickness were made for the various sandwiches, the values shown in Fig. 18 were obtained. It appears that for every value of compression except that of 150 lb per sq in., a mean curve can be drawn to give reasonable accuracy. A value of from 50 to 75 lb per sq in. compression would perhaps be a fair value to use in practice.

Fig. 18 also shows a curve for a sandwich tested under 50 lb per sq in. lateral compression at 158 F. The curve shows stiffening above that obtained at room temperature, which is to be expected because of the Joule effect. Stretched rubber, heated, undergoes a contraction in the direction of load and there is, therefore, a greater total load on the rubber in that position than before. At 30 per cent shear deflection for rubber of durometer 40, it is seen that the mounting deflects about 2 per cent less at 158 F than at room temperature. At temperatures below that of the room, the effect would be the opposite.

In Figs. 17 and 18 it is to be noted that the curves bend off toward the deflection axis after passing the point where proportionality ceases. The springs become weaker. Can this be attributed to bending of the rubber? If we assume that the rubber sandwich takes the form shown in Fig. 19, which it is reasonable to believe, and we figure the deflection of a beam fixed at both ends with an active length of beam of 2 in., for two 10 × 5-in. × 1-in-thick sandwiches of durometer 40, under 50 per cent deflection, at which point the total load is 3000 lb, we find the maximum deflection from bending to be only 0.0018 in. or 0.18 per cent when expressed in terms of original thickness of rubber of one sandwich. The curve in Fig. 17 indicates a departure of 1.7 per cent from the straight line at this place, or nearly 10 times that derived from bending.

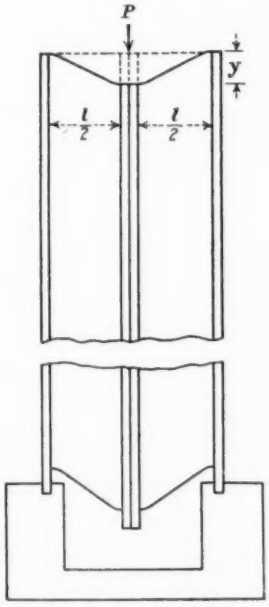

FIG. 19 ASSUMED FORM OF A RUBBER SANDWICH IN SHEAR

($y_{max} = Pl^3/192EI$, where y = deflection, in.; P = load, lb; E = modulus of elasticity, lb per sq in.; l = length of two sandwiches as shown, in.; I = moment of inertia = $bd^3/12$, where b = width of the sandwich, in.; and d = height of the sandwich, in.)

The characteristic stress-strain curve for rubber in tension perhaps accounts for most of the weakening of the shear spring after passing the point where proportionality ceases. For rubber of durometer 60 the stress-strain curve in tension starts to bend toward the deflection axis at about 15 per cent deflection while for rubber of durometer 40 it is at a point where the stretch is about 30 per cent. This softening effect in tension rubber continues up to about 100 per cent stretch for 40-durometer rubber before the stiffening action or point of inflection of the curve sets in. If stress were based on the instantaneous cross-sectional area of the test specimen during tension, the straight portion of the curve would be considerably extended. The S-shaped curve is linked inseparably with the structure of rubber; and, the theory of some writers, who think that rubber is a bundle of kinky fibers, explains this shape by saying that at the second point of inflection of the curve the slack has been taken out of the fibers. At some future time we undoubtedly will know the real reason.

If we deflect the rubber of the 10 × 5-in. × 1-in-thick shear sandwich 1 in. in shear, the elongation in a strand of rubber perpendicular to the two steel plates to which it is bonded will be 41 per cent, since the new length of this strand will be $\sqrt{2}$ in. This strand forms practically a straight line, although, as shown in Fig. 19, it is perpendicular to the plate for a short distance even when under load.

What is the practical limit of thickness of rubber to be used in shear-type springs? If, in the foregoing example of bending, we increase the thickness of rubber to 2 in., the deflection due to bending will be eight times that obtained with rubber 1 in. thick. The increased softening due to bending and the fact that the time of vulcanization of rubber varies approximately as the square of the thickness would seem to limit the maximum thickness to 2 to $2^1/_2$ in. per section. The thicker the rubber the lower the temperature of vulcanization to be used in order to obtain uniformly cured rubber throughout the mass, so the cost of curing becomes an important item where long-time cures must be used on very thick sections.

Rubber torsion bushings of the type shown in Fig. 20, can be designed by use of the formula

$$\theta = \frac{WL}{4\pi bG}\left(\frac{1}{r_1^2} - \frac{1}{r_2^2}\right)$$

where θ = angular deflection, radians; WL = torque, in-lb; b = effective length of rubber section, in.; G = modulus of elasticity in shear, lb per sq in.; r_1 = inner radius of rubber section, in.; and r_2 = outer radius of rubber section, in. In a design of this type the rubber is stressed higher near the center metal member than near the outer metal member because the volume of rubber increases with the square of the radius.

A typical loading curve of the bushing of Fig. 20 is also shown. The graph was made to show that after 120 oscillations through the loading range of 2750 to 6000 in-lb torque the spring rate becomes very nearly constant as the slope of the curve indicates; for this particular spring the rate is 100 in-lb per deg. Some hysteresis loss is shown between the loading and unloading curves even after 120 oscillations of the spring, but under a rapid cyclic test at a speed approximating spring action in service, the hysteresis loss would diminish very much below that shown. Hysteresis loss diminishes materially with temperature rise in the rubber and also with speed of oscillation. The inherent damping, therefore, of a spring of this type, using rubbers designed to keep the creep to a minimum, is of a low order, although the little there is may be beneficial under certain conditions of service.

Fig. 21 shows a double unit torsion spring of such design that nearly a straight-line characteristic is obtained up to 70 deg as shown by the graph. The heavy dot-dash line was plotted from the theoretical equation given above, showing close conformity to the empirical curve. The rubber units act in series to give

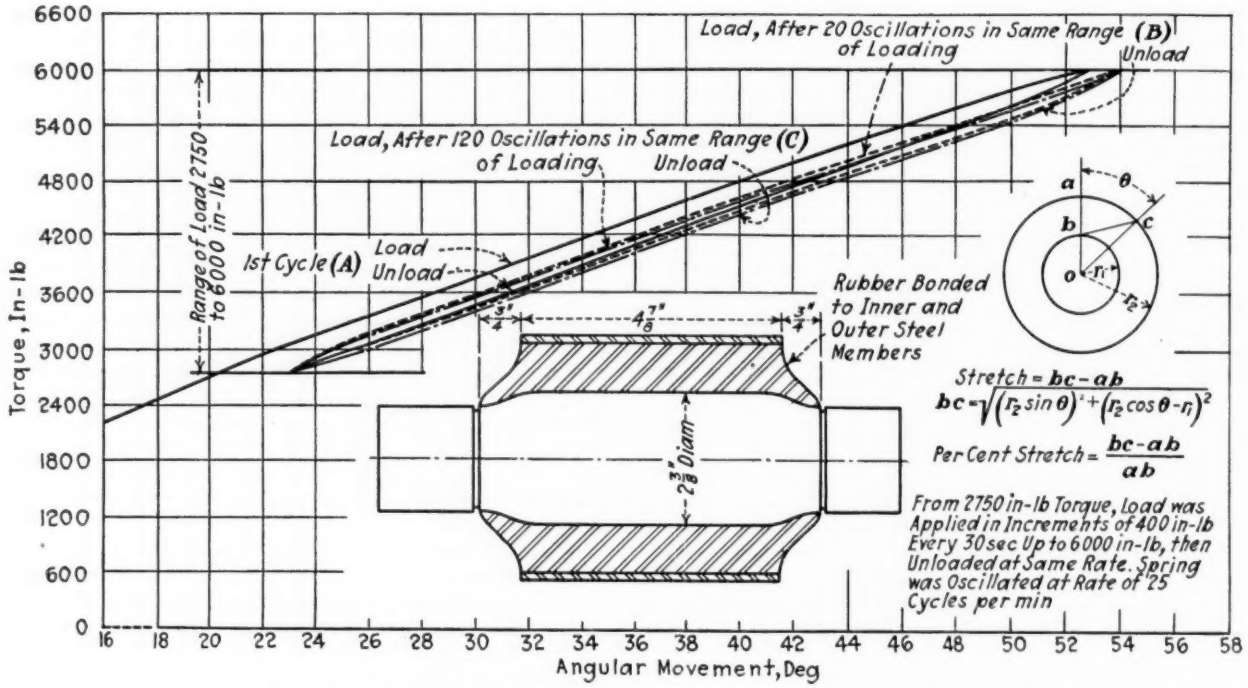

FIG. 20 RUBBER TORSION SPRING OF SPLIT-SHELL CONSTRUCTION AND HYSTERESIS-TEST DATA

twice the angular deflection for a given torque as would be obtained with one bushing. Series arrangements of this kind can be used to obtain very large distortions without going to excessive thicknesses of rubber wall.

Other constructions may be used, such as pressing a bushing, made up with 50-durometer rubber, into another bushing which has rubber of 40 durometer. These bushings are also in series arrangement for obtaining large angular movements, the hardness of rubber being graded off in order to obtain approximately equal angular movements in each bushing.

In bushings of this type the best practice is to bond the rubber to a central metal tube and to an outer shell split in halves. By doing this, full pressure can be obtained on the bonded areas during vulcanization. Inasmuch as vulcanization takes place anywhere from 270 to 320 F, the rubber on cooling, after being removed from the mold, may shrink as much as $^3/_{16}$ to $^1/_4$ in. per ft. The split shell permits this shrinkage to adjust itself. Furthermore, the split shell permits the rubber to be placed under radial compression when the bushing is assembled. It has been definitely proved that such compression very materially adds to the fatigue resistance of the rubber and reduces the amount of creep which takes place in the structure. Such initial radial compression has the added advantage of reducing the deflection of the inside metal member of the bushing in the rubber when placed under radial load. Such bushings can therefore be designed to make the rubber its own bearing with very little out-of-center movement of the inside metal member, thereby affording a complete rubber isolation between the inner and outer members of a rubber torsion spring.

Where torsion bushings are to be used as springs and the rubber is to form its own bearing without the aid of auxiliary bearings, it is important that the radial deflection of the central steel tube in the rubber be known. As the central shaft moves downward in the rubber, all that the rubber can do is to flow around the shaft, like fluid displacement. In bushings of the proportions in which the author has been working, where the ratio of wall thickness of rubber to central shaft diameter is under $^1/_3$ and the

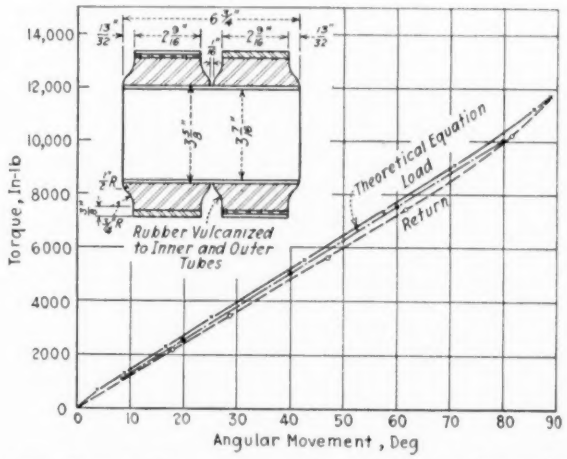

FIG. 21 TORQUE CURVE OF THE DOUBLE-UNIT OR SERIES-TYPE SPRING SHOWN
(Durometer hardness of the spring is 40.)

ratio of central shaft diameter to length of rubber section is under $^1/_4$, it has been found that

$$d = S_p/kE$$

where d = radial deflection of rubber, in.; S_p = lb per sq in. of projected area of central shaft or tube; E = modulus of elasticity of the rubber; and $k = 12$, approximately.

More data will have to be collected to determine this relation but that given previously seems to hold for a number of bushings tested, the extremes in size being for a bushing of 1 in. diameter shaft and a rubber section 5 in. long with a $^3/_{16}$-in. wall of rubber of durometer 60, the other for a bushing of $2^3/_8$ in. diameter shaft, and a rubber section 11 in. long with a $^3/_4$-in. wall of rubber of durometer 45. For this latter size of bushing, at a load of 120 lb per sq in. of projected area, the radial deflection amounted to only 0.03 in.

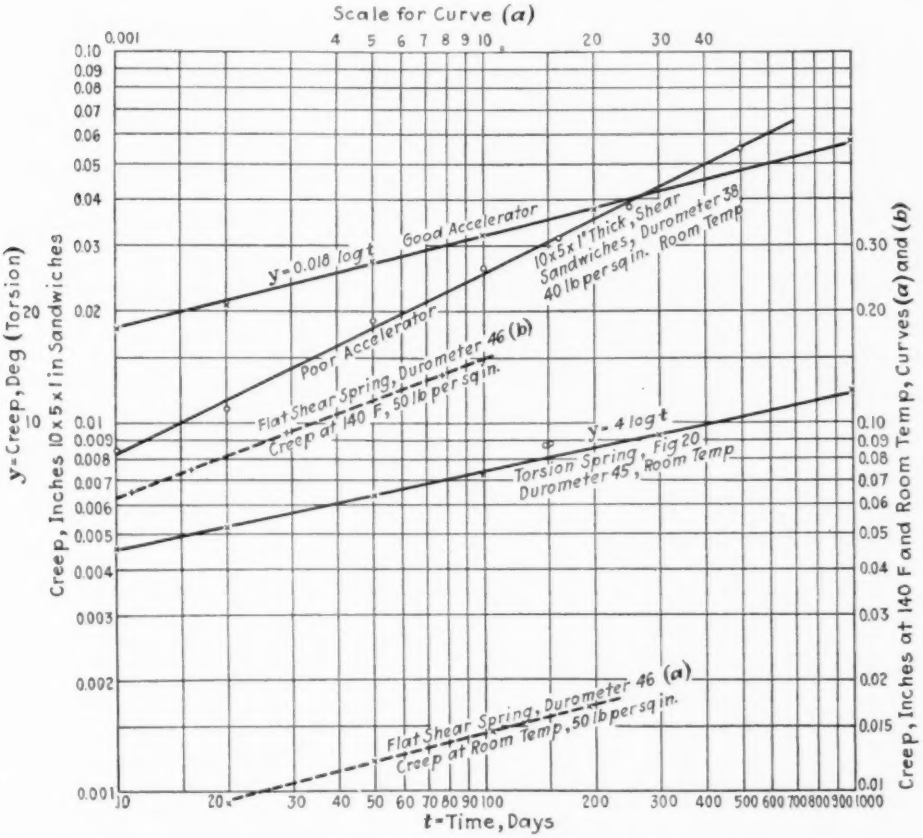

FIG. 22 CREEP IN RUBBER SPRINGS

The amount of stretch in the rubber of torsion springs is as important to control as is the stress at the area where the rubber is bonded to the central shaft, in order not to get excessive long-time creep. Referring to Fig. 20, the strand of rubber *ab* in the unstressed bushing may be said to take the position *bc* when the bushing is twisted through the angle θ. This line *bc* will have an inflection near each of the bonded surfaces, but for practical considerations it is very nearly a straight line. Therefore, we can estimate the stretch in the strand of rubber as being *bc* — *ab*. If we know the radii of the inner and outer bonded areas, then *bc* can be determined for any angle θ.

It is obvious from studying Fig. 20 that if a small r_1 is used with a thick wall of rubber, the percentage stretch in the rubber will be low but the stress at the bonded area may be dangerously high. Or vice versa, if the wall of rubber is small in proportion to r_1 the stress at the bonded area per inch length of bushing may be small but the percentage stretch in the rubber may be dangerously high. Both factors must therefore be watched in any successful design of torsion spring. The limitations of each of these two factors in design work depends to a large extent on the creep that is obtained on the particular compounds of rubber used in such springs. As indicated before, creep in the rubber is linked up with its physical and chemical structure. Merely changing the vulcanization catalyst, ordinarily called accelerator of cure, in a recipe may change the creep by 400 per cent. The problem then is to narrow down the list of compounds to be used to those of a specified range of hardness which are compounded to resist creep and at the same time will have a good flexing life. We know definitely that overcuring reduces creep, but shortens the flexing life. The creep in the best compounds designed for use in springs varies quite closely with the logarithm of the time.

A creep test on a torsion spring made up from one of the best low-set stocks of durometer 45 is shown in Fig. 22. This was obtained for the spring shown in Fig. 20. The stress at the bonded area was 110 lb per sq in., and the percentage stretch in the rubber under the constant torque load was 80 per cent. Although the maximum stress at the bonded area figured 110 lb per sq in. under 6000 in-lb torque, the mean stress in the rubber section is about 72 lb per sq in.

For the curves shown in Fig. 22, which quite closely follows the equation

$$y = n \log t$$

where y = creep in deg, and t = time in days; the torsion spring constant n is about 0.004. Also, in Fig. 22 are shown two creep curves for 10 × 5-in. × 1-in-thick flat-type springs. One is for a stock of 38 durometer with a poor accelerator for resistance to creep and the other for a stock of the same hardness which has a good catalyst of vulcanization. This curve for the latter compound follows the equation $y = 0.018 \log t$, where y is the creep in in.

In this same figure, curves (*a*) and (*b*) are for a $^5/_{16}$-in-thick flat-type spring of durometer 46, loaded to 50 lb per sq in. Curve (*a*) is for a test conducted at room temperature and (*b*) at 140 F. This would indicate that rubber springs should not be operated for long periods at elevated temperatures. The work of Lessig (5), with the Goodrich flexometer, also shows this effect. For two stocks compounded to resist creep, Lessig obtained the results, shown in the tabulation following on page 158, when pellets 1 in. high and 0.7 in. diameter were tested under 96 lb per sq in. compression at a stroke of $^1/_4$ in. and speed of 1800 rpm:

Durometer hardness	Permanent set at room temp, per cent	Permanent set at 212 F, per cent
45	0.8	8.4
33	1.4	10.16

Lessig also showed, by the same method, that high pigment loading increased the permanent set or creep in the structure. The temperature rise is a direct measure of hysteresis loss. Using a compression stroke of 0.175 in. and a loading of 140 lb per sq in., he tested four recipes at optimum cure with the only change being that in the gas black content. The results are shown in Table 5. From what the author has been able to collect to date,

TABLE 5

Compound	Volume loading of gas black	Temperature rise during flexing, F	Permanent set measured after flexure, per cent
A	0	27	1.1
B	10	37	1.4
C	20	56	3.1
D	30	89	8.8

after studying a tremendous amount of data, it appears that rubber stocks with high hysteresis effects have high creep, and vice versa. This observation is not inconsistent with the theory of elasticity, and is supported by the recent work of Kosten (6) who showed that in measuring the static and dynamic properties of rubber in compression the internal loss indicated "the elastic imperfection" of the compound. Naunton and Waring (7) recently measured the change of modulus at various frequencies by means of a special resonance type of testing machine. Fig. 23

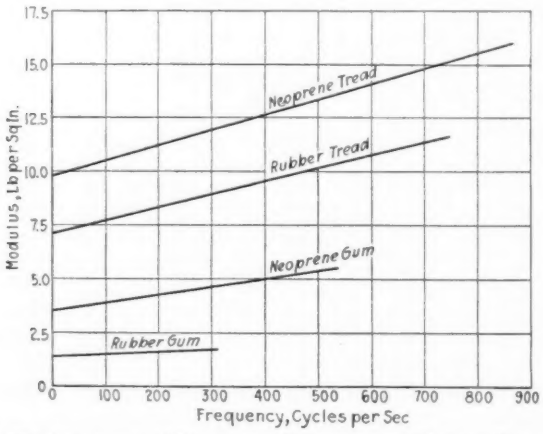

FIG. 23 CHANGES OF MODULUS OF ELASTICITY OF VARIOUS RUBBERS WITH FREQUENCY

shows some of their results graphically. The least change of slope is in the curve for rubber gum, indicating that the heat developed by hysteresis loss was least in this compound since we know that modulus stiffens with temperature rise. It would appear, then, that springs designed to incorporate appreciable damping must be worked at lower stresses than otherwise, in order not to incur trouble from creep.

It was shown previously that a shear or torsion spring has a stiffer load characteristic at elevated temperatures, due to the Joule effect. Similarly, the spring would have a weakened characteristic at low temperatures for the same reason were it not for the fact that the crystalline structure of rubber causes it to stiffen at low temperatures. The following results are for shear-type springs of rubber durometer 33 when loaded to 30 lb per sq in. stress, the results being an average of three tests on each spring:

Durometer hardness	Deflection, per cent, at Room temp	Deflection, per cent, at −20 F	Deflection, per cent, at −63 F	Stiffening, per cent, at −20 F	Stiffening, per cent, at −63 F
33	2.13	2.05	1.93	3.75	9.40
40	1.45	1.40	1.31	3.44	9.65

These tests are the result of a single load placed on each spring after the spring had been reduced to the required temperature for several hours. In service the internal working of the rubber of a spring, even though in an atmosphere of low temperature, will develop some heat and raise the internal temperature of the spring to counteract the stiffening effect.

The author has presented some of the characteristics of rubber in which engineers may be interested from a design standpoint, without going into detail on every phase which might affect design. There is still a vast amount of data which should still be collected, especially to establish accuracy on some points that seem to be in doubt. In order to obtain such data accurately it will be necessary that the tests be conducted in rooms where the temperature, and possibly the humidity, is closely controlled. The accuracy of tests to determine the moduli of elasticity and the creep of shear and torsion springs is very decidedly affected by the temperature because of the Joule effect. The previous history of a spring, as to the number of loadings to which it has been subjected, must always be considered in analyzing results. True measurements of hardness are especially difficult because of the human element which still enters into such measurements. As time goes on, rubber men will undoubtedly standardize on basic recipes for springs, accurately determine their fundamental characteristics, and together publish them.

Discussion

Carbonaceous Zeolites—An Advance in Boiler-Feedwater Conditioning[1]

HUGH R. CARR.[2] The methods described by the author are well illustrated and the numerical values are comparable, however, the writer believes that the question of residual hardness was not covered fully.

The author stated that, following the zeolite treatment, phosphate aftertreatment is added to react to the hardness in the condensate returns. The writer has found that there is less hardness in the condensate than in the effluent from zeolites, and his experience with one acid-zeolite system and many sodium-zeolite systems has indicated that residual hardness in the effluent runs from 4 to 9 ppm as $CaCO_3$. With an acid-zeolite system the writer found that on the average, with 1,000,000 lb evaporation and 40 per cent make-up, 9 lb of disodium phosphate was required to maintain soft water and 50-ppm phosphate alkalinity in the boiler. Repeated analysis of the condensate indicated no hardness. In this case no appreciable chlorides were present in the condensate, indicating no hardness from circulating water, since the circulating water was sea water. The residual hardness must certainly be taken into account and no treating system should be designed without provision for full aftertreatment and disposal of the sludge made by such aftertreatment. Cost comparisons should account for the cost of aftertreatment of residual hardness.

The writer believes that the author takes much for granted with reference to the removal of CO_2 by the cold degasifier; apparently, he assumes a slightly alkaline water for degasification. Either method *A* or method *B* described by the author would indicate such to be the case, at least for the degasification at the feedwater heater. The writer's experience has indicated that the cold degasifier on slightly alkaline water removes very little CO_2; however, the writer believes that the performance would be far better on slightly acid water, say pH of 6.0 or less, which most feedwater heaters will handle, since the condensate from boilers treated with mono- or meta-phosphates rarely shows more pH than this, a serious fault with phosphates.

The author mentioned that the carbonaceous zeolites do not add silica to the water. It has been the writer's experience that any properly selected zeolite adds little or no silica to the water, that is, thousands of times less silica than is carried in the raw water. The author failed to mention that zeolites of any type fail to have any beneficial action on the effect of silica in boilers. The aftertreatment required to eliminate the silica content in the boiler should be taken into account when comparing zeolite systems with other types of external treatment.

In discussing permissible boiler concentration the author mentioned 2500 ppm total solids as a general limit. The writer believes that this is too broad a generalization. It has been the writer's experience that with phosphate aftertreatment, the suspended-solids concentration is the first limitation in dealing with waters of low permanent hardness and/or low nonincrustant salts, but the total-solids concentration is the limiting factor with waters of high permanent hardness and/or high nonincrustant salts. In comparing costs this should be taken into consideration. It is possible that by the use of coagulants or sludge deconcentrators, instead of phosphate aftertreatment, the suspended solids from residual hardness might be cleared away sufficiently to maintain 2500 ppm or more total boiler solids.

It should also be pointed out that the cost of softener backwash should be taken into consideration when comparing zeolite systems with other methods, such as internal treatment, lime-soda-phosphate, and external hot-phosphate systems such as are used in Germany.

AUTHOR'S CLOSURE

Mr. Carr first states that according to his experience with one hydrogen-zeolite system and many sodium-zeolite systems, the residual hardness in the effluents averages from 4 to 9 ppm as $CaCO_3$. It will be noted in Tables 7 and 8 of the paper that the average total hardness of from 0 to 2 ppm was used for the zeolite effluents. These figures are based on actual experience with several large-scale hydrogen-zeolite plants and literally thousands of sodium-zeolite units. Furthermore these figures have been checked by the gravimetric method as well as by the soap-titration method and the Blacher method. Confirmation of these facts may be found in many papers that have been published in the technical press from time to time by disinterested writers who have described their experience with such equipment. Interested persons who wish to confirm these facts may readily do so by having analyses made of the actual effluents of such plants. It can only be concluded that Mr. Carr's experience in this connection has been limited to units that were either improperly designed or operated, or were operating on waters of abnormal quality.

As an illustration, Mr. Carr states that in a given case 9 lb of disodium phosphate was required per million pounds of evaporation. It is impossible from these figures to conclude what portion of the phosphate was used for hardness precipitation since he does not indicate whether the phosphate was anhydrous or otherwise; nor does he state whether the 50-ppm phosphate in the boiler was expressed as PO_4; nor the ratio of concentration in the boiler saline compared to the feedwater. For example, if he were using $Na_2HPO_4 \cdot 12H_2O$ he would require 3.78 ppm of this phosphate for each ppm of PO_4. Assuming a concentration ratio of 20 times the concentration in the feedwater, and 50 ppm PO_4 in the boiler salines, he would require 2.5 ppm of PO_4 in the feedwater to maintain this 50-ppm PO_4 concentration in the boiler salines and replace the PO_4 lost in the blowoff. This would require $2.5 \times 3.78 =$ over 9 ppm of phosphate which would indicate that both the make-up and the condensate were free from hardness. This particular calculation may not apply in the case in point but it merely illustrates the need for detailed data in checking phosphate-consumption figures.

Under the heading, "Chemical Results on Two Typical Waters" in the paper, each of the factors influencing the amount of phosphate that must be fed to the boiler feedwater was enumerated, and Tables 7 and 8 made provision for such phosphate aftertreatment on the basis of certain definite assumptions which were stated in the paper.

With reference to the CO_2 removal performance of cold degasifiers, Mr. Carr states that according to his experience very little CO_2 can be removed by such equipment, particularly when the water is slightly alkaline. This statement conflicts with com-

[1] Published as paper FSP-60-11, by Howard L. Tiger, in the May, 1938, issue of the A.S.M.E. Transactions, p. 315.

[2] President, Mech-Chem Engineering, Inc., Newark, N. J. Mem. A.S.M.E.

mon experience in various branches of water conditioning such as the treatment of well waters high in CO_2 and iron, where aeration is commonly practiced for CO_2 removal and iron precipitation. There are any number of data to prove that degasifiers remove most of the CO_2 in the cold and there are in operation at the present time several of these H_2Z plants where initial CO_2 contents of from 100 to 200 ppm CO_2 are being continuously reduced by such equipment to less than 10 ppm CO_2. This slight residual CO_2 is then effectively removed in the feedwater heater. Such results are usually guaranteed and can be readily verified by anybody interested in inspecting such installations.

Mr. Carr is correct in stating that the carbonaceous zeolites do not remove silica from water. However, it is well known that with siliceous zeolites there may be appreciable silica pickup, particularly when the influent to such equipment is low in silica content, as is the case after proper silica-removal treatment or with waters naturally low in silica. In fact, some of the most prominent consulting engineers in the country have already authorized replacement of siliceous zeolites by carbonaceous zeolites operating on the sodium cycle for the sole purpose of avoiding such silica pickup and a number of installations of this type are operating in some of the largest steam-producing plants in this country.

The 2500-ppm total-solids concentration used for the calculations in Tables 7 and 8 were merely illustrative and Mr. Carr is quite correct in stating that one cannot generalize broadly on the maximum allowable concentration. This was well illustrated in a group of papers[3] that was recently published which showed boiler concentrations varying from 250 ppm in the case of Dayton Power & Light Co. to 1800 ppm in the case of Virginia Electric & Power Co.

Mr. Carr is doubtless correct also when he states that the suspended solids such as result from phosphate aftertreatment may in certain cases limit the concentration that may be safely carried in a boiler.

In his last paragraph, Mr. Carr states that the cost of softener backwash should be taken into consideration. Reference to Tables 7 and 8 of the paper shows that this point was specifically covered in the note under the table of chemical costs where the volumes of waste water for backwashing, rinsing, and so on, are discussed in detail. These waste-water figures were not converted into terms of dollars and cents because such conversion obviously depends upon local costs of water which may vary within wide limits. Thus an illustrative figure would be meaningless but with the data set forth in the note, the actual cost for any specific case can be readily calculated.

Influence of Pressure on Film Viscosity in Heavily Loaded Bearings[1]

H. C. Dickinson.[2] The writer does not believe that the author is justified in extending the term "oiliness" to cover effects of pressure changes on viscosity as made on page 356 of the paper in reference to the works of Herschel[3] and Hersey.[4] Herschel's original definition referred to liquids "of the same viscosity and at the same temperature, and under identical operating conditions." The writer is sure that Herschel's intent was to define conditions in which the mechanical effects of viscosity are identical. Changes in viscosity due to temperature are so well recognized that Herschel, like everyone else, recognized the need of eliminating this factor. If important similar effects of pressure had been anticipated, it is a fair assumption that Herschel would have included the same limitation here. In other words, we are accustomed to think of "oiliness" as applicable to differences between oils which do not depend upon differences in the mechanical effects of viscosity itself.

Considering the problem more in detail the classical equations deal with fluids, the significant mechanical properties of which are constant throughout the region and during the process which they represent. Any departure from the constancy of viscosity obviously entails an approximation in the use of the equations. It has long been recognized that the viscosity in the equations must be that at the bearing temperature. The same is true, of course, of pressure, except that the effects of changing pressure are smaller than those of changing temperature.

No one seems to have taken into account the fact that the temperature in any heavily stressed oil film is not constant, even through the thickness of the film. It would be difficult if not impossible to solve the equations with the inclusion of this additional factor. However, we should not lose sight of the fact that the effect of variable viscosity is included, nevertheless, on account of both temperature and pressure variations within the bearing.

If the classical equations could be so modified as to include an approximation to the effects of varying viscosity, and still be capable of solution, an important step in progress would be made. However, to solve the problem completely, we should be able to introduce both the pressure and the temperature effects on viscosity, as well as the end-leakage and tangential-flow corrections, the general effects of which are well recognized.

F. C. Linn.[5] The test results and applied theory which the author has presented in this paper[1] give information which is of extreme value for low-speed heavy-duty bearing applications. It is interesting to note that for this particular type of service a fitted liner is essential in order to obtain satisfactory bearing qualities. The question of bearing clearances is one wherein there is a great deal of misunderstanding. Some designing engineers use the same clearance regardless of speeds and loads, which, of course, is a mistake, since at low speeds and high loads the author shows that it is essential to operate with fitted liners, whereas, at high speeds, that is, velocities of 100 to 200 fps, large bearing clearances are required. A case was recently called to the writer's attention wherein the clearance of a 4-in. journal operating at 400 rpm and loadings up to 1000 lb per sq in. was 8 mils. Bearing failures occurred after a few hours' operation. Failures were eliminated by decreasing the bearing clearance to 3 mils. On the other hand, a 4-in. bearing operating at 10,000 rpm should have bearing clearances of from 12 to 16 mils.

The problem of starting and stopping high-speed journals is one with which designing engineers are continuously faced. High-speed bearings should have relatively large clearances for optimum operating conditions at speed. The large clearances are unsatisfactory at very low speeds, but shafts have to be started and stopped. This problem may be outside the scope of the paper under discussion. However, the author undoubtedly made some tests which may be applicable to this problem and a discussion of them would be beneficial. In other words, has the relationship of maximum load versus bearing clearance for various oil viscosities been determined for very low speeds?

[5] Turbine Engineering Department, General Electric Company, Lynn, Mass.

It is gratifying to note that the author has one explanation for the property previously known as "oiliness," and it is quite possible that as further experimental work is conducted the indefinite property of the film to withstand high loads at low speeds, which has been attributed to oiliness in the past, will be definitely understood.

A curve of calculated minimum friction (λ_a) is presented in Fig. 2 of the paper, which calculation is based upon end-leakage condition. In Fig. 9 of the paper are calculated curves of λ and λ_a based upon the conditions of $r = 0.0000755$ (lb per sq in.)$^{-1}$ and $r = 0$, respectively. Since the calculation of the coefficient of friction in Fig. 2 has been made taking into effect end leakage, the writer wonders why the author did not include the effect of end leakage in his formula, instead of basing his theoretical work upon the assumption of an infinite-width bearing.

The increase in viscosity with pressure has the effect of increasing the coefficient of friction at the higher loads and yet, when the observed values are plotted on a curve of coefficient of friction versus ZN/P_A, there is a less variation between the observed curve and the calculated curve for minimum friction at the lower values of ZN/P_A than there is at the high values. A discussion of this by the author would be appreciated. It is also interesting to note that the curve of the coefficient of friction versus ZN/P_A for minimum friction is a straight line when plotted on log-log paper. This fact has been recognized and log-log paper has been used by the writer in presenting test data on high-speed bearings. Because of being able to draw straight-line curves on log-log paper for coefficient of friction versus ZN/P_A, it is very convenient to extrapolate beyond the range of test data in predicting bearing performance.

G. L. Neely.[6] The author covers very comprehensively the subject of the effect of viscosity rise through increase in pressure in heavily loaded bearings. His data appear to be accurately determined and he presents very convincing arguments that there is an increase in viscosity of the oils in heavily loaded bearings that markedly influence the performance. The method of preparing the bearings is of particular interest, since in most work it has been found that bearings become better after running-in and are more easily lubricated after use than when freshly prepared. The fact that the opposite was true in the case of the very heavily loaded bearings is further evidence that ordinary conditions do not prevail when such loads are used.

It is true that differences between the lubricants, that might be called oiliness by Herschel's definition,[3] were found in the heavily loaded bearings, but it is doubtful that this should be called a true oiliness effect. Such results might be obtained in other testing machines such as the Almen, Timken, or other devices employing suitable friction-measuring equipment, as well as in commercial bearings. In the absence of adequate pressure-viscosity data, it would seem preferable to consider the phenomenon one of oiliness rather than to ignore it completely. On the other hand, in work on oiliness conducted in the laboratories of the company with which the writer is affiliated, we have endeavored to set up testing conditions where the effects of pressure are not measurable, that is, where the coefficient of friction is not influenced by degree of loading. This condition eliminates the necessity of correcting for viscosity or pressure-viscosity effects that cannot be adequately evaluated.

In view of the author's work and certain previous work along similar lines, such as that of Dr. Everett of The Pennsylvania State College, there seems no doubt that the viscosity of the oil in a journal bearing is influenced by the pressure conditions in that bearing. The value of this work for practical applications is such that it can be very profitably continued

[6] Standard Oil Company of California, Richmond, Calif.

G. B. Karelitz.[7] No chain is stronger than its weakest link, and no machine is sounder than its weakest detail. It is therefore sometimes strange that our machines, notably prime-mover engines, work at all. Considering, for instance, a turbogenerator or an internal-combustion engine; the operation of these depends on the behavior of an oil film in its bearings. Should the 0.001-in. or 0.004-in-thick oil film refuse to perform, a major disaster would occur to the equipment. This paradox was brought home to the writer rather forcibly when reports were made on the maiden trip of the Italian liner *Conte di Savoia*. On that trip her power-generating equipment failed due to breakage of an outboard discharge valve, and consequent flooding of the generator room. At the time the gyrostabilizers were in operation, of which the rotors weigh 110 tons each, and rotate at 900 rpm. Failure of the power supply stopped the motor-driven oil pumps, and there was no oil to the bearings. It takes four hours to stop these runners with all the braking available. The crew had an anxious time hand-pumping grease into the bearings of the gyroscopes. One can easily imagine what would happen should one of the bearings seize.

Therefore it is only appropriate that the performance of this oil film, which has such an important function, should be studied in minute detail; at least as much as the strength features of other parts of machines.

It happens that the equations involved in this study are complicated, often defying solution. However, engineers cannot be obstructed by this fact and approximate solutions have been worked out resulting in tables and graphs at the service of designers. It is the task of research engineers to bring the problems encountered to that stage of usefulness. From this viewpoint the paper is very important and timely.

The steel-mill industry is now reequipping its mills with rationally designed bearings, to save both power and the high cost of bearing replacement. The designers of these bearings will welcome this thorough and well-founded contribution, particularly so because the theoretical findings are compared with tests, or rather because the theory presented explains so well the test observations reported.

There is no doubt that the results published by the author will be of value in many other fields where heavily loaded bearings are employed. It may be wished at present that the large amount of available information on the mechanism of an oil film be brought together in a coordinated and simplified form, so that designers may use it conveniently.

Author's Closure

Mr. Linn has observed that since increase in viscosity with load increases friction coefficients to values above those calculated, it would be expected that when test results are plotted against ZN/P_A, as in Fig. 17, the agreement with theory should become closer as the load is reduced. At low values of ZN/P_A the observed friction coefficients lie above the theoretical curve because of increased viscosity due to pressure. Since the pressures are not great enough to influence viscosity at high values of ZN/P_A, closer agreement with theory should be found in this region. That such is not the case is due principally to inaccurate gage readings at low pressures. In Fig. 17, the value $ZN/P_A = 40$ corresponds to a gage reading of approximately 200 psi. The lowest value of ZN/P_A on the same chart corresponds to a gage reading of 5000 psi. Observations to the right of $ZN/P_A = 40$, forming more than half of the chart, were taken at gage readings below 200 psi. In the type of pressure gage used, inaccuracies at the ends of the scale are to be expected. At higher loads the

[7] Professor of Mechanical Engineering, Columbia University, New York, N. Y. Mem. A.S.M.E.

percentage of error is small but at lower loads it becomes appreciable.

Mr. Linn's question as to why the influence of end leakage was not included in the analytical work is readily answered by the fact that this inclusion would make a rigorous mathematical solution impossible. The question is more fully discussed on page 350 of the paper.

The author has no experimental data to offer at the present time on the effect of varying clearance at low speeds. However, reference (6) in the bibliography of the paper will throw some light on this problem from the analytical point of view.

With reference to the comments of Dr. Dickinson and Mr. Neely regarding the paragraphs on oiliness, it may be well to repeat that from the observed facts it can only be concluded that the phenomenon known as oiliness can be produced by the influence of pressure on viscosity. The author recognizes that the viscosity-pressure effect was not what Herschel had in mind when he published his definition of oiliness; and in all probability it is not the same thing that Neely refers to as "a true oiliness effect." It is unfortunate that the cause or causes of oiliness are not definitely understood. However, it was not the author's intention to suggest viscosity-pressure effects as a general explanation of oiliness, but merely to call attention to the fact that the outward signs of the two are similar. It should be remembered that the experiments indicating pressure effects on viscosity were made with complete fluid films, whereas oiliness is generally associated with incomplete or boundary lubrication.

The author is of the opinion that eventually it will be shown that oiliness is due to some property, or group of properties, yet undefined. It has yet to be proved, however, that oiliness is entirely unrelated to viscosity.

Tests of a 7 by 10½-In. Bearing at 3600 Rpm[1]

H. Steen-Johnsen.[2] In spite of the volume of data available from research investigations on bearing performance, data that pertain to the particular problems of turbine-generator bearings are still extremely meager. The author points out that information available covers the majority of applications. Unfortunately, the turbine bearing does not fall in this majority classification; however, with the tests discussed in the paper, research is taking a step in this direction, in so far as a standard turbine bearing has been tested at 3600 rpm.

In studying the author's results we find that they show closer agreement with earlier tests at lower speeds, and the theory developed from those tests, than they do with the performance observations made on turbines in commercial service. The writer notes in the test results that a larger proportion of the losses are due to the top half and the side reliefs than was found in earlier tests at lower speeds. In this connection it would be of interest if the author would elaborate on the theoretical method used for calculating the side reliefs and the top half of the bearing. The writer presumes it is done by using the expression for a guide bearing. It would also be of interest to see some of the readings obtained from the thermocouples located in the babbitt and the oil film.

In the case of the turbine bearing, the major problem that faces the designer of the lubricating system after the size and type of bearings has been decided upon is the quantity of oil required by the bearings and the amount of cooling capacity necessary in the oil cooler.

If we use the bearing-test data available, a certain kilowatt loss is obtained, which corresponds to a certain quantity of oil at the temperature rise selected. The oil requirement obtained in this manner is on the order of from one half to two thirds of the actual quantity required to keep the bearing in question cool. In other words, considerably more heat is removed from a turbine bearing than is indicated by the kilowatt loss due to friction in the oil film. This difference between calculated and actual heat removed becomes greater as the operating temperature of the unit increases.

For the majority of turbines operating at 750 F and above, the quantity of oil required becomes quite indeterminate, unless previous experience is available. The journal of the bearing in question supports a rotor which at a distance of approximately 18 in. from the journal is at a temperature of say 800 F. Naturally, heat will flow from the rotor toward the journal, and in order to maintain a suitable operating temperature of the bearing, the heat received from the rotor must be removed by the oil in addition to the heat generated in the bearing.

The writer has had occasion to check the temperature of the oil and babbitt in the lower half of a bearing operating under these conditions, and the temperatures observed were comparable to those of the bearing discharge temperature. But we do not know the temperature of the oil film that adheres to the journal, nor do we know the temperature of the journal at the surface, nor the temperature of the inside of the journal.

Shutting a unit of this type down, we know that within a very few minutes the temperature of the babbitt in the bearing reaches approximately 200 to 250 F. We also know that if the bearing be dismantled quickly and a thermocouple be held against the journal and covered with asbestos, a reading on the order of 300 to 350 F can be obtained.

The additional amount of oil required to carry away this heat conducted through the spindle to the journal is supplied to the bearing by having special grooves provided in the top half for additional oil flow, and also by increasing the oil-supply pressure to the bearing, so as to force more oil through the clearance space.

One of the first questions which presents itself in connection with the particular phase of lubrication that is experienced in turbine units is: What is the best method of supplying the additional oil for cooling the journal? Should this additional oil be provided by increased supply pressure, or by increased passages, and at what points in the bearing should the additional oil be supplied and drained, in order to have the best cooling effect and the best chance of removing the film that adheres to the journal so that oil at inlet temperature will at all times be available for the film on which the journal floats?

The heat from the rotor also brings up another problem peculiar to the turbine bearing. The average temperature along the diameter of the journal will be considerably higher than the temperature of the bearing shell. The resultant difference in expansion between the journal and the bearing will decrease the clearance ratio an unknown amount, and thus increase the losses and decrease the oil flow.

Some engineers believe with a water-cooled gland the temperature of the journal will not be much higher than the temperature of the bearing. However, it is difficult to subscribe to this opinion after calculating the rate of heat transmission from the narrow gland runner to the water that surrounds it. Most of the wall surface that surrounds the water in the gland is the gland case, bolted to the cylinder, and most of the heat absorbed is from the gland casing, conducted to it through the cylinder.

Even though the paper[1] covers tests of the type of bearing that is used in turbine design, there still is a great amount of work to be done before a clear picture can be obtained of the performance of a turbine bearing. The present tests have unquestionably

[1] Published as paper RP-60-8, by L. M. Tichvinsky, in the July, 1938, issue of the A.S.M.E. Transactions, pp. 393–397.

[2] Engineer, Turbine Division, Westinghouse Electric & Manufacturing Company, Philadelphia, Pa. Jun. A.S.M.E.

furnished desired information on the kilowatt loss in the bearing in so far as the rotational losses are concerned, but it does not touch upon the actual oil requirements of a turbine bearing in commercial service.

Design of High-Capacity Boilers[1]

M. K. DREWRY.[2] The emphasis that this paper places upon furnace temperatures and furnace heat transmission (not upon furnace volume) suggests that the formerly used poor criterion of furnace conditions, namely, Btu per cubic foot, is at last being discarded like the term boiler horsepower.

That tangential firing causes a boiler-inlet gas temperature 200 F lower than horizontal or vertical firing (all with wet-bottom design) deserves attention. This difference in thermal performance seems related, for instance, to better radiant-heat absorption with pulverized coal than with stokers. It recalls that radiant-heat transfer from burning fuel particles is much greater at the same temperature than from heated gases.

The method of firing that stores the least heat in hot gases, which is most nearly isothermal, and which facilitates the best heat absorption from the burning fuel particles, causes lowest boiler-inlet temperature. This statement suggests that the combination of dry-bottom design and of firing methods that create most combustion near heat-absorbing surfaces, will result in minimum boiler-inlet temperature.

Dependability requirements are well emphasized in the paper. The value of high reliability in reducing investment costs is usually underestimated. Designers and operators ought always to strive for higher availability, even through years of low loads.

For the ultimate in steam-temperature regulation, disposition of superheating and evaporating surfaces similar to that indicated in the paper seems inevitable. Side-by-side positioning of steam and water tubes cancels all variables and creates rugged inherent control that is truly dependable. The paper indicates that demands of higher steam pressures and temperatures have already exceeded capacity of the convection superheater. Experience with radiant superheaters will be valuable when ultimately more heat is absorbed in superheating than in evaporating.

H. J. KERR.[3] There are certain points in the author's paper which the writer would like to discuss.

Fig. 1 of the paper apparently indicates a box-header boiler. It might be misunderstood to represent a sectional-header boiler. Fig. 2 of the paper represents a sectional-header boiler of the double-deck type, though the baffling arrangement shown would hardly be used except for some very special reason. These two figures are given in the paper as representing boilers having inadequate circulation for high capacity.

Fig. 4 of the paper may be taken to represent a four-drum Stirling boiler. It is presented as a type of boiler that has inherently some circulation difficulty. Incidentally, it is referred to as having some limitations on good steam quality. In this figure the steam outlet is shown on the middle drum, an obsolete ar-

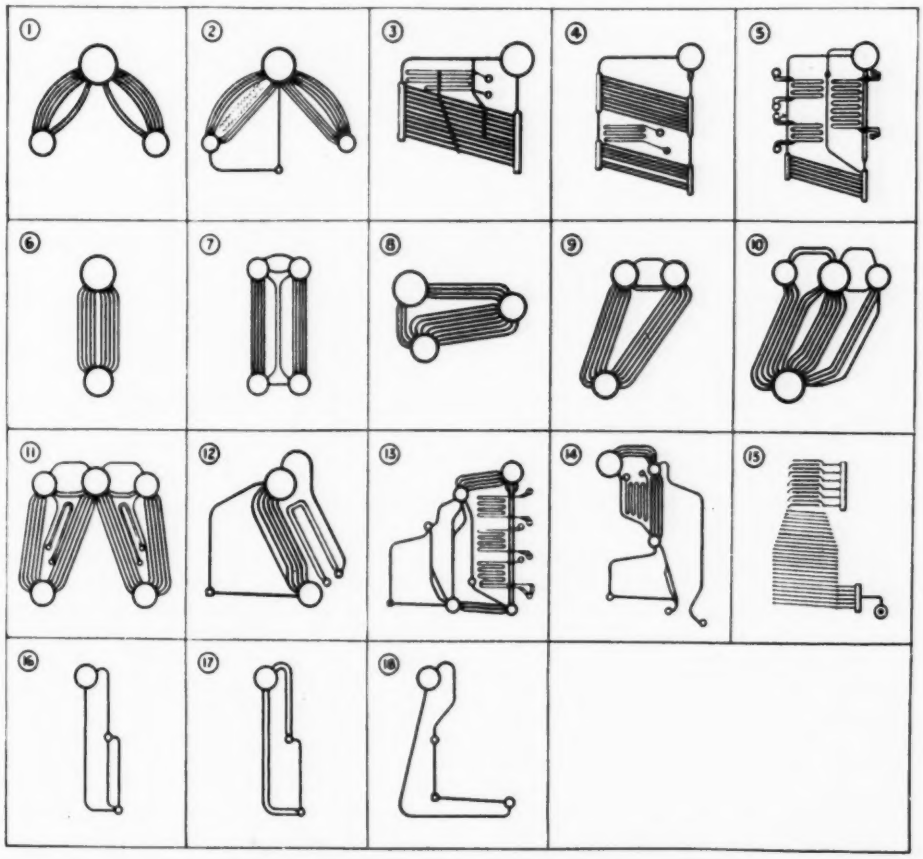

FIG. 1 VARIOUS TYPES OF BOILERS AND WATERWALLS

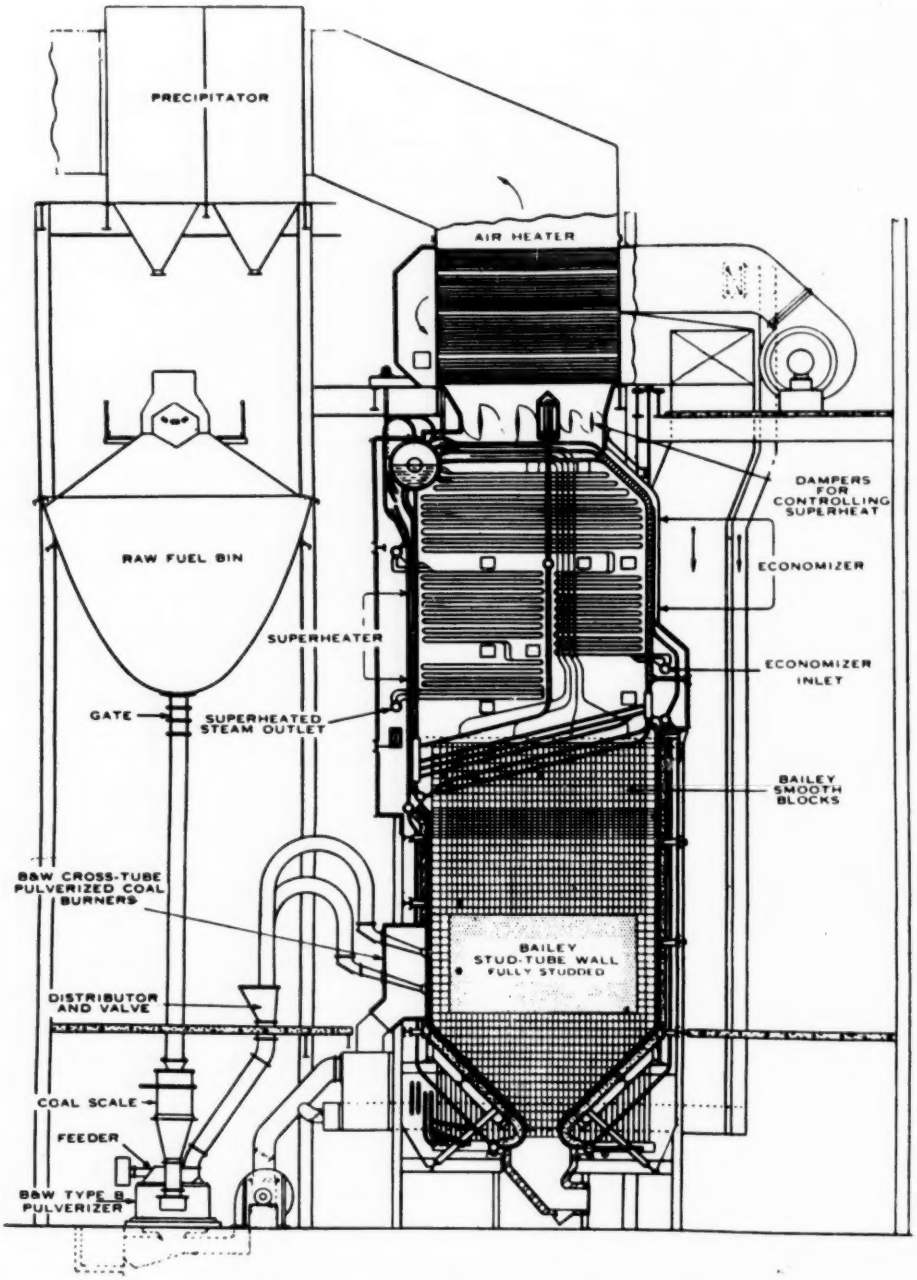

FIG. 2 RECENT INSTALLATION FOR DAYTON POWER & LIGHT CO.

rangement which disappeared 17 years ago. It is hardly believed that the author's statements on poor steam quality are intended to include this type boiler when the steam outlet is on the rear drum. The writer knows of no type of boiler capable of carrying such high concentrations as this type unit has successfully handled with high steam quality and steaming capacity.

The paper seems to indicate that the author believes certain types of boilers are immune from circulation trouble while others are not. In Fig. 1, herewith, are shown diagrammatically some fifteen types of boilers and three types of waterwalls all of which have been, or are being built by the company with which the writer is connected. The boiler types represented are familiar: The three-drum type, so closely related to Yarrow's classic test work on circulation; the express-type marine units which operate with a furnace heat release of 400,000 Btu per cu ft; the sectional-header types, many of which are in service throughout the world; the various so-called bent-tube types including the four-drum Stirling boiler; the integral-furnace boiler; the open-pass boiler of 1400 lb pressure, lately installed at West End Station in Cincinnati; the Essex type unit now being put into service; and the series-pump-circulation boiler with from 100 to 200 lb pressure differential between the ends of the circuits. The figure also shows a recirculation waterwall, a straight-through-circulation waterwall, and a furnace waterwall connected to floor tubes of the furnace. In regard to all these the writer can say definitely that each boiler has a circulation problem as is also the case with the waterwalls. It is necessary to recognize that fact and design the unit on reliable data and experience.

On page 487, referring to tangential firing, the author states that, from his data, the furnace exit temperature for a given furnace would be 200 F lower than with horizontal or vertical firing in the same furnace due to greater heat absorption, thus indicating the superiority of this type of firing in comparison with other burners and burner arrangement.

Since there is great difficulty in obtaining true gas temperatures in a furnace, it would add to the value of the paper if the author would give, in as much detail as possible, the method used in obtaining these temperatures. It would be particularly interesting if he would advise whether high-velocity thermocouples, bare-wire thermocouples, or optical pyrometers were used. It is recognized that there may be 200 or 300 deg difference obtained by these various methods of measuring temperatures in addition to the variation which will be obtained over the furnace cross section perpendicular to the gas flow.

Obviously, the conclusion reached by the author as to the superiority of this method of firing is not concurred in by others.

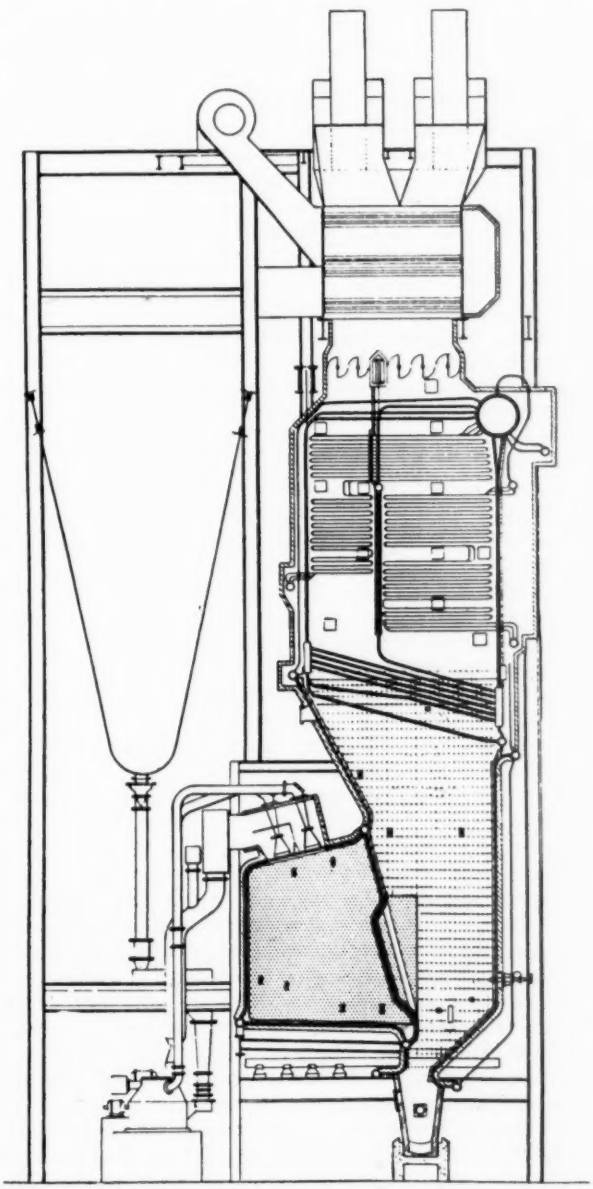

FIG. 3 SHOWING TWO-STAGE FURNACE

The writer particularly refers to the reports on tangential firing as carried out at Buffalo at about the time when slag-tap bottoms and direct mill firing became effective. The work at this station, supplemented by a great deal more experience since, may lead others to the quite different conclusion that the type and position of burners in each case must be considered and also the arrangement of furnace before a general statement can be made of the superiority of one method as compared with another.

In checking over Fig. 9 (of the author's paper) at 200,000 Btu release per sq ft of furnace envelope cooling surface, the writer understands this to mean that the average heat absorption per square foot with tangential firing is approximately 100,000 Btu. Since part of the furnace walls are necessarily slag-covered it might be expected that the local transfer rates might greatly exceed this average. Information on this point, particularly in connection with high-pressure units, would be of great interest.

One might understand the author's statements to mean that an economizer should be insured against steaming. Units in service for many years have demonstrated that the steaming economizer is an economical, dependable piece of equipment.

Dealing with waterwall design, the author states it is good practice to avoid any recirculation in waterwalls. The successful operation of a great many waterwalls with recirculation is evidence that this statement cannot mean that recirculation is bad or that absence of recirculation is superior. The opposite may be true. The writer has a considerable number of data showing that the increase in concentration in the wall in comparison with the concentration in the drum of the boiler is relatively small and the following is a typical example in terms of sodium chloride: Drum, 54.5 ppm; bottom header of the wall, 54.0 ppm; top header of the wall, 57.0 ppm. In some cases the concentration in the drum may be higher than in the wall itself. It would be of great interest if the author would present any complete data which he has contrary to these results.

Figs. 2 and 3 herewith represent two high-capacity high-pressure units, which will serve to bring out the various points which have been discussed. Fig. 2 represents two high-head units put into service last year at Dayton Power & Light Co., Dayton, Ohio. These units were designed for and operate at 375,000 lb of steam per hr at 1250 lb pressure with a constant steam temperature of 900 F from 40 per cent of load to full load. The furnace release is close to 40,000 Btu per cu ft.

(*a*) Actual measurements taken on the job show that the water flows upward in all tubes at a rate in excess of that which is required for the heat absorption and no marks whatever of water levels can be found.

(*b*) Waterwalls are designed for recirculation. There has been no difficulty whatever.

(*c*) The steaming economizers give approximately 12 per cent steam by weight and are operating without difficulty.

(*d*) Constant superheat is referred to in the paper. This is an example of what can be accomplished by a simple arrangement of parallel gas flows. The units have operated at 900 F steam temperature from full rating to below 40 per cent of capacity and in addition at full load the steam temperature has been held below 850 F.

Fig. 3 shows one of the units installed at the Rivesville Station of the Monongahela West Penn Power Company. The units were designed for 350,000 lb of steam per hour at 1250 lb pressure and have been operated materially in excess of this capacity. In general, the units are similar to the Dayton units and designed on the same principles. The primary difference is the two-stage furnace which, in this case, is operating with coal containing ash of 2100 F fusion temperature. The heat release at normal load is 36,000 Btu per cu ft.

This furnace design and the results being obtained show that

exceptionally good results can be obtained by other methods of firing.

T. E. PURCELL.[4] This paper contains specific information on existing installations, data based on scientific facts, and the opinions of the author on various designs and operating characteristics. In general the writer agrees with the paper. However, there are a few items upon which he wishes to make comment.

Unquestionably, the use of pulverized fuel has made it possible to build extremely high-capacity superboiler units. There are, however, some who will not agree that units of this type are commercially justified. In this respect each individual installation must stand upon its own merit. That the use of water-cooled furnaces is absolutely necessary where exceedingly high capacities are to be developed is generally conceded. It should be the ambition of design engineers so to proportion the boiler and furnace surfaces as to cause a complete solidification of the ash before the closely grouped boiler tubes are reached in order that troublesome slag accumulations in the gas passes may be avoided.

It is suggested that the greater development and use of radiant superheaters may offer a possible solution to the superheat problem where gas temperatures must be reduced to a low value to avoid slag accumulations in the steam-generating tubes.

The lower gas temperature reported with tangential firing when compared with vertical or horizontal firing is, of course, the result of more rapid heat transfer to the waterwalls when the flame is directed tangentially. There is, however, a definite limit in any installation to the rate at which heat can be transferred to a given amount of surface without causing its failure. Because of this limitation, there is a possibility of developing vertical or horizontal burners to utilize more effectively the entire furnace volume and obtain equally effective heat transfer with burners of either of these types.

Data with respect to friction losses of mixtures of water and steam flowing in tubes would be valuable. Determination of the flow characteristics over a broad range of conditions should make an excellent subject for study by some research foundation.

The writer believes that a certain percentage of recirculation in furnace waterwalls can be used without detriment or danger of excessive concentrations since usually, where feedwater treatment is properly controlled, the concentration of salts can be materially raised without the deposition of solids. To avoid excessive impurities in the steam, it is usually necessary to limit the concentration of the water in the boiler proper much below the point where any detrimental effects to heating surface, thin scale formation, or deposition of solids will result.

The impurities in the steam which are given at 0.7 ppm with water washers is not exceptionally good in view of the fact that there are many installations operating without steam scrubbers which are producing steam, the impurities in which do not exceed 0.2 ppm.

The author states that the limit in the range of operation of the so-called wet-bottom furnaces is often restricted to from 0.75 to 1. This ratio is far greater than the load factors on most power systems and the installation of units having such a narrow range of capacity may be a great handicap inasmuch as one of the most difficult problems faced by the operating man is that of taking care of boilers during idle periods. The greater the number of units with restricted range of capacity, the greater the number that will have to be taken out of service during low-load periods. It should be the aim of the boiler designer to increase materially the economical operating range of boiler units.

[4] General Superintendent of Power Stations, Duquesne Light Company, Pittsburgh, Pa. Mem. A.S.M.E.

E. H. TENNEY.[5] The author's reference to the difficulty of obtaining high superheat with ash of low fusing temperature and at the same time avoiding slagging of boiler tubes and damage to the superheater itself is one of particular interest to burners of some Illinois coals. It is a problem which can be met in part by careful distribution of steam through the superheaters so as to cool the tubes adequately. Our new Cahokia boilers designed for a steam release of 260,000 lb per hr have thirteen leads from the steam drum to the superheater inlet header to assist in obtaining adequate cooling effect. The author mentions that the width of a boiler furnace, which it is economical to keep down, is largely determined by questions of draft loss and rates of steam release. It might also be well to add that space for burners is frequently the limitation; that furnace width in many designs may be definitely determined by the room required to place the burners across the front wall.

Reference is made to the three T's of combustion—time, temperature, and turbulence. As the author says in effect, referring to Mr. Kreisinger's comments on certain Bureau of Mines studies, the highest temperature is not always conducive to the most rapid combustion. It has been our experience at Cahokia that the element of time may also be overstressed. With good mixture of air and coal practically complete combustion is achieved in less than 0.6 sec, which requires less than a fourth of the distance from burner tip to boiler tubes. In reference to turbulence, the writer prefers to consider the problem one of mixing coal and air which can be done in the burner where mechanical surfaces can be interposed in the coal stream to accomplish mixing effectively. It has been demonstrated that maintaining a relative velocity between a moving gas stream in a furnace and a buoyant burning particle of pulverized coal is mathematically limited to an extremely short distance and time. It is like trying to throw a feather against the wind. Thus, as the author indicates, a special interpretation of the three T's is necessary in designs of modern high-capacity boiler furnaces.

AUTHOR'S CLOSURE

The author is not entirely in agreement with Mr. Drewry's statement of the method of firing that will produce the lowest boiler inlet temperature. Tangential firing in a dry-bottom furnace will produce exit temperatures equally as low as in wet-bottom furnaces but not at the same rate of combustion. With dry-bottom furnaces and tangential firing, the burners must be located a greater height from the floor of the furnace to avoid slagging of the ash pit.

The author believes that rapid combustion in the bottom part of the furnace and a high scrubbing velocity of hot gas on the water-cooled furnace walls are the most effective methods of obtaining a low boiler-inlet temperature.

Mr. Drewry's comments on the emphasis on dependability are appreciated. Dependability should be the aim of the designer and a requirement of the buyer. If steam pressures and temperatures go much higher than are now used, radiant superheaters or reheaters will be necessary.

In reference to Mr. Kerr's comments, Figs. 1 to 5 are intended as diagrammatic representations of a few boiler types and are not intended to illustrate any particular make.

The author fully agrees with Mr. Kerr's statement that the Stirling boiler with outlet on the rear drum is capable of high steaming capacity with high steam quality.

The author does believe that certain types of boilers are free from circulation troubles up to the capacities and pressures at which such boilers have been used, and at the same time will deliver steam of satisfactory quality. Certain other types also

[5] Chief Engineer of Power Plants, Union Electric Light & Power Co., St. Louis, Mo. Mem. A.S.M.E.

have good circulation but at high capacity cannot deliver dry steam. Referring to Fig. 1 in the discussion, the author believes Mr. Kerr will agree that on types 1 and 2 it has been necessary to add downcomers outside of the gas passage in order to avoid overheated or steam-bound tubes at high capacities. Types 3 and 4 will, when operated at extremely high capacity, have partly dry tubes in the high end of the upper tubes. The author doubts that the type-8 boiler would be satisfactory from a circulation standpoint at high pressure and at evaporation rates of 15 lb per sq ft. No comment is called for regarding types 11 to 18, inclusive, except that it does seem probable that in some of them the circulation might be a problem.

As to furnace exit temperatures and method of determining them, such temperatures have been taken with a bare platinum-rhodium thermocouple. The highest reading with such couples before any slag or ash adhered was assumed to be the gas temperature subject to a radiation correction of a few degrees. The temperatures were checked by figuring back from the temperature of gas leaving the superheater to the temperature of gas entering the superheater, to which was added the probable temperature drop through the front row of boiler tubes.

As to the superiority of the tangential method of firing, no claims are made but the results obtained are satisfactory to many users. It is true that this method is not universally applicable.

Mr. Kerr's assumption that the rate of absorption of 100,000 Btu corresponds to a release of 200,000 is not entirely correct. For 200,000-Btu release the absorption may be anywhere between 100,000 and 70,000 depending on many factors. Local rates of absorption may well be in excess of 100,000.

A steaming or nonsteaming economizer may be considered a matter of preference or an unavoidable feature of design. The author's preference is for a nonsteaming economizer.

No statement was made that the use of recirculators in waterwalls is poor practice or that walls without such circulators are superior. The author stated and believes that the use of walls without recirculators constitutes good practice.

Comments on the balance of Mr. Kerr's discussion would be controversial and would serve no useful purpose. The author feels, however, that the discussion is timely and will be helpful in bringing out certain details not covered in the paper.

Mr. Purcell's suggestion of the use of radiant superheaters is logical but the problem of application in a furnace having a high rate of heat release is not simple. Port Washington[6] presents a good example of what can be done in a low-heat-release furnace.

The limit of heat absorption in waterwalls has not yet been reached. If water can be kept flowing through furnace wall tubes there seems no reason why absorption rates of 200,000 Btu per sq ft cannot be safely obtained. There is undoubtedly a limit but this limit has not been reached in commercial furnaces.

Equations for friction loss of water flowing through tubes give widely varying results. Little is known of friction losses of flowing mixtures of water and steam. Certain empirical equations are used in the design of the La Mont boiler which have given reasonably satisfactory results. A study suggested by Mr. Purcell would be valuable in the art of boiler design.

The author agrees that recirculation in waterwalls may be used without danger. Referring to Fig. 16 in the paper it will be seen that risers from side and front waterwalls completely cover and protect the upper part of the furnace. Recirculators on this unit are definitely not desirable.

As to the performance of steam washers, the accuracy of determinations of $^1/_2$ ppm to within $^1/_2$ part are open to question. The purpose of a steam washer is to remove those salts that, when present in high-pressure steam, deposit on turbine blades to an extent that definitely reduces the output of the turbine. Any washer which prevents such deposits and enables the turbine to carry its rated load indefinitely is performing satisfactorily regardless of whether tests of quality show $^1/_2$ or 1 ppm.

The range of operation of wet-bottom furnaces depends on many factors. With ash of low or moderate fusion temperature, the range may be 1 to 3, and under some conditions of fluctuating load 1 to 5.

Mr. Tenny is quite correct in stating that the width of furnace is often fixed by the number of burners required. It may be well to add here that to meet these conditions by using fewer larger burners is not always possible nor desirable.

As to Mr. Tenny's comments on time, it should be borne in mind that time in combustion is relative. Turbulence is necessary to reduce time. Change of direction of coal and air streams, impingement of flame on walls, or streams of coal and air directed against each other produce turbulence and additional mixing. By such methods most of the combustion is completed quickly, or in a short period of time. The time required for a given completeness of combustion will depend then on the type or method of firing. This is the case with either solid, liquid, or gas fuels.

Investigation of Stress Conditions in a Full-Size Welded Branch Connection[1]

J. M. Aiton.[2] The writer has read this paper with great interest because he has lately carried out a series of tests to destruction on similar branches, and has formed the opinion that the type of reinforcement adopted by the authors is not the best available.

Fig. 1 Failure of Welded Branch With Reinforcing Ring

The writer's experiments were carried out on pipe $12^1/_2$ in. OD × 0.400 in. thick.

In one of the tests a reinforcing ring was used equal in thickness to the pipe wall and, therefore, in proportion somewhat wider than that used by the authors. This failed in the form of a long tear at the crotch extending into both the body and the branch. Fig. 1 shows two views of this branch after failure.

The final design of reinforcement consisted of a strap and

[1] Published as paper FSP-60-12, by F. L. Everett and Arthur McCutchan, in the July, 1938, issue of the A.S.M.E. Transactions, p. 399.

[2] Aiton & Co., Ltd., Derby, England.

FIG. 2 THE STRAP-AND-CRAVAT WELD

cravat, as shown in Fig. 2. This burst in the body of the pipe remote from any welding.

Fig. 12 in the authors' paper, which shows their manifold after test to destruction, does not appear to be a very good result, because the tear seems to start adjacent to the welding of the reinforcement in that part of the body, the structure of which may have been affected by the welding. This does not prove that the branch and the metal adjacent to it is as strong as the original. The writer's test proves conclusively that the strap-and-cravat method of reinforcement produces a branch which, together with the metal adjacent to it, is stronger than the main pipe.

F. C. FANTZ.[3] The authors of the subject paper have contributed a great deal toward the solution of the problem of reinforcing branch connections in welded piping. It is believed that certain things should be pointed out for further thought and study on the part of the authors and those engineers interested in design.

First, the paper states, "The ring type shown in Fig. 1*c* which has been used extensively because of its simplicity and the fact

Fig. 3 Fig. 4

FIG. 3 SADDLE FOR REINFORCING WELDED BRANCH CONNECTIONS

FIG. 4 METHOD OF APPLICATION OF SADDLE

that it can be made without die equipment. . . ." It is assumed that the reference is to a plate ring that could be rolled to the radius to fit the header and have the proper hole cut for the branch pipe.

Fig. 4 shows a reinforcing ring extending above the center line of the header approximately 2 in. along the side of the branch pipe. It is not clear how this reinforcing ring could be made to extend along the branch as shown, without the use of dies. Fig. 1*c*, as well as the photograph of the destroyed manifold, Fig. 12, does not show this extension along the branch but rather shows the type of ring described. It is agreed that the extension as shown in Fig. 4 is beneficial at the critical section, which is the flat side of the intersection. It is also believed that this extension should go beyond the top of the header in order to reinforce the entire flat section. It is pointed out in the paper that considerable deformation took place at this flat section above the reinforcing ring.

[3] Vice-President, Midwest Piping & Supply Co., Inc., St. Louis, Mo.

The primary object of reinforcing a branch connection in a header is to compensate for the material cut out of the header, and to take care of the irregular shape of the cross section at this point. In order to compensate properly for this irregular shape, the reinforcing ring or saddle should have a ring section encircling the branch connection to a point at least above the top of the header. Such a reinforcing saddle is shown in Fig. 3 herewith.

Fig. 4 shows the application of this saddle and the method of making the branch weld before the saddle is welded to the branch and header. After the welding of the branch, the saddle is slipped down to a fit on the header and welded for strength. It should be pointed out that the weld on the saddle is not for tightness but for strength alone.

In this connection it may interest engineers who are applying either this type of saddle or the ring type on structures that are to be stress-relieved or annealed after fabrication, to know that a hole should be drilled in the ring or saddle to prevent generation of pressure during the heat-treating process of the assembly, at which time this section is heated and is in a more plastic condition. Serious deformation has been observed when this precaution was not taken.

The saddle method of reinforcing does require the use of dies in the manufacture of the saddle. These saddles however can be obtained from stock of several manufacturers in sizes and combinations up to 24 × 24 in.

Tests to destruction have shown that the flat surface on the side of the manifold will not distort to any appreciable extent due to the reinforcing of the ring band of the saddle. This extended ring also tends to prevent stress concentration at the junction of the branch and header caused by the expansion and contraction of the members joined to the header. It can be assumed that the perfect pipe layout would be one in which all members and connections are of the same cross-sectionalstrength and degree of flexibility. Since perfection is an ideal seldom achieved the designer should refrain from too rigid sections at any one point in the line. The saddle type of reinforcing shown in Fig. 3 was designed with the thought that reinforcing would not concentrate undue stresses at any one point. A comparison of the three types shown in Fig. 5 demonstrates this principle. With the saddle type the strength weld of the saddle is not connected rigidly to the

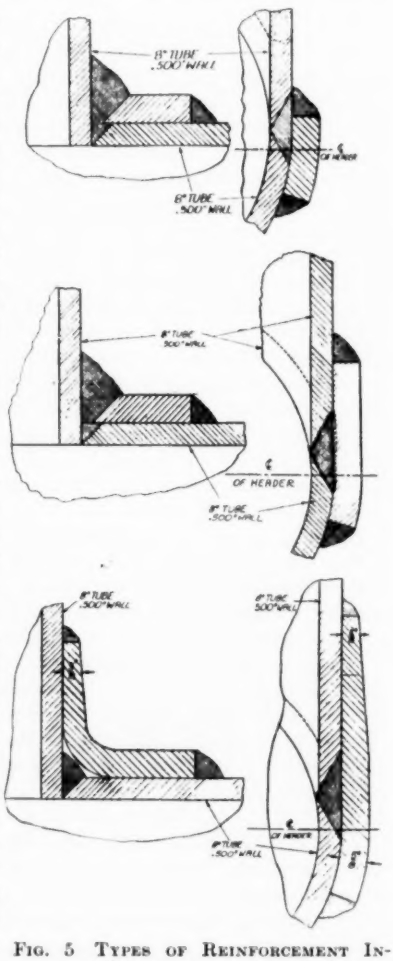

FIG. 5 TYPES OF REINFORCEMENT INDICATING FLEXIBILITY OF SADDLE TYPE

weld that holds the pressure and considerable flexibility is allowed without impairing the strength of the connection.

It is believed that the method of preparing the branch and header for the weld that is to hold the internal pressure, whether or not it is to be reinforced, could be improved. This of course will have nothing to do with the method of reinforcing or the stresses set up by the application of the reinforcing ring. However, it is conceded that the easier it is made for a welding operator to prepare the connection and deposit the metal, the better chance there is for obtaining uniform good-quality welds.

In the preparation illustrated in Figs. 3 and 4 of the paper, detail *A* shows the branch inserted to the ID of the header, and the header wall at this point beveled to 45 deg. The branch connection changes from a square cut to a 60 deg angle shown in the cross section. This method requires a very careful layout and

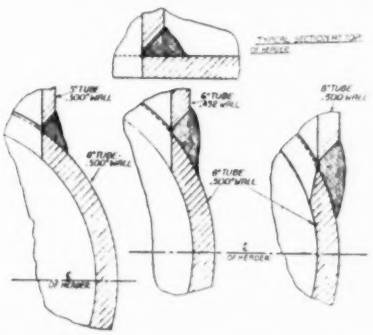

FIG. 6 SUGGESTED METHOD OF CUTTING HEADER FOR BRANCH CONNECTIONS

fit in order to have the proper welding groove. In cases where the distance from the center line of the header to the end of the branch pipe must be made to a fixed tolerance, the operator is faced with making the proper cut in both the header and the branch the first time, and cannot do any subsequent cutting to fit. This is true in a size-on-size connection and, of course, the difficulty is increased with a branch of smaller size than the header.

What is thought to be a better method of preparation for a branch connection is shown in Fig. 6. In all cases where this method is used the hole in the header is cut to the ID of the branch pipe and parallel to the side walls of the branch. This does not require any elaborate technique; in the case of small branch pipes the hole can be drilled or bored and the larger sizes can be cut with the acetylene cutting torch, guided either manually or by machine. It should be noted that considerably less material is removed from the header by this method than by the one shown in the paper.

The preparation of the branch pipe is a true development of a cylinder intersection and can either be laid out on a paper template or cut by a machine-guided torch which is capable of developing this intersection. Such machines are on the market. In the case of a hand-manipulated torch it is held at a constant angle with relation to the axis of the pipe. This manipulation is not difficult for the average welder.

It should be remembered that as the application of welding increases, angle connections will be used to a greater extent and the design and reinforcing of this type of connection is more difficult. It is also thought that the application of the ring type of reinforcement does not lend itself to this type of connection.

D. S. JACOBUS.[4] Tests of the sort described in the paper are most useful in establishing safe and dependable designs; the authors and The Detroit Edison Company should be commended for conducting so painstaking and exact an investigation.

The design of branch connections requires widely different methods, depending on the conditions and the working stresses involved. Designing the penstocks and branch connections at Boulder Dam was a far more involved problem than that of designing piping and fittings for the usual power-plant construction.

The penstocks at Boulder Dam had a maximum diameter of 30 ft and the hoop stress was made to correspond to about one half the yield strength of the material. The effect of the gravity component of the contained water had to be taken into consideration in order to limit the amount of departure from a truly circular cross section and to avoid undue stress concentrations at the points of support. As brought out in an article[5] published in *Mechanical Engineering*, photoelastic investigations were made by Prof. S. C. Hollister. Four models of branch connections were made $^1/_6$ scale and a large model of a girth joint, 15 ft in diameter using plates $2\ ^3/_4$ in. in thickness to which water pressures were applied and strain-gage measurements made to determine the stresses.

In the case of steel flanged fittings which are covered by the A.S.A. standards, the body thicknesses were determined by an approximate rule which was found to conform fairly well with the existing practice of a number of manufacturers, and this approximate rule, through extended use, has been found to give safe and consistent results. The two cases are cited to show the wide difference in the way in which the problem may be handled to meet different conditions.

In the ordinary construction of boilers unreinforced holes are used into which tubes are expanded into the drums and in some cases for attaching nozzles. The Boiler Code Committee was asked to include rules to give the allowable size of such openings. The problem was referred to a number of authorities but no rules of a form that could be embodied in the Code were suggested. The Boiler Code Committee finally published the rules referred to, which were based on data secured through the use of a great number of constructions which had given satisfaction in long-time service. As brought out in the paper under discussion, the rules were limited to a narrow field, which was, however, broad enough to cover any construction normally used in boilers. The rules have been criticized as not being based on a scientific stress analysis, and in each case the Boiler Code Committee has requested those who made the criticism to suggest other rules of a more complete and scientific nature, but so far none has been presented for the consideration of the committee. It is gratifying to note the statement in the paper that despite the limits indicated by the Boiler Code Committee, branch connections made up with reinforcements which compensate for material removed in cutting the branch opening, in accordance with the Boiler Code rules, have been found to develop the full strength of the pipe under hydrostatic tests to destruction.

G. S. LARSEN.[6] The authors are to be congratulated on starting an investigation in a field, which so far has been too little explored. Our general knowledge of the stress conditions in and around welded branch connections is extremely limited and the question of whether the neck itself constitutes sufficient reinforcement for the opening in the header or if additional reinforcement is required has been a constant problem to the piping designer.

[4] Advisory Engineer, The Babcock & Wilcox Co., New York, N. Y. Past-President A.S.M.E.

[5] "Penstocks for Boulder Dam," by C. M. Day and Peter Bier, *Mechanical Engineering*, vol. 56, August, 1934, pp. 451–465.

[6] Engineer, Pittsburgh Piping & Equipment Company, Pittsburgh, Pa. Mem. A.S.M.E.

Where reinforcement has been considered necessary, the efforts of the individual designer have led to a great many different applications as may be seen from the illustrations in Fig. 1 of the paper. As no failures in service have come to this writer's attention, it may be assumed that most of these different types of reinforcement have added sufficient strength. However, piping for the low and medium pressures has usually been designed with a comfortable margin of safety and the possibilities are that most of these necks would have given satisfactory service even without any reinforcement.

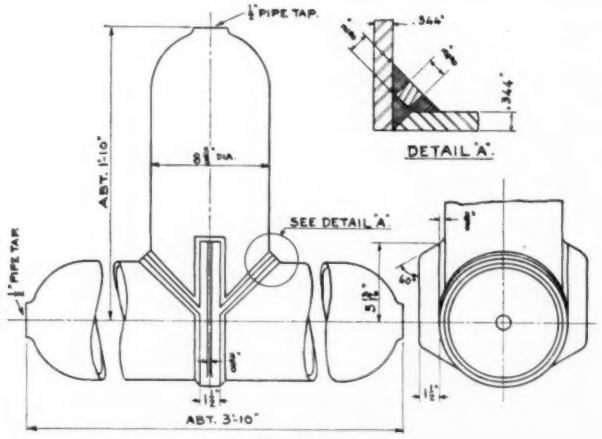

FIG. 7 DETAILS OF REINFORCEMENT SHOWN IN FIG. 8

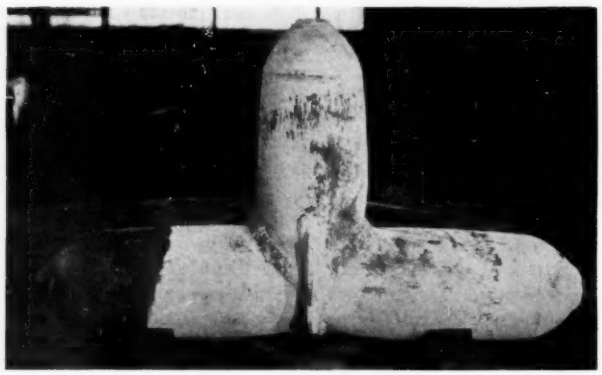

FIG. 8 MANIFOLD AFTER TEST AT 5500 POUNDS PRESSURE

It is also possible that some of the types of reinforcement may have caused increased stresses in some sections of the header or branch. This apparently was the case with the ring type of reinforcement chosen by the authors for investigation, and although this type of reinforcement in the test seemed to develop ample strength, the writer is of the opinion that it is not the best nor the most economical type.

The ring type of reinforcement has one inherent drawback, namely, the fact that unless the basic weld attaching the neck to the header is perfect, the internal pressure may be acting directly on the reinforcing ring. This would entirely change the stress distribution and cause greatly increased stresses in the ring and in the welds by which the ring is attached. It seems that it should be mandatory in the case of ring reinforcement that the basic weld be subjected to a hydrostatic test before the ring is attached. A considerable number of tests on various types of reinforcement will be required in order to develop the best and most economical type.

Some years ago the company with which the writer is connected was required to furnish a number of welded manifolds which were specified to be in accordance with the A.S.M.E. Unfired Pressure Vessels Code and of a design satisfactory to the purchaser's insurance carrier. The purchaser expressed some doubt as to the strength of the type of reinforcement proposed and it was decided to construct a test manifold in accordance with the details shown in Fig. 7. The pipe selected was $8^{5}/_{8}$ in. OD × 0.344 in. wall, made of seamless steel in accordance with A.S.T.M. Specification A-106, Grade A. Unfortunately the detailed reports on the test were destroyed during the flood in Pittsburgh a couple of years ago, but briefly the test procedure and results were as follows:

As no strain gages were available, the manifold was given a coat of whitewash to permit observation of strain lines. Hydrostatic pressure was applied by means of a triplex test pump up to a pressure of 1500 psi. Above this limit the pressure was boosted by means of an intensifier capable of producing pressures up to 20,000 psi. Some strain lines started to appear in the whitewash at a pressure slightly above 2000 psi. The pressure was gradually boosted to about 5500 psi and it proved impossible to raise the pressure beyond this point as the intensifier could furnish only 60 cu in. per stroke and the swelling of the manifold increased the internal volume by a corresponding amount. As the manifold was designed for 400 psi working steam pressure, it was felt that the safety of the neck reinforcement had been proved and the test was stopped without being carried to destruction. Fig. 8 is a photograph of the manifold after the test and it will be noted that while the outside diameter of the pipe had increased from $8\ ^{5}/_{8}$ in. to about $10\ ^{1}/_{2}$ in., little distortion had taken place at the weld.

It may also be of interest to note that the end closures, made by rolling down the pipe and closing the end with a pad welded on, showed little distortion.

On account of the large amount of welding required, the type of reinforcement used on this test manifold is not considered to be the best that can be developed but it is believed to have some advantages over the ring type of reinforcement.

E. R. SEABLOOM.[7] The authors are to be congratulated on their paper. This type of information is much in demand by fabricators and designers as there is a definite scarcity of published data, design rules, and code regulations pertaining to welding design of piping, such as we have on boilers and pressure vessels.

As stated by the authors, after the completion of their investigation, the manifold was turned over to the subcommittee on welded branch connections of the A.S.A. Sectional Committee B31 for further tests. The members of the Pipe Frabrication Institute are cooperating with this subcommittee in the fabrication and testing of manifolds to determine suitable designs of reinforcement for welded branch connections. The Crane Company's part in this program is to serve as the testing laboratory for the committee and consequently the header was sent to this company's research laboratories for the test to destruction.

This discussion is, therefore, virtually a report covering the final tests of the header, although additional data gleaned from other investigations are included to substantiate some of the authors' statements.

Test Procedure. The manifold was first stress-relieved at 1200 F to remove the effects of cold working produced by the previous tests at the University of Michigan. As the manifold had been so thoroughly explored by means of strain gages, there was no need for additional investigation of this character. It was decided, however, to measure deformations of the manifold

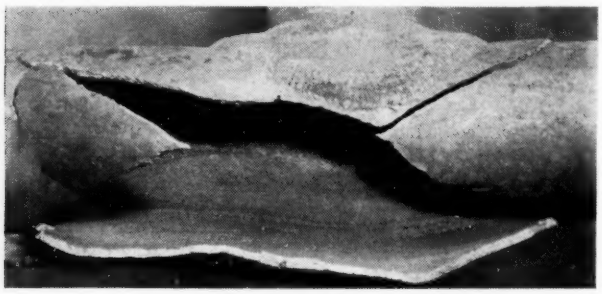

FIG. 13 SHOWING SMALL DRILL HOLES IN FRACTURE

by means of dial indicators, as this would supplement the strain-gage readings and possibly bring about a better understanding of what occurs in the highly stressed areas.

Forty-two Federal dial indicators, graduated in thousandths of an inch, were located around the manifold as shown in Fig. 9. The dials were located diametrically opposite each other, in most cases, in order to eliminate as much as possible, errors in measurement due to shifting of the manifold on its supports when expansion occurred. Internal hydrostatic pressure was applied gradually in 400-lb increments by means of a hydraulic ram, capable of building up pressure to 60,000 psi, and dial readings were recorded at each increment of pressure up to and including 4400 psi. The deflection readings obtained are tabulated in Table 1, and some of the deformations are expressed graphically in Figs. 10, 11, and 12.

It will be observed that the maximum deflection occurred on the nozzle, immediately above the reinforcing ring at right angles to the run of the manifold, as indicated by dials 7 and 8. Considerable deformation also occurred adjacent to and in the reinforced area. This is due to the deviation from a circular cross section when a full-size nozzle is attached, producing a weaker structure to resist internal pressure.

Test to Destruction. The dial indicators were removed and the internal pressure was gradually increased to 8200 psi, when serious leakage occurred through one of the drilled holes which was used for the attachment of strain gages. This leak was repaired by welding and pressure was again built up until failure occurred at 8750 psi. See Fig. 12 of the paper. The failure apparently was influenced to some extent by small drilled holes in the proximity of the reinforcing ring, which are evident in Fig. 13 of this discussion. The rupture, however, is typical of pipe failure under hydrostatic pressure, as illustrated in Fig. 14.

These pipes are a few of a series that were tested to destruction on hydrostatic pressure. They were $8^5/_8$ in. outside diameter, A.S.T.M. Specification A-106, of standard-weight lap-welded

material, 22 ft long. The failure pressures ranged from 4000 to 4400 psi and the failures represent the types generally obtained on piping.

Physical Properties of Material. After the test to destruction, longitudinal and transverse strips were removed from the manifold. One half of these were stress-relieved at 1200 F, and the other half were left in the strained state. Test bars were machined from the strips and tested to determine the physical properties of material. The results are shown in Table 2. Averaging the tensile strengths indicated by the transverse flat and round bars in the strained condition, a value of 76,375 psi is obtained. Applying this tensile value in Barlow's formula, the theoretical bursting pressure of a pipe without any openings would be 8855 psi, thus showing that the ring reinforces the manifold at the nozzle connection sufficiently to bring the failure pressure up to that equivalent to a straight length of pipe.

Test on End Closures. Sections approximately one foot long containing the three types of heads, were removed from the manifold and nozzle. The open ends were closed by means of welded-in flat heads $2^1/_2$ in. thick and the assemblies were tested to destruction on hydrostatic pressure. The failures are illustrated in Fig. 15. The first and third assemblies failed at 10,500 psi. The center assembly failed at 11,200 psi and the increase in bursting pressure over the other two is due to the shorter span of pipe between the heads. These end closures are described in the paper.

Tests on Other Manifolds. Some time ago a series of tests was organized to determine the reduction in strength caused by the attachment of nozzles to piping or manifold. One phase of this investigation was conducted on 8-in., Schedule 40, A.S.T.M. Specification A-106, Grade A carbon-steel tubing, and all of the tests were made on 5-ft lengths cut from one length of pipe in order to avoid discrepancies in results due to variations in physical properties of material.

The straight length of pipe shown in Fig. 16 ruptured at 4600 psi. The manifold shown in Fig. 17, having an 8-in. unreinforced nozzle at the center failed near the crotch at 3200 psi, or 33 per cent lower than the straight length of pipe. The manifold, with an 8-in. reinforced nozzle, employing a ring of somewhat similar design and proportions as the one investigated by the authors, fractured outside of the reinforced area at 4550 psi, which is approximately the same as for the straight length of pipe. See Fig. 18. The manifold with a 4-in. unreinforced nozzle failed in the crotch, as shown in Fig. 19, at 4650 psi, or practically the same pressure as the straight length.

Fig. 20 shows the results of deflection readings obtained on the straight length of pipe and various manifolds at the center sections under pressure. While considerably greater deformation occurred on the reinforced header compared to the straight length of pipe, both failed at practically the same pressure, thus indicating that the ring reinforces the structure as far as ultimate failure is concerned.

Stress Conditions in Crotch. The authors deduced analytically that high stresses existed in the inside wall of the manifold at the crotch. This interpretation is correct, despite the fact that the stresses on the inside cannot be satisfactorily measured, as practically all structures of this type, such as tees, elbows, and valves, generally fail in the crotch. Evidence of this is furnished by Figs. 21 and 22, which show failures of a cast-steel tee and welding elbows.

When testing large oval-section cast-iron gate valves to destruction on pressure, better observations of stress conditions are obtained, as deflection and strain-gage measurements are of greater magnitude. Fig. 23 shows a portion of a 48-in., 25-lb working pressure, cast-iron gate valve set up for test. The central area of the flat side deflected outwardly 0.154 in. at 105

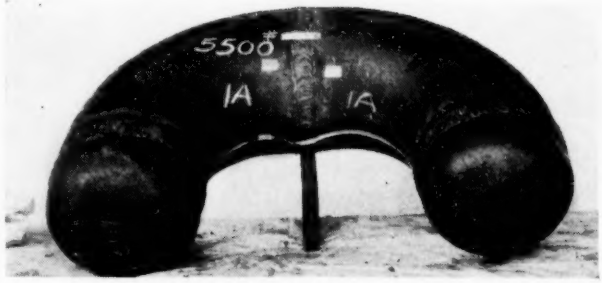

FIG. 22 FAILURE OF CAST-STEEL WELDING ELBOWS

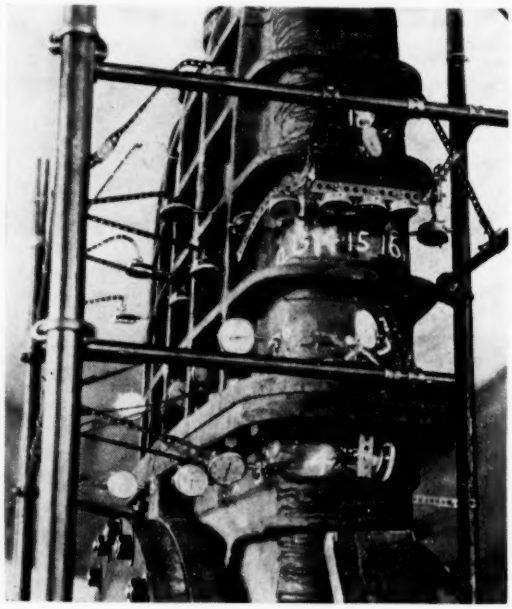

FIG. 23 TEST ON 48-IN. CAST-IRON GATE VALVE

FIG. 24 FAILURE OF 48-IN. CAST-IRON GATE VALVE

psi internal pressure, while the narrow side deflected inwardly —0.034 in. Strain-gage readings indicated that high tensile stresses existed on the outside of the flat sides, while compression stresses were in evidence on the outside of the narrow sides. Consequently, the stresses on the inside of the walls were reversed from the conditions on the outside. Cast iron is approximately four times stronger in compression than in tension, yet the valve failed on the narrow side as shown by Fig. 24, which indicates that rupture commenced on the inside of the narrow wall. We have produced further evidence of this fact by redesigning cast-iron oval-section valves in such a manner that all reinforcing ribs are placed in compression, that is, the ribs on the flat sides were located internally and on the narrow sides externally, with the result that bursting pressures have been increased over 100 per cent, even though failures occur on the narrow sides.

Reviewing all of the test data presented, it is evident that the findings and conclusions of the authors are substantially correct, and that the paper is a valuable contribution to the technical literature on this subject.

F. E. Wertheim.[8] The authors have proved the need of reinforcing a full-size welded pipe-branch connection, and have also proved the efficiency of the ring-type reinforcement, thereby furnishing a basis for sound design.

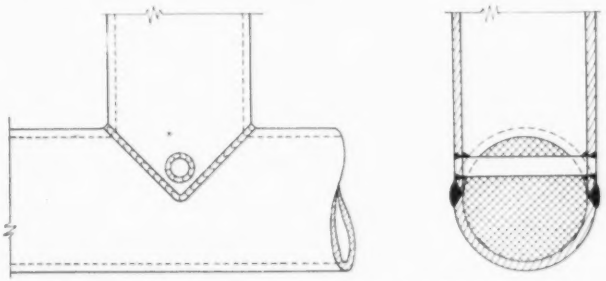

Fig. 25 Showing Use of Stay Bolt for Reinforcing

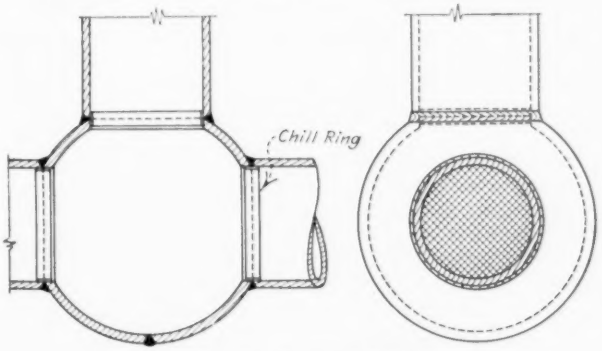

Fig. 26 Backing Ring

If this type of reinforcement receives the indorsement of the special subcommittee on welded branch connections of A.S.A., Sectional Committee B31 on Code for Pressure Piping; then it would appear advisable to add such reinforcing rings to commercial lines of welded fittings, even though, as stated, the ring can be made without die equipment.

All three divisions of these tests, i.e., (1) exploring the unreinforced weld, (2) exploring the ring-reinforced weld, and (3) bursting tests, emphasize the appreciable deformation of, and the consequent bending stresses in, the flat portion of the structure. The writer wishes to suggest the advantage of minimizing, or eliminating, bending stresses, with their tendency to create severe stresses in the crotch.

Fig. 25 shows a simple welded stay-bolt construction; the stay bolt is to be welded into the nozzle before it is joined to the header. The bolt should be strong enough to compensate, to a considerable degree, for material removed for the branch opening. Objections that the bolt obstructs flow are valid, nonetheless, stay bolts are still widely used in water legs of various kinds of boilers.

Fig. 26 shows a construction free of bending stresses, in which only simple butt welds are required, and which can be fabricated

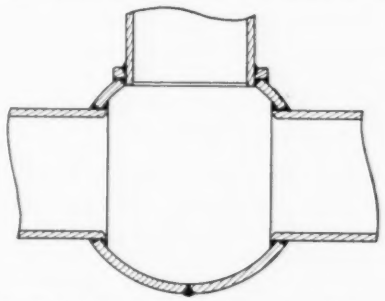

Fig. 27 Two Methods of Reinforcing Spherical Openings

from welding fittings (semispherical welding heads) to be had on the market. An alternate construction is possible by swagging a full-size pipe to form the spherical portion. Since the spherical part is shown with thicker wall than the pipe, and the openings are strengthened somewhat by the pipe and welding bead, reinforcement at the openings may not be necessary. Fig 27, however, shows two methods of reinforcing openings in the spherical portion.

These designs are submitted for the consideration of the special subcommittee on welded branch connections, with the hope that they will at least rate high enough for some tests with half-size models. No originality is claimed; the stay bolt is an ancient device; and the spherical construction has been shown previously.[9]

In Mr. Crocker's construction, the openings in the spherical end are reinforced with dished rings.

F. S. G. Williams.[10] The authors are to be complimented on the comprehensive work done in the investigation reported in this paper. The remarks by Dr. Timoshenko raised a point that is really quite vital in the study of branch connections, namely, the effect of the branch connection and its reinforcement upon the stress conditions in the area surrounding the reinforcement. Obviously Dr. Timoshenko had in mind the possibility of transferring the stress concentrations from the area immediately adjacent to the branch into the body of the header and the data submitted by the authors would indicate that such a transfer did occur in the unit under investigation.

It is well worth directing more pointed attention to it as one of the basic principles of design which must be given proper consideration in high-pressure work. It is necessary to know how much reinforcement to apply to any given connection but it is equally important to know the shape and proper distribution of the reinforcement required to produce a proper balance of the flexibility of all sections of the completed structure and to reduce

stress concentrations to safe figures for design purposes without creating additional stress concentrations in other areas.

Apparently there has been a tendency on the part of the authors and on others, as evidenced by the discussion submitted by Mr. Seabloom, to consider only the problem of so-called fabricated branch connections. It would leave a false impression with the casual reader if it were not pointed out at this time that the most recent high-pressure installations have, as far as possible, avoided the use of the built-up branch connections with their attendant reinforcing pads of one type or another and have employed seamless forged-steel tees in which the reinforcement has been carefully distributed to attain the desired uniform flexibility and in which the welding procedure has been transferred from the complicated problem of branch welds to the now well-established and controllable circumferential weld. It would seem, therefore, that any further investigation along the lines of this excellent work should give due consideration to the effect of the distribution of reinforcement in an effort to develop a badly needed body of data from which quantitative rules could be formulated.

Recently a hydrostatic-pressure test was made on 5-in. and 8-in. Taylor Seamless Welding Tees. The fittings tested were regular stock items and the material was in accordance with A.S.T.M. Specification A-106, Grade A, seamless. This pipe has a minimum tensile strength of 48,000 psi and, based upon this the bursting strength of the 5-in. and 8-in. standard-weight pipe is 4670 and 3700 psi, respectively. An internal pressure of 5000 psi was applied to both the 5-in. and 8-in. tees, and this was well above the theoretical bursting pressure for corresponding pipe.

Authors' Closure

The authors wish to thank those who have contributed so much to the value of their paper by their interest and discussion. The strap and cravat reinforcement proposed by Major Aiton is novel and for certain types of loading may be a desirable, though possibly expensive, form of reinforcement. The attachment of the cravat in common with all gusset types of reinforcement gives high stress concentration which under pulsation, or vibration, may result in cracking of the weld. The failure of the ring-reinforced manifold in the crotch as shown in Fig. 1 of his discussion is contrary to all tests made in this country where the cross section of the ring has been made equal to the metal removed from the header in accordance with A.S.M.E. Boiler Code rules. Possibly the fact that the ring was made in two parts with a weld at the crotch location may have had some bearing on the location of this failure.

Mr. Fantz has emphasized the advantages of a method of preparation in which the branch alone is beveled. Subsequent to constructing the test manifold, The Detroit Edison Company investigated the advantages of the construction favored by Mr. Fantz as shown in Fig. 6. To obtain a practical design for a full-size branch connection it was found necessary to make supplementary V cuts and to bevel the header at the sides, otherwise the design shown in Fig. 6 is believed to be entirely satisfactory. One advantage of this construction not mentioned by Mr. Fantz is that it permits the use of a backing ring, an improvement not feasible with other methods of preparation. Backing rings permit adequate separation of the branch and header so that the designed weld cross sections actually can be obtained at all points around the intersection.

While recognizing the simplicity of forged saddles, the authors prefer a modification of the reinforcement used in their tests. This modified reinforcement consists of a ring which extends lower on the sides than the test ring to cover the region where final failure occurred and separate side plates which, in conjunction with the redesigned ring, should prevent excessive distortion at the sides of the manifold.

The remarks of Doctor Jacobus relative to the tests and special factors involved in designing the penstocks at Boulder Dam are of interest. The authors were pleased likewise to find that the Boiler Code rules give a satisfactory basis for proportioning the crotch reinforcement.

The test data supplied by Mr. Larsen on a different type of reinforcement are a welcome contribution. This reinforcement while not as economical as might be desired apparently prevents bulging of the sides of the manifold and is in other respects entirely adequate. Since we have never had leakage occur on hydrostatic tests of high-pressure welded joints, the need for venting the reinforcing ring mentioned by Mr. Larsen has never developed but it may be good general practice. Where reinforcing saddles have been used, vent holes were provided.

The discussion by Mr. Seabloom is so comprehensive and contains so many valuable test data that it can be considered as a complete paper in itself. The authors are greatly indebted to Mr. Seabloom and to Crane Company for their cooperation in making the final tests and for their thoroughness in presenting the results.

The use of a stay bolt to prevent bulging of the sides, suggested by Mr. Wertheim, has possibilities, although the high concentration of stress where the stay bolt is welded to the manifold is undesirable. For the particular manifold tested, a stay bolt of approximately 2 in. diam would have been required which, as noted by Mr. Wertheim, would have caused some restriction to flow. The spherical construction has certain advantages, particularly for Y fittings. Commercial welding caps or heads are of ellipsoidal rather than hemispherical shape which destroys some of the economy and convenience of this method of construction. Its undoubted advantages from a distortion standpoint might offset the probable increase in cost over the conventional branch weld.

Mr. Williams' point is well taken that some types of reinforcement may result in high stress concentrations where large changes in rigidity of the composite structure occur. Where adequate thickening at the crotch and sides of welding tees is provided and if the material is comparable with the pipe material, the natural tendency would be to use ready-made tees. The relatively high cost of such tees and the present necessity of making the larger sizes by boring out solid forgings has caused particular emphasis to be placed on fabricated branch connections.

The authors are gratified that their paper has brought forth so much worth-while discussion by many competent engineers whose comments have served to clarify the presentation and augment the results.

Development of the Focke Helicopter

By HEINRICH FOCKE,[1] DELMENHORST, GERMANY

The paper gives a description of the methods used in the development of the Focke helicopter. After a short review of the analytical and experimental information regarding the helicopter in existence prior to 1932, the author states the fundamental requirements to be met and indicates the procedure adopted to satisfy them. The analytical discussion is based on the Glauert-Lock theory of the autogiro rotor, and the author shows in outline the various steps in extending the theory to cover the helicopter rotor.

Finally, the construction and testing of the first machine are described, together with its successful flights.

HIGH SPEED, the great gift which the airplane has given man, is also a curse, from which he has not yet been delivered. The inability to stand still in the air, to rise vertically, and to sink vertically, besides making necessary the use of large areas for airports, produces many dangers; dangers in taking off and on landing; dangers of poor visibility, of flight over unsuitable terrain, in mountainous regions, and over extended forests or marshes.

We all know the means which have been employed with great success in the airplane to secure minimum speed, and from the very nature of these methods it is impossible to reduce the speed to zero. This is because the necessary down-wash of air, required to produce lift in the airplane, is produced by the forward speed, and furthermore it is impossible to deflect the air through as much as 90 deg, the ideal but unattainable optimum. The third factor, the mass of air affected, can only be increased by increasing the area of the lifting surfaces, and the extent of such increase in area is governed by structural limitations.

Nevertheless it is easy to see why the airplane was the first successful type of flying machine. The reason is found in its simple construction. In the early days when all was unexplored territory in this uncommon and difficult problem it was a tempting idea to have no moving parts on the flying machine itself other than the control surfaces, and with the airplane, the moving mechanism, outside of the engine, was simple, as the propeller could be mounted directly on the motor shaft.

With the first visible successes in the years 1907 to 1909, there arose a situation, which we can now see to have been extremely regrettable, a situation that created limitations where there should have been no limitations. As soon as one type of construction was successful, that type of machine, the airplane, was demanded exclusively, and attempts at flight along other lines were forgotten. We had to wait from twenty to thirty years before we could see that the practical achievement of one solution was not proof that another solution was impossible. The obstinate adherence to the methods with which the first flights had been made, is in itself understandable, as is also the oversight of the fundamental defects of this first solution.

We know exactly what limitations the airplane has today. We allow for these limitations and adjust ourselves to them. We improve the airplane continually, within the limits of its possibilities. That is right and must be so but, in doing this, we must not forget one thing for the future: We can only achieve new fields of application by going back to fundamental principles and exploring new paths.

When the problem of making aircraft independent of the forward speed is put before us one requirement becomes paramount. We must give the supporting elements their own movement relative to the air. This requirement must be met in practice with the least possible complication. Flapping and feathering hold some technical attractions but, after sober reflection, we must conclude that one of the simplest and theoretically best-known machine elements, the airscrew, is most appropriate for this purpose.

As we all know, the idea of the power-driven airscrew on a vertical axis, is quite old, going back to Leonardo da Vinci who drew up the first direct-lift machine. The interesting subsequent history of the lifting airscrew must be omitted here because of lack of space, but we know that it is only recently that it has progressed beyond the laboratory stage.

Two impulses in quite recent times have greatly increased interest in lifting airscrews. One came from necessity. For many military, geographical-exploration, photogrammetric, and radio purposes a craft is required that can take off and land with little or no run, can hover in the air, and land or climb vertically or at any desired angle. Such a craft also opens up the possibility of extensive private flying because it can be turned and maneuvered at will and does not require a large landing field. With the helicopter, roof and garden landings are no longer Utopian.

The other impulse came from the technical side. De la Cierva has shown with his autogiro, that a large rotating airscrew is a reliable element of support, and he has so stated many times. However, his machine is not a direct-lift machine and, apart from the jump take-off, cannot rise or sink vertically or hover in the air, as the airscrew is not driven by the motor but "autorotates" freely in the air stream. The forward speed is produced in the usual manner by the motor and the propeller. The connection between the lifting airscrew and de la Cierva is only a loose one, and de la Cierva himself refused its possibilities.

Without doubt the autogiro represents an interesting transition between the airplane and the helicopter. It has no better take-off than the airplane, but it can land at a speed of around 40 km (25 miles) per hr, and has a further valuable property in that the rotating blades have their own velocity relative to the air and hence cannot be stalled, with resulting loss of control. The common feature of rotating blades has led to the general appelation for both types of rotating-wing aircraft.

The very existence of the autogiro rotor has provided theoretical information without which the helicopter would have been a long time developing. The British Air Ministry, when examination and tests of the de la Cierva autogiro were under way, commissioned aerodynamic experts like Glauert and Lock to undertake the mathematical investigation of the peculiar phenomenon of autorotation, that is, the free rotation of a large airscrew placed at small angles of attack relative to the air stream.

We shall see later that an extension of the Glauert-Lock theory can be applied to the forward flight of a power-driven helicopter rotor, down to quite small velocities. We must also add that for

Presented by W. Laurence LePage.

Contributed by the Aeronautic Division and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., December 5–9, 1938.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the helicopter lifting rotor with a purely axial air stream, that is, a rotor without forward velocity, a series of theoretical calculations and experiments had been carried out by von Kármán, Flachsbart, and Helmbold. There were also methods for obtaining the best thrust distribution along the radius, and a stability investigation by von Kármán which drew pessimistic conclusions. These constitute roughly the scope of the theoretical development of the autogiro rotor and of the direct-lift rotor up to about 1932.

In practice, by 1932 the following performances for the helicopters had been accomplished by Pescara (France), d'Ascanio (Italy), and Oehmichen (France), which were official or at least officially confirmed: distance, about 1 km; duration, about 10 min; height, about 18 meters. There had been no real sustained flight with helicopters up to that date.

On the other hand the autogiro was already in regular use, although its performance was and is today somewhat inferior to that of the airplane. To develop a true helicopter five years ago, without the attendant limitations of the autogiro, was, therefore, to develop an entirely new type of craft, not to improve an already existing machine, and, while inventive effort is worthy, sober reflection upon the aspects of the problem and a thorough investigation of each phase is a far better approach.

Fundamental Requirements of a Helicopter

The fundamental requirements of a direct-lift aircraft are, in order of their importance, the following:

Ability to Make an Emergency Landing After Failure of the Power Plant. This most important basic requirement, which has become self-evident with the airplane, no helicopter had as yet fulfilled, although theory had indicated that it would be possible to convert the lifting rotor into an autorotative system such as had been demonstrated by Cierva. To accomplish this it is necessary that the pitch angle of the blades become smaller than that used with the power-driven lifting system. This involves a mechanical complication which cannot, however, be avoided because an aircraft without the capacity to land smoothly after failure of the motor or the transmission is unthinkable in aircraft practice.

Controllability and Stability. The aircraft must be controllable, at least with normal skill, in all flight conditions including hovering. It must also have static stability about all three axes, and it is desirable to have dynamic stability about these axes. In this question of stability had been the weakest spot of all previous helicopter experiments. Helicopters up until this time had possessed little or no stability, and only by lightning-quick movements of the controls had it been possible to maintain flight and then only for a short time. For other types of helicopters, which later failed of accomplishment because of other defects, it was said that they would have been stable, but the reason for such claims of stability was never clear. Von Kármán's pessimistic predictions regarding stability led many to think that a really practical helicopter was impossible.

The autogiro has given no particular difficulty in this regard at normal speeds but theory and practice have shown that below a speed of about 40 mph, the autogiro becomes dynamically unstable about some axes at least, and to some extent unstable about all three axes. In practice this instability at low speeds had caused no difficulty, because the slowest speeds were employed only for short periods. With the helicopter, the outstanding characteristic of which is its ability to hover, this question of stability must be considered much more carefully. We must have, if not complete static and dynamic stability, at least normal controllability which must be maintained for hours, and under all weather conditions.

General Reliability of Functioning. In this respect the helicopter has had a great weakness. One could not speak of reliability of functioning when the duration of flight was of the order of a few minutes. The nonmoving structural parts are not subject to any greater stresses than are the wings of a normal airplane. The transmission parts must have at least the reliability of the motor, and these transmission parts have of necessity to be smaller than the structural elements of the wing cells. It should be understood that we are speaking of general reliability, in addition to which the requirements for emergency landing, already mentioned, must be immediately available, and must confer the ability, comparable to that of an airplane, to make an immediate forced landing.

Simplicity of Handling by the Pilot. The technical phases of design are only a part, perhaps the smallest part, of any new problem. The design must be such that the average pilot can handle and fly the machine. It is, therefore, essential to lighten the task of the pilot as much as possible. He must be provided with a control system and other operating means to which he is already accustomed in the airplane. At most only a few more manual operations must be demanded of him than are required in the operation of the airplane. The controls must not only operate in the usual directions, but also their movements must be of the usual magnitudes.

Performance Must Be Acceptable. It is of course self-evident that we cannot, at least at first, realize in the helicopter the high-speed performance of the airplane. We must pay a price for the special ability of rotating-wing aircraft in the slow-speed region. But it would reduce the practical value of a helicopter greatly if it could only hover in the air and we must seek, therefore, a performance for the helicopter which is at least comparable with that of the airplane.

Reasonable Maintenance. Naturally, all personnel handling new apparatus must become accustomed to it, yet it must be possible to maintain the helicopter structure in much the same fashion as the structure of a conventional aircraft, and the power plant should be susceptible of the same maintenance as the motor of a conventional airplane.

This summary of the most important requirements of the ideal helicopter, indicates that the solution will not be found in a remarkable patentable solution, by a so-called Egg of Columbus. There is only one path really open: To investigate many very different questions with equal care, and with equal thoroughness, and to keep them all in mind when undertaking the construction of a helicopter. Many of these questions, such as the many stability problems, lie in the region of theory, while others, such as easy handling and control, are in the region of the practical arts. In between lie the difficult constructional or mechanical problems.

In this work, as in some earlier work with a direct-lift machine, the procedure was as follows: First, many comprehensive experiments in the wind tunnel; then full-scale tests of the structural elements; and finally full-scale construction and flight tests with verification of every step with scale models. I have found that this took relatively the shortest time, and also assured the greatest success.

Let us summarize what has been said before. Prior to 1932 we had the practical autogiro, the rotors of which were not motor-driven, which afforded low minimum speeds; and, hardly beyond the laboratory stage of development, the helicopter. We saw that, for hovering, for prolonged steep-angle or vertical climbing, and for taking off and landing in the smallest possible space, the helicopter solution was still to come and would have to be combined wth autorotation as an emergency landing feature.

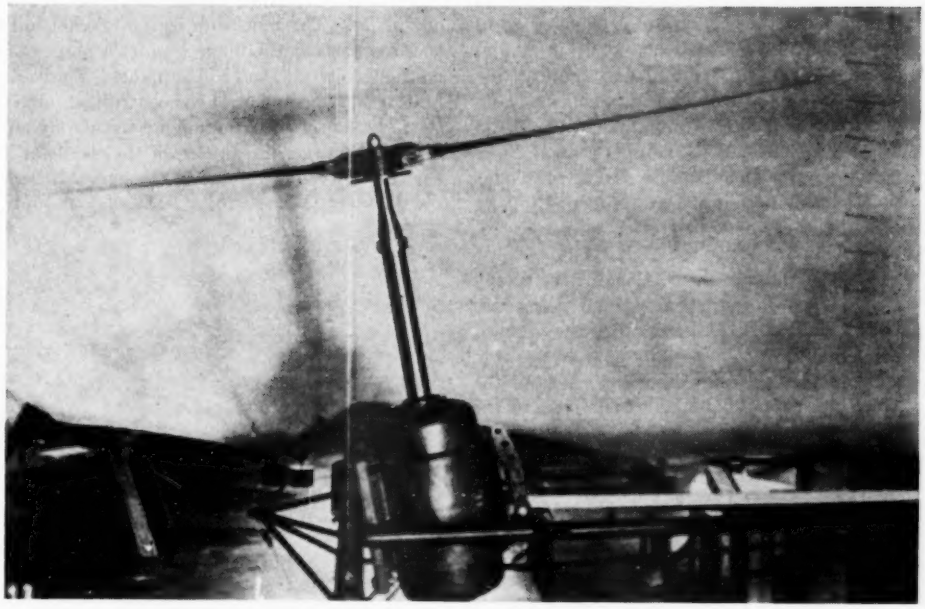

FIG. 1 MODEL OF THREE-BLADED LIFTING ROTOR WITH TEST MOUNTING IN WIND TUNNEL

LIFT PRODUCTION WITH POWER-DRIVEN AND AUTOROTATING AIRSCREWS

The creation of thrust, which is here identical with the production of lift, by an airscrew offers nothing new and I shall assume that the facts relating to the creation of lift or thrust are well known.

In the first place we must consider economy of power. We must seek the best thrust distribution along the radius of the rotor for the least power and the greatest thrust. Some compromise is necessary here, because of our fundamental requirement of emergency landing. The rotor must always autorotate when the power plant fails. If, because of this requirement, some loss in efficiency is incurred, this need not be disturbing.

At the beginning of my own helicopter investigations six years ago, the blades of all successful autogiro rotors, whose autorotation had been demonstrated, were flat (not twisted). If one did not wish to abandon a good thrust distribution along the radius, then the only method was to use strongly tapered blades, of trapezoidal form. These blades were connected to the hub by Cardan mounting, as Colonel Renard had already done in 1904 and as is current practice in most of today's autogiros and helicopters, so as to relieve them of bending moments at the root.

Naturally, these blades were constructed only after much calculation and many measurements in the wind tunnel, both as power-driven and as autorotational systems. Fig. 1 shows a model of the three-bladed screw, driven by a 3-hp electric motor, suspended from the wind-tunnel balance, which measures all forces and moments. Fig. 2 shows some of the test results. The nondimensional power coefficient k_d and also the thrust coefficient k_s are plotted against the pitch angle of the blades ϑ in degrees. According to Bendemann the efficiency of the screw with rotary motion only is given by $(k_s)^{3/2}/2k_d$. The best value of this expression is found to be when ϑ equals 12 deg, and has the value 0.71. That is a good value in spite of the flat (i.e., not twisted) blades. Let us consider the same airscrew, turning freely as an autogiro rotor. The rotor is now started by the motor, the wind tunnel is put into operation, and the rotor is set into autorotation when a certain wind velocity is reached, since a free-wheeling device operates, and disconnects the motor.

The polars can now be measured, just as in the case of the

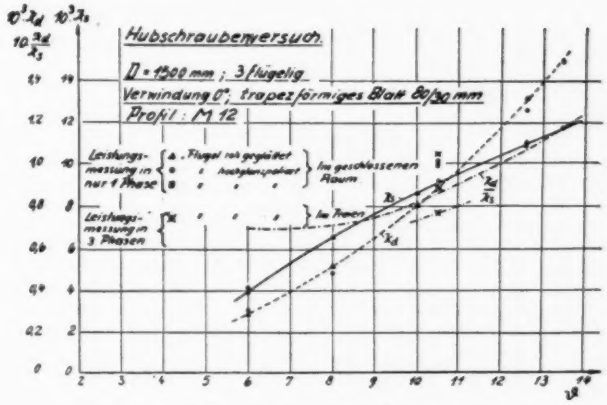

FIG. 2 SOME TEST RESULTS ON MODEL OF FIG. 1

(Power coefficient k_d and thrust coefficient k_s are plotted against the pitch angle ϑ of the blades.
Diam = 1500 mm; three blades, not twisted, tapered from a width of 80 to 30 mm.

autogiro. The air speed, the pitch setting of the blades, and the angle of attack of the plane of the rotor, which is termed α_T can be varied. Fig. 3 shows an example of the many polars which have been obtained with a blade pitch of $\vartheta = 4$ deg. The dotted curve in this figure will be referred to later. If the value of ϑ is increased, autorotation is endangered at a smaller value of α_T, that is, in rapid flight. When the value of ϑ is decreased, then the rotor turns faster for the same value of α_T and the polar curve becomes worse. If we keep a pitch setting of $\vartheta = 4$ deg, then we see that for transition from the helicopter rotor, for which $\vartheta = 12$ deg, to the autogiro rotor, the blades must have a pitch decrease of 8 deg, that is to say, the pitch decrease is of appreciable magnitude.

It has been assumed that the choice of the diameter of the rotor has been made beforehand. It is well known that from the point of view of the helicopter rotor, the large slowly revolving rotor is preferable. The diameter is limited only by construc-

tional difficulties. Again the ability to land in an emergency is the deciding factor. The polars of the autorotating rotor go to a maximum value of $C_a(= C_L) = 1$. If the steady minimum speed is placed at 50 km (31 miles) per hr (from American experiments the "unsteady" value of maximum lift coefficient goes to $C_a(= C_L) = 2$ which would lead to a minimum speed of 35 km (22 miles) per hr), we can use a disk loading of about 35 kg per sq m (7.18 lb per sq ft). Such loadings are also favorable for the direct-lift condition, as they permit a thrust of from 7 to 8 kg (15 to 18 lb) per hp, and the diameters are such as can be embodied in practical construction.

For the calculations of the autogiro rotor, I shall refer briefly to the principles of the Glauert-Lock papers without going into the whole development. See Fig. 4. Glauert adds the forward speed v and the rotational speed $R\omega$ vectorially at each position along the radius, and assumes that only the components of the resultant velocity which are at right angles to the span of the

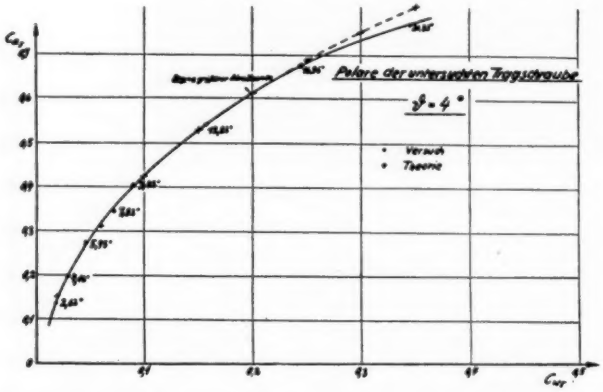

FIG. 3 EXPERIMENTAL AND THEORETICAL POLAR CURVES OF AUTOGIRO ROTOR

(Ordinates, lift coefficient; abscissas, drag coefficient; pitch angle of blades, 4 deg; degree figures on curve refer to angle α_π; dotted curve, theoretical; solid curve, experimental.)

blade need be taken into account for the computation of the air forces. Naturally the local angles of attack change in accordance with the momentary position of the blades during rotation. He designates this local angle of attack by ψ and calculates from the rearmost position of the blades as a base.

In the calculations he employs the air velocity in the form of two parameters, an axial parameter $x = v_d/R\omega$, where v_d is the axial velocity through the plane of the airscrew disk, and also a tangential parameter $\mu = v \cos \alpha_\pi/R\omega$ where $\cos \alpha_\pi$ occurs due to the inclination of the plane of the rotor with reference to the air stream. As the hinged blades are free to take up an equilibrium position, which is the resultant of the weight, the centrifugal force, and the aerodynamic force, and, therefore, bear relationship to the thrust or lift, Glauert is obliged to take the motion of the blades into his calculations. The hinging of the blades allows a forward flight of the rotor, free from the rolling moments which would be present on a rigid rotor, because of the greater lift on the advancing blade. The centrifugal force alone would keep the blades in a plane perpendicular to the axis of rotation as in Fig. 5 (*a*). Under the influence of the thrust the blades rise upward through an angle β and describe an inverted conical surface, of which the angle β may be called the "coning angle."

Glauert sets up the equation of equilibrium of the masses and aerodynamic forces about the hinge and secures the equation of Fig. 5 (*e*)

$$I_1\left(\frac{d^2\beta}{dt^2} + \beta\omega^2\right) = \int_0^R r dS_1 \ldots\ldots\ldots\ldots [1]$$

where I_1 is the moment of inertia of a blade, and S_1 is the thrust of one blade. The first term in the bracket indicates the moment of the masses of the blade against a perpendicular up-and-down motion, which we shall call flapping. The second term within the bracket is the moment of the centrifugal force of the blades. On the right side of the equation are the aerodynamic-force moments in the form of an integration of the elements of thrust. Glauert neglects the moments due to the mass of the blades, as they are

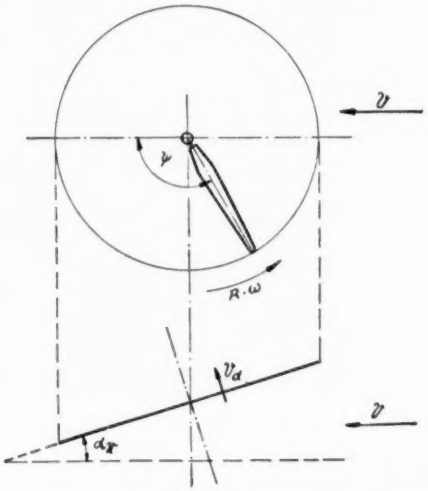

FIG. 4 DIAGRAM OF NOTATION FOR AUTOGIRO ROTOR

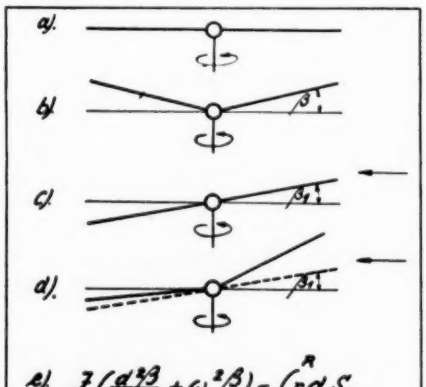

FIG. 5 DIAGRAM FOR GLAUERT-LOCK THEORY

small compared with the moments of the air forces and centrifugal forces. He then develops β and $\int r dS_1$ in a Fourier series and arrives, after some tricks and neglect of terms which I shall not discuss, at the result that the whole cone of the revolving blades is directed backward through an angle β_1 so that β changes periodically with the cycle of revolution, has its maximum value when the blade is in the foremost position, i.e., when $\psi = 180$ deg (Fig. 4), and its smallest value in the rearmost position when $\psi = 0$, when it coincides with the coning angle β. See Fig. 5 (*d*).

Glauert gives formulas only for rectangular blades, with a constant chord t. The whole Glauert-Lock theory was extended by my co-worker Bansemir for trapezoidal blades, in which

extension $t = t_0 - (t_0 - t_1)(r/R)$. Here t_0 is the chord at the root of the blade and t_1 that at the blade tip. The chord decreases proportionately to the radius of the blade. After carrying through the integration of the right side of Equation [1] we obtain, as in Fig. 5 (*f*)

$$\beta_1 = \mu \frac{x\left(\frac{t_0}{2} - \frac{t_1}{3}\right) + 2\vartheta\left(\frac{t_0}{3} - \frac{t_1}{4}\right)}{\left(\frac{t_0}{4} - \frac{t_1}{5}\right) - \frac{\mu^2}{4}\left(\frac{t_0}{2} - \frac{t_1}{3}\right)} \quad \ldots\ldots\ldots [2]$$

The tipping of the whole blade-system cone signifies, therefore, that the advancing blade rises and the retreating blade falls. Now we secure an important insight into the reason why the rotor with hinged blades experiences no tipping moments about the longitudinal axis of the aircraft. The advancing blade, because of its rising path in space, operates at a smaller angle of

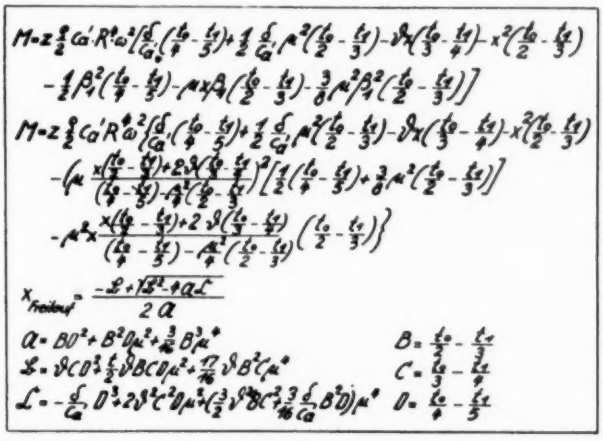

FIG. 6 CHARACTERISTICS OF AUTOGIRO ROTORS

attack, and thus the extra lift due to the vectorial addition of the forward speed and the rotational speed is eliminated. The converse is true with the retreating blade. The regulating cause of this phenomenon is found in the centrifugal force which, at the same speed of revolution and with the same weight of all blades, must be the same everywhere.

Having obtained β_1 the tipping angle, we can determine the further aerodynamic characteristics of the rotor. See Fig. 6. For the rotational moment which with the autogiro rotor must be zero, Glauert deduced the axial parameter x, the thrust S_1, and the distribution of thrust over the radius of a blade dS_1/dr. See Fig. 7. Finally, he deduced the longitudinal force H, which plays the part of the tangential force of an airfoil, and so lies in a plane perpendicular to the axis of rotation and in the direction of flight.

The rest is simple. Out of the normal force, which is in this case the thrust, and out of the longitudinal force, which is the tangential force, we can derive C_a and C_w, the lift and drag coefficients of the whole rotor. Then the polar diagram is available, of which Fig. 3 is an example. Mention has already been made of the wind-tunnel measurements. The dotted curve of Fig. 3 shows how well the English theory, in spite of its various assumptions and simplifications, agrees with the experimental results.

There is only one thing that the theory does not point out. We cannot predict our trial in terms of our first fundamental requirement, the ability to make a safe emergency landing. The dangerous possibility of cessation of autorotation is not indicated by the theory because it assumes a linear slope for $dC_a/d\alpha$ and autorotation ceases precisely because the greater part of the blade, in the region of stalling, assumes large drag coefficients coupled with small increase in lift. There is a factor of safety in the Reynolds numbers, smaller than occurs with the airplane, at which wind-tunnel experiments are made, if the boundaries of autorotation are determined in this manner. The

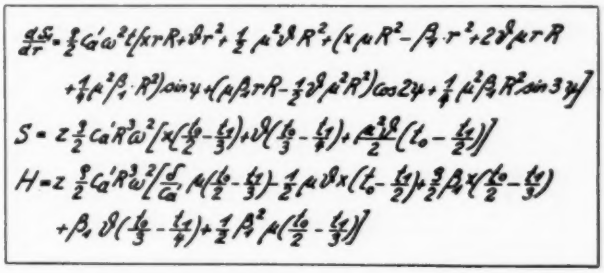

FIG. 7 CHARACTERISTICS OF AUTOGIRO ROTORS

danger zone lies in quite a narrow region of the pitch settings, With medium blade thicknesses and values of ϑ below 4.5 deg. measured from the angle of no lift, there is no danger of loss of autorotation. In the region $\vartheta = 6$ deg, there is always great danger, as unfortunate accidents have shown, particularly at high speeds and low disk loadings. We note also that the cessation of autorotation behaves in exactly the opposite fashion from the stalling of an airplane.

In our problem of a helicopter that possesses the emergency landing features of an autogiro the hazard of cessation of autorotation plays no great part. If there were any doubt as to the continuation of autorotation all that we would have to do is to reduce the pitch angle ϑ somewhat. Then we shall have completely satisfied our first fundamental requirement.

We have so far considered the production of lift only for the lifting rotor in a stationary position, and as an autogiro rotor. I have thus far purposely neglected the forward flight of helicopter airscrews. Lock has already begun to extend the Glauert considerations to this flight condition. We shall, therefore, pattern the calculations for the helicopter airscrew, in forward flight, on those of the autogiro rotor and then discuss the experiments in this condition. We only need to introduce the moment term about the axis of rotation and we have the helicopter instead of the autogiro rotor. All other considerations remain valid, and the calculations retain the same procedure. Instead of the customary lift coefficients we utilize thrust coefficients as, in the helicopter condition of hovering flight, the coefficient C_a becomes infinity. It is the relationship between the forward flight of the helicopter and its hovering flight, that is particularly interesting. According to the procedure adopted by Flachsbart, we shall, instead of C_a, take the vertical component of the thrust K_{sv}. We shall refer also to the circumferential velocity instead of the forward velocity, and substitute the horizontal component of the thrust K_{sh} for C_w.

In the helicopter condition the value x changes its sign. The flow through the rotor is downward and this remains true in forward flight. The angle of the rotor to the flight path α_π (or in the wind tunnel to the direction of the air stream) has no significance in hovering flight, but in translational flight it can have any value from zero to plus or minus 180 deg, since backward flight is also possible. It is noteworthy that, with the slowest vertical climb, it has a value of —90 deg and, with the slowest vertical descent, a value of +90 deg. In the forward flight of the helicopter, in which there is no other means of propulsion, such as a tractor propeller, the angle of attack α_π must

always be negative, as the axis of rotation must be tilted forward, in order to achieve a sufficient forward component to overcome parasite drag.

The results of the calculations for forward flight, will be compared later with the results of experimental work. The measurements of forward-flight conditions were made with the same apparatus as that employed in testing the autogiro rotor. The motor was coupled, and the performance calculations were made with the aid of electrical readings of the power required. The tests also included tachometer measurements of the rotational speed. Great care was required, as there were many chances of

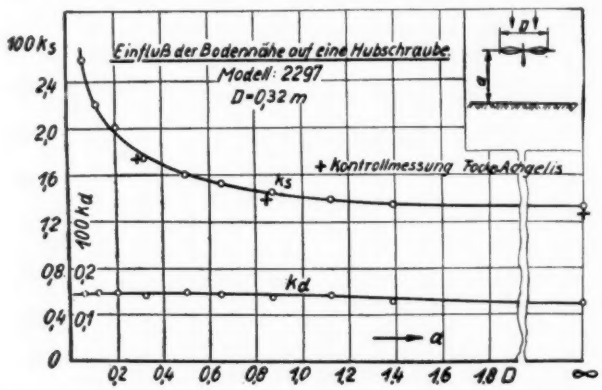

FIG. 8 INFLUENCE OF GROUND EFFECT ON A LIFTING AIRSCREW (k_s = thrust coefficient; k_d = power coefficient.)

error, which I shall not discuss in detail. I will mention, however, a single factor, the presence of the ground influence. When the ground is level over a sufficiently large area, the thrust increases, as does also the torque. This effect becomes apparent within a height above the ground equal to the rotor diameter. Thus, with a certain throttle setting, the helicopter will rise, but will not rise over a few meters without increase in the throttle setting. A helicopter with too little excess power does not rise over this "swimming level." On the other hand this phenomenon results in a welcome help on landing. In the laboratory it is unpleasant because one can never work far from rigid objects. Up to the present, few experiments have been made on the influence of ground proximity, of which the best ones are those made by Flachsbart in 1928, which our own measurements confirmed rather well. The upper curve of Fig. 8 shows this increase of thrust and the lower curve the increase in torque plotted against the distance from the ground expressed in diameters of the rotor. The three crosses indicate our own control measurements.

CONTROL AND STABILITY

No control is conceivable, unless we first of all establish an equilibrium of moments. There exists with the helicopter the well-known difficulty that in part has influenced the whole question of the direct-lift machine. The slowly rotating airscrews exercise on the aircraft a turning moment of the order of magnitude of thousands of kilogram-meters. The manner in which this torque is removed influences the whole constructional aspect of the helicopter. Many forms have been suggested as Fig. 9 indicates: (*a*) Two screws, one over the other, rotating in opposite directions (Bréguet, d'Ascanio, Pescara, Asboth); (*b*) two screws, one behind the other (Cornu), and also four placed at the corners of a square (de Bothezat, Oehmichen); (*c*) two screws rotating in opposite directions, and placed side by side (Berliner, Focke); (*d*) peculiarly enough, two screws rotating in the same direction, with axes of rotation so disposed relative to one another, that the resulting side moments have been removed (Florine, Belgian government); (*e*) a single large screw on the blades of which small screws are placed (Isacco, Curtiss-Bleeker); (*f*) on which the blades themselves perform oscillations so that a moment does not arise at all; (*g*) a single airscrew, and at the end of the fuselage one or more propellers whose thrust counteracts the torque (Baumhauer, Holländisch Rykstudiedienst); (*h*) a propeller blowing air backward against deflector surfaces (Hirtenberger Patronenfabrik, Austria); (*i*) surfaces in the slip stream of the helicopter rotor (Hafner and Nagler, Austria); and finally (*k*) a jet-reaction orifice with smaller screws and compressed air (Dornier patent, Papin and Rouilly, France).

From all these proposals we can separate out those which add appreciable drag or loss of efficiency. These are: (*e*) In which the efficiency of the small propeller reduces the efficiency of the helicopter as a whole, by about 30 per cent; (*g*) and (*h*) in which, for the production of the antitorque force, there is needed a continuous expenditure of power, which is of the order of

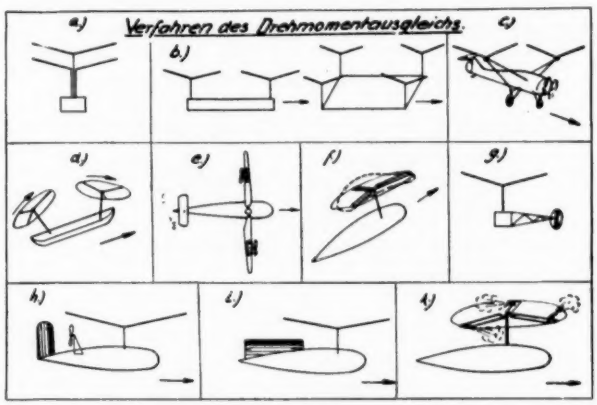

FIG. 9 PROPOSED METHODS OF BALANCING THE TORQUE IN A HELICOPTER

FIG. 10 BRÉGUET-DORAND HELICOPTER

from 20 to 30 per cent; (*f*) and (*i*) reaction and flapping drive—both are perhaps destined to play a part later on; (*d*) the inventors of which wished to retain the gyroscopic effects which are lost with rotors turning in opposite directions, offers no advantages as compared with (*b*) and (*c*). When we eliminate the use of more than two airscrews because of mechanical complication, then there remain only three cases; two screws, placed over each other, behind each other, and side by side, rotating in opposite directions. The first of these three arrangements has been most frequently employed hitherto. The helicopter which was most successful up to the last year, that of Bréguet-

Dorand in France has this arrangement as shown in Fig. 10. The disadvantages of this type are:

(*a*) Excessive vibration is set up by the passage of the blades past each other.

(*b*) The efficiency of two rotors in line is much less than with separate rotors.

(*c*) The slip stream blows over the whole structure so that the effective thrust is further reduced, and the longitudinal balance is affected.

(*d*) The saving in weight of the arrangement is balanced out by having a smaller disk area for emergency landing.

The only arrangement which entails no prejudicial interferences is the form in which rotors are disposed side by side. Vibrations of the blades disappear, both rotors offer their full disk area in emergency vertical descent, and they mutually provide high lateral stability. The efficiency is as high as that of the single rotor, and in the down-wash of each there lie only the most necessary elements of the structure. Also the difference in space requirements is not much, since what is saved in span by using two rotors placed over one another, is balanced by the greater length of the machine and above all by the greater height.

Now we can consider the stabilizing and control problems. Many helicopters have been controlled and stabilized by means of control surfaces after the manner of the airplane but, in the hovering condition, this is not possible. We can indeed think of surfaces or control surfaces placed in the slip stream of the lifting airscrew rotor, or in the slip stream of the ordinary propeller. We have ourselves tried both with little success. More suited to the nature of the helicopter is a control and stabilizing system through the action of the blades themselves. We must go back here to theoretical calculation and consider next longitudinal stability and control.

(*a*) *Longitudinal Stability and Control*

The tipping of the blades β increases, as Equation [2] showed, with the tangential parameter μ and, therefore, on the whole, with the speed. As the longitudinal blade pull is practically the only force which can be put into the hinge at the hub and as this force is the same in all blades, it is clear from considerations

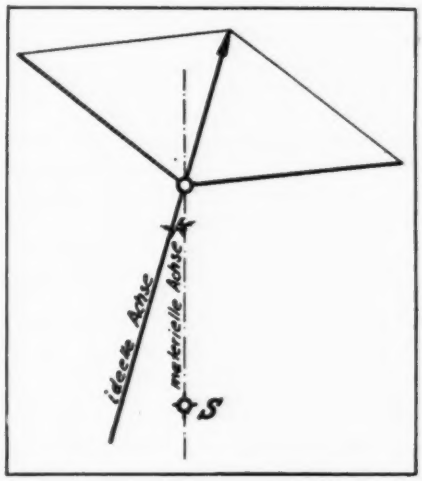

FIG. 11 DIAGRAM INDICATING ACTUAL AND VIRTUAL AXES OF ROTATION OF HELICOPTER ROTOR

of symmetry that the parallelogram of forces is a rhombus the diagonal of which is the resultant direction of force. See Fig. 11. It lies at an angle β_1 behind the actual axis of rotation. In other words, there is a virtual rotational axis which slopes downward and backward from the blade hub at an angle β_1 with the actual axis. This is only approximately correct, as the thrust distribution and the air skin friction on the blades influence its position, but the heart of the phenomenon is not seriously influenced by these considerations.

If the center of gravity of the whole aircraft lies below the airscrews, it becomes evident that there is longitudinal static stability due to the airscrew alone. An increase in speed, that is, a greater inclination of the virtual axis allows the thrust to move ahead of the center of gravity, as β_1 increases. The converse is true with decrease in speed. As the same formulas serve for the helicopter as well as for the autogiro, the principle holds true for both types of aircraft. Therefore we can calculate the longitudinal moments in both cases, or determine them

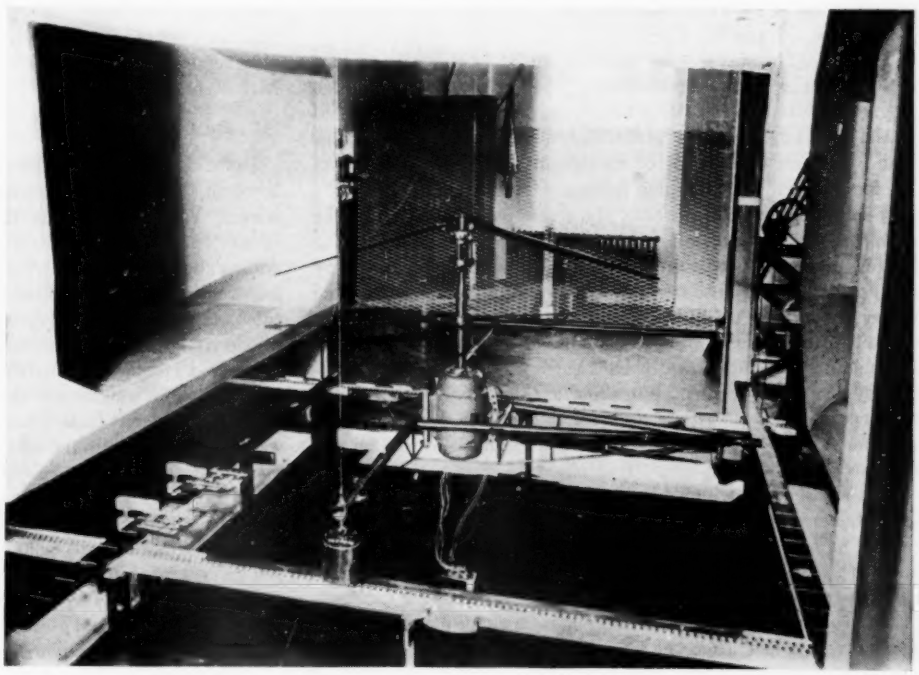

FIG. 12 ARRANGEMENT OF WIND-TUNNEL FOR STEREOPHOTOGRAPHIC MEASUREMENTS ON BLADES

by tunnel tests, in which both the magnitude and direction of the resultant can readily be obtained. As the resistance, because of many corrections and because of the size of the suspension wires, cannot be determined with great accuracy, we have been led to other experimental investigations.

First it was desired to know the position of the blades during the whole cycle of rotation, as many constructional requirements—for example the kinematics of the blade positioning—require such information. The English have carried out such an investigation with mirrors. To Professors Schering, Finsterwalder, and Flachsbart I owe the proposal and execution of a stereophotogrammetric method, which for an airscrew of $1^1/_2$ meters diam, gives the correct location of the blade at half radius with an accuracy of approximately 1 mm. See Fig. 12. Between the objectives of a stereocamera, an illuminating spark is introduced giving an illumination time of 0.000001 sec which, at a speed of 1700 rpm, allows us to see a row of white dots painted on the airscrew. With the airscrew and the wind tunnel operating, from 20 to 30 sparks are induced, giving on the exposed pair of plates a row of photographs of the white dots at random positions, but sufficiently well distributed to give a complete picture of all blade positions, after evaluation with the stereocomparator. An auxiliary system includes a measurement system on the floor of the wind tunnel. An example of such a photograph is shown

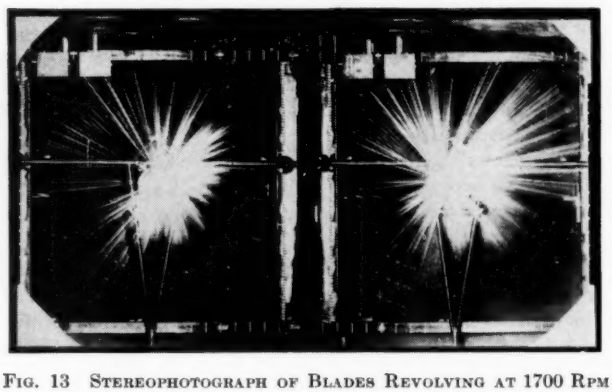

FIG. 13 STEREOPHOTOGRAPH OF BLADES REVOLVING AT 1700 RPM (Distance of white dots from the center is a measure of angle β.)

in Fig. 13. The star-shaped figure is caused by the reflections of the blades and has no significance. The method is well adapted to give information regarding the so-called change of phase, that is, the actual displacement of the highest and lowest points of the blade path out of the cone of revolution owing to the inertia of the blades during the flapping motion.

It follows that on the whole, the screw behaves not only like an airfoil with a constant center of pressure, but also like one having inherent stability. When this stability is produced by the position of the resultant, it becomes possible to control the rotary aircraft by deliberately changing the position of this resultant force. Cierva, in the C-30 autogiro, has secured control by inclining the hub forward, backward, or sidewise. Controllability has been secured, but some accidents when going into high speed, that is, with strong forces, lead to a doubt as to whether longitudinal stability is always maintained in Cierva's direct-control system.

In a small work which has been sent to interested parties, I have shown that a peculiar hazard is produced. The direction of control at high speeds changes signs or at least the control moment attained is independent of the positioning, so that the pilot has the sensation of loss of control. If the pilot decides to pull or push through even if the beginning of his control movement has the contrary effect, then the aircraft will eventually right itself. The real danger is that in the instant of apparent loss of control, such high diving speeds can be obtained that autorotation ceases. The thrust decreases, and the restoring longitudinal moment even after the successful effort, is insufficient to prevent further downward curvature of the flight path in space.

It is a mistake to think that the fixed stabilizer is the only guilty element. It was an error on Cierva's part to think that his direct control was solely a center-of-gravity control system. At high speeds, high moments are produced from the fixed stabilizing surface. I have therefore proposed that with rotary aircraft a movable horizontal surface should always be included which could work effectively under all circumstances to produce moment equilibrium. Then every danger on this score would be excluded. The D.V.L. has made independent investigations and has come to a similar conclusion. Nevertheless Cierva's direct control is not employable in the helicopter. It gives large control forces, which go into the whole aircraft, through the lever arm produced by β_1, which is not always negligible. If transmission is added to the system, then it will be seen that the large tooth and bearing loads, which change with the performance, cannot but have an effect on the control system when a tiltable hub is employed.

If, then, it is not possible to change the actual axis of the airscrew, we can change the "virtual" axis by varying β_1. We saw that the equilibrium of the air and dynamic forces prescribed the position of the flapping blades during a cycle of revolution, so that they took the corresponding angle of attack. As we must change the angle of the blades in going from helicopter to autorotative operation, we can reverse this process, and force the blades to have an angle of attack, variably controlled throughout the revolution, so that they must follow a desired path in space suitable for control.

Lock had already shown that the imposition of a sinusoidal variation in the angle of setting during each revolution produces the same effect as inclining the whole airscrew. Hence, control with the virtual or with the actual axis of rotation is equivalent, but it is important to note that control by means of varying the angle of setting, with the use of a blade having a constant center of pressure, theoretically introduces no forces into the control system. In practice, only the skin-friction forces and small mass forces are introduced. The change of the angle of attack is therefore an ideal control relay. Moreover the mechanism for the change of the angle of incidence is under little stress, and can be both light and reliable.

(*b*) *Dynamic Stability*

Up to this point everything has been relatively simple. Now, however, the most difficult question, that of dynamic stability, arises. When we began the construction of our machine, almost no information was available in this field. Nothing was known about either the helicopter or the autogiro rotor. We have followed two paths simultaneously. First we adapted the normal calculations for the airplane for use with the helicopter. Then we derived the equations for the hovering helicopter from the forces and moments involved. Numerical data were obtained in part by careful weighing of the degree of reliability of the Glauert theory, and in part from wind-tunnel work. Particular attention was paid to the stability and control processes at the instant of transformation from helicopter to autogiro flight. From these calculations we were able to give the pilot careful instructions about the movement of the controls and the setting of the stabilizer. The calculations were verified in practice, and the first test gave a perfect three-point gliding landing from a height of 400 m (1300 ft). Some two seconds after the transformation, the machine was in normal gliding flight. One can say that with this achievement of Pilot Rohlfs on May 10, 1937, the realization of

the practical helicopter was assured. The haunting thought of power-plant failure had lost its terrors.

Of our fundamental requirements we have therefore obtained both stability and calculable controllability about all three axes, both for hovering and in forward flight. We have obtained the transformation from helicopter into autogiro glide flight in a few seconds. We have secured simplicity and reliability in the arrangement of the control system, since with only two principal movements on the screw hub, there have followed four controls, two linear—transformation and rolling control—and two of a sinusoidal character—height and yawing control. Finally, the condition of simple effort by the pilot has been met because the three customary movements of hand and feet have only been increased by another operation with a lever placed at the right side of the seat. This is for the transformation from helicopter to autogiro rotor, and is used only in take-off and in special emergency cases.

I cannot conceal the fact that the theoretical and experimental effort in securing these results was very great. In particular, the stability calculations were most complicated. As one is entering unknown territory it is necessary to be very conscientious and to avoid all approximations and neglecting of terms. Where approximations could not be avoided, due to mathematical limitations, they had to be supported by special lengthy investigations. The success attained has justified this enormous effort. The first free flight of the machine lasted 28 sec, the fourth 16 min, and, although much is to be attributed to the skill of the pilot, Rohlfs, such success in the tests would have been unthinkable without a thorough technical understanding of the entire subject.

Performance

(a) *Autogiro*

In considering the polar of the autogiro rotor, Fig. 3, it is striking that the drag is large with large values of C_a, many times greater than that of a good airfoil. That is explainable not only on the ground of the low aspect ratio $\pi D^2/4D^2 = \pi/4$ which is unchangeable, but also is traceable to the C_{wp} which is a special characteristic of the autogiro rotor. On the other hand, with small values of the lift coefficient C_a, C_w is small, that is, the drag coefficient is small at high speed. This circumstance is specially emphasized by the small loading of the blades when referred to the whole circular disk. The lift-drag ratios at small lift coefficients approach those of good airfoils, and lie around 8 to 1 or 10 to 1. Even an L/D of 12 seems attainable. But these are, in contradistinction to the airfoil, the highest possible values of L/D. At high speeds therefore the autogiro rotor should not be far inferior to the fixed airfoil. The autogiro will have a maximum speed about 15 per cent less than that of the airplane.

Schrenk has given an interesting comparison between the airplane and the autogiro in the form of characteristics curves, Fig. 14. The really striking difference rests in part on the greater parasite drag, which difference could be reduced by better streamlining of the hub, starting rig, and other parts. Therefore it can be estimated that the autogiro will be some 10 per cent lower in top speed than the airplane but, on the other hand, will have about half the minimum speed.

Things look worse in the climb. Now we are working on the higher parts of the polar curve and the resistances become large. The lowest power required is much higher than with the airplane and also occurs at slower speeds, which is undesirable because of the resultant inefficiency of the propeller. That strengthens us in the conviction that the autogiro is only destined to play an intermediate part between the airplane and the helicopter. The autogiro solves less than half the problem, that of landing in a small space, but does not permit a zero velocity, while the take-off and the performance in climb are worse than before. There is, however, no inferiority from the point of view of weight. On the contrary, in large machines the freedom from bending moments should more than counterbalance the weight of the hub and starting gear. This is one of the great advantages of all rotary aircraft.

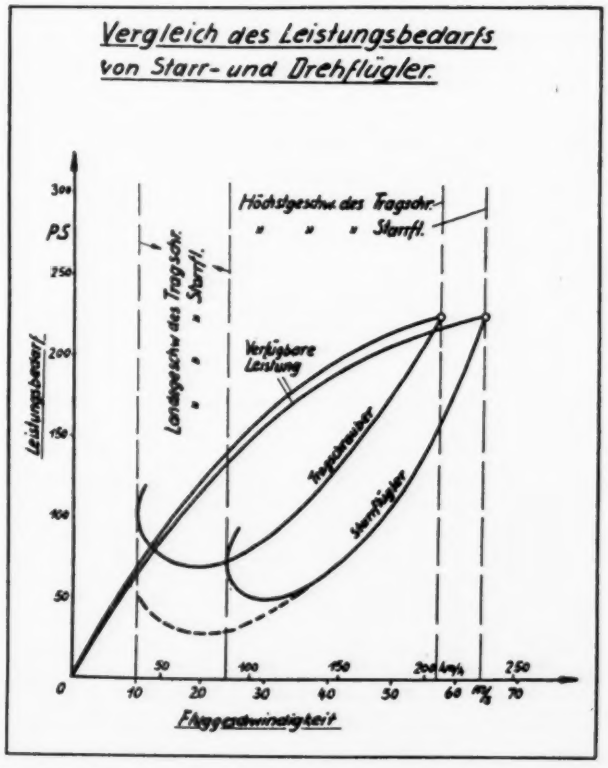

Fig. 14 Comparison of Power Requirements of the Airplane and Autogiro

(Ordinates, power required, hp; abscissas, flying speed, m per sec and km per hr; landing speed of autogiro, 10 m per sec; landing speed of airplane, 25 m per sec; maximum speed of autogiro, 57 m per sec; maximum speed of airplane, 65 m per sec; *Verfügbare Leistung = power available.*)

(b) *Helicopter*

We must make proportionately the largest sacrifice regarding weight in the helicopter. The transmission must function with complete reliability under full output of the motors, which places the helicopter in small sizes at a serious disadvantage with the airplane. Bréguet has on the other hand designed a 16-ton helicopter flying boat, and finds a saving in weight as compared to the corresponding high-speed airplane. If this appears somewhat optimistic the fact nevertheless remains that, with greater size, the weight of the transmission of the helicopter will become less of a disadvantage.

When high speeds are considered, the question arises: Is it advantageous to let a given rotary aircraft fly as an autogiro or as a helicopter without a propulsive airscrew? It is conceivable that a machine could be designed to have zero velocity and yet be flown as an autogiro. We have made careful computations, reinforced by wind-tunnel tests, with the interesting result that the same machine flown as a pure helicopter is somewhat faster, even if we deduct 10 per cent for motor cooling. Practical experience with a helicopter has fully confirmed this view. The machine after installation of a normal propeller instead of the cooling blower could be flown as an autogiro, and gave with streamlining of all tubing and parts a speed of 120 km (75 miles) per hr, as compared with the 126 km (78 miles) which had been

calculated. Streamlining for the helicopter could not be incorporated without reconstruction. The horsepower requirements of the unstreamlined bracing and parts could be determined in special tests, however, and at 120 km (75 miles) per hr, amounted to 46 hp. Thus the streamlined helicopter would be 25 km (15 miles) kilometers faster. That would give 147 km (91 miles) an hr for the helicopter as compared with the calculated value of 152 km (94 miles) per hr.

As we saw that the autogiro, in so far as top speed is concerned, is only slightly inferior to the airplane, we can conclude that the helicopter could at least equal the speed of the airplane. Here also the decrease of the parasite resistance is the chief point of further development. There is, however, a certain limitation to the helicopter. As we cannot obtain a forward-speed parameter of over 0.5, the tips of the helicopter blades will reach the speed of sound at half the forward speed of the airplane. Then the addition of speed has to be reckoned with in the advancing blade. At a speed of about 400 km (250 miles) per hr, the prospects of the helicopter become much worse than those of the airplane. Of course it must be remembered that in the same speed ranges, difficulties regarding compressibility effects also begin to occur with the conventional propeller.

The climb of the helicopter appears to be remarkable. In Table 1 are shown the initial climbs of the Fw 44 Stieglitz, of the de la Cierva C 30, and of the helicopter, flown as an autogiro and flown as a helicopter, all of them provided with the same motor, the Sh 14. In particular it should be noticed that there was no equality of gross weight. The helicopter is the heaviest, nevertheless it has the greatest climb. The autogiros are quite inferior.

TABLE 1 INITIAL CLIMBS AND WEIGHTS OF VARIOUS TYPES OF AIRCRAFT WITH THE SAME MOTOR

Machine	Initial climb M per sec	Initial climb Fps	Flying weight Kg	Flying weight Lb
Fw 44 Stieglitz airplane.....	3.5	11.5	870	1920
Cierva C30 autogiro.....	1.5	4.9	815	1795
Fw 61 helicopter as an autogiro..	1.3	4.26	950	2095
Fw 61 helicopter as a helicopter.	3.6	11.8	950	2095

I must particularly emphasize here that the helicopter does not secure its justification by the existence of superior climb or speed, relative to those of the airplane. Its special characteristics give the helicopter special duties and possibilities. It will be all the more worth while however if it shows that it is not inferior in performance characteristics.

It is hardly necessary to speak of the take-off and landing characteristics. The ideal sought for is attained, at least technically. Doubtless the full utilization of all the possibilities of the helicopter will make new demands on the skill of the pilot and the personal equation will enter. But I can report that contrary to anticipation, no acrobatic skill is needed. Miss Hanna

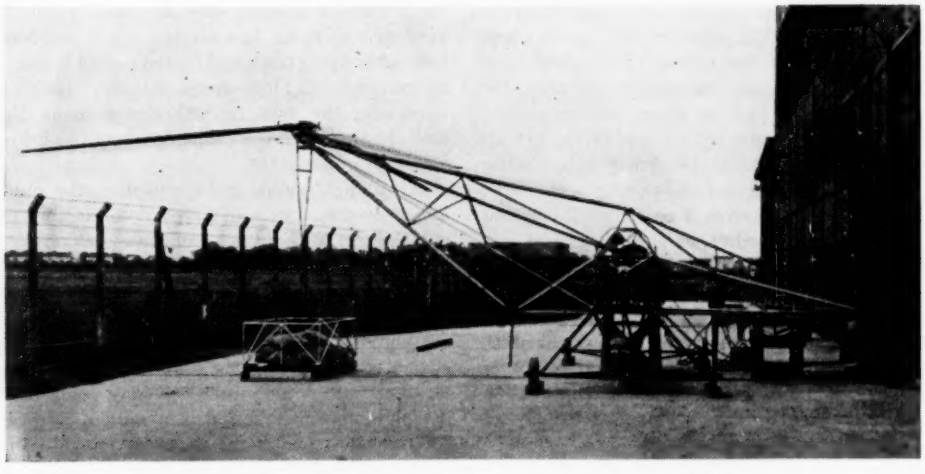

FIG. 16 HELICOPTER WITH ONE ROTOR LOADED FOR TESTING

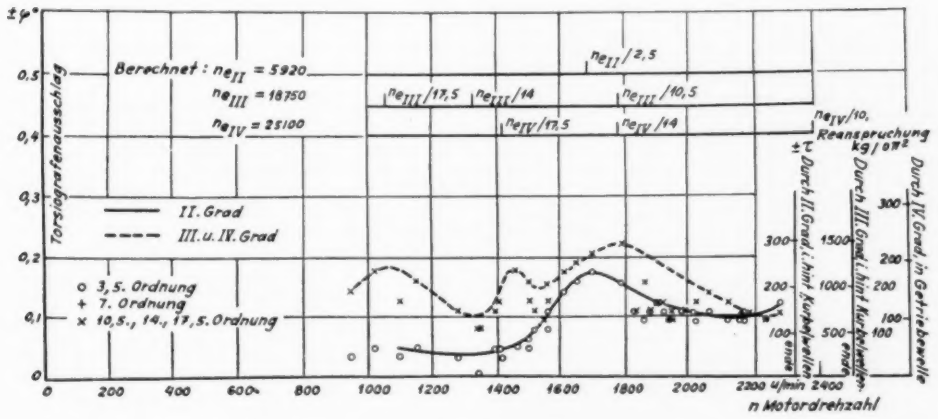

FIG. 17 TORSIOGRAM OF POWER TRANSMISSION

Reitsch and Messrs. Dipl. Ing. Francke, Ballerstedt, and Bode have flown my helicopter splendidly with short technical instruction, and made smooth landings.

Due to the accidents with autogiros caused by cessation of autorotation at small angles of attack and large pitch angle, and to the consideration that small angles of attack must inevitably occur in gusts, the opinion has arisen that all rotary aircraft are sensitive to gusts. As the connection with autorotation shows, this conclusion is not at all applicable to the helicopter, and we have seen already that with the autogiro there is no danger if an adjustable horizontal surface is provided. Besides it is to be surmised that, as a result of the flexibility of the blades, the rotor would be less sensitive to gusts. By means of simultaneous tests of an airplane and of the helicopter, it was shown that the pilot of the airplane experienced severe bumps, while the pilot of the helicopter hardly felt the gusts. At other times the gustiness was perceptible at wind velocities of 40 km (25 miles) per hr. It therefore seems probable that the character of the gust is to be considered. It is interesting to learn that, on the small factory landing field of Focke, Achgelis & Co., the helicopter was easily controllable, even in the disturbed regions of buildings, in gusts of from 6 to 10 m (20 to 33 ft) per sec.

I have so far considered only the investigations which were necessary to the development of the helicopter. I cannot emphasize too strongly in what measure pure science was the foundation on which new knowledge was based. The second and still more difficult stage of our work was in embodying in practice the information thus gained.

CONSTRUCTION

The first step was a free-flying model, driven by a 0.7 hp two-cylinder motor. See Fig. 15. It had a flying weight, with 50 g of benzene, of 4.9 kg (10.8 lb). It is easily understandable that the model was more frequently in bits than whole, nevertheless many worth-while experiments were made with it. In November, 1934, it reached a height of 18 m (59 ft), equaling what was up to that time the world's record for a helicopter with a pilot. The model is now in the Deutsches Museum in Munich.

It was decided further that the transmission, coupling, and flap control should be submitted to the same tests as a new engine. The Brandeburg Motor Werke, which under the personal direction of Director Wolff, had undertaken the difficult task of this construction and of the conversion of the Sh 14-a motors, built one side of the system. See Fig. 16. It was provided with a single airscrew and its structural supports. A Leonhard electric drive was used, so that the performance requirements of the airscrew could be measured in full scale. The thrust was measured

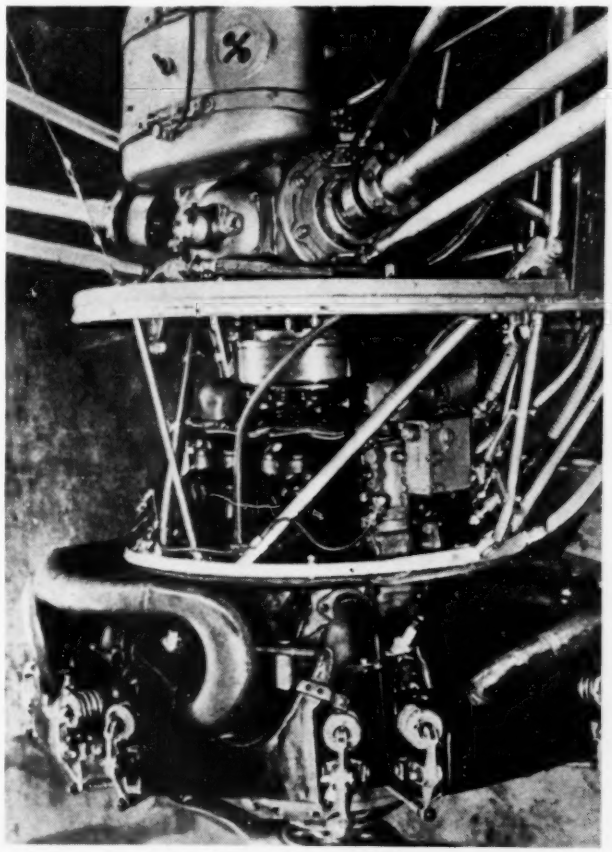

FIG. 18 SHOWING ENGINE, FRICTION CLUTCH, AND AUTOMATIC MECHANISM FOR CHANGING TO AUTOROTATION

by means of ballast and by making the fuselage rotatable about its longitudinal axis, taking due account of the ground effect. This constituted a valuable supplement to the wind-tunnel tests at full-scale evaluation. A 50-hr test was made and, after overhaul of the transmission, another 10-hr test. The controls were continuously tested at the same time.

A vibration investigation of the whole transmission system was made for the D.V.L. by Professor Lürenbaum and his associates. The calculations were confirmed by tests with the torsiograph, in which the aircraft was flown as a kite. This was all the more necessary since the electrical drive used in the first test was not

FIG. 21 COMPLETED HELICOPTER IN CAPTIVE FLIGHT

sound from a vibration point of view. Fig. 17 shows a torsiogram, of which I will only say that the most highly stressed part was within the motor and not within the helicopter. Fig. 18 shows the transmission with the friction coupling, and the safety provisions which, by failure of the motor or of the gears, or the reaching of a certain minimum rotating speed, automatically causes transformation into the autogiro state. Fig. 19 shows one of the screw hubs with controls for the blade motion.

The construction of the framework and of the rotors was undertaken as for a normal airplane. New ideas in the design office and the unconventional constructional elements made difficult work for my associate Ing. Körper. Under these conditions it is gratifying that maintenance, while not ideal, is adequate. For the new problems in stress analysis, the calculations and experiments previously made were utilized, and in some respects these had to be supplemented.

For the cooling of the motor in flight in one spot, a propeller-type blower was developed, and the cooling was investigated by cylinder-temperature measurements in cooperation with the Brandeburg Motor Werke. See Fig. 20.

Flights

The completed prototype was often flown in a captive condition, as shown in Fig. 21. Captive flights are an excellent method of investigation, as everything happens under flight conditions while one is only from $^1/_2$ to 1 meter above the ground. No further steps in the proving were undertaken until the conditions were clarified by further calculations or tests. On June 26, 1936, Rohlfs made the first flight. On June 25 and 26, 1937, he was able to bring to Germany all the world helicopter records, with fifteen times the performance existing up to that time. See Fig. 22. I have already spoken of the important glide landings. The height reached, 2439 m (8000 ft), which did not long remain the maximum height, has brought me the undisguised charge of deceit from Mr. Asboth in a foreign technical paper. The lack of foundation for this accusation is shown by the many witnesses of the flight and through the immediate recognition of all records by the Fédération Aéronautique Internationale.

In June and October, 1937, the first and second machines, respectively, were taken over by the Reich. With the latter Miss Reitsch flew, in October, 1937, from Bremen to Berlin surpassing the record between Stendal and Tempelhof by over 108 km. Bode, on June 20, 1938, surpassed this record by flying 230 km after a larger fuel tank had been installed.

Nobody had expected such performances. The future is bright.

The Interpretation of a Failure of an Ordnance Structure[1]

By G. F. JENKS,[2] WASHINGTON, D. C.

For the analysis of a failure of a war model of a 240-mm howitzer at half pressure, a fragment was furnished the laboratory. The problem was divided into three phases: First, the origin of failure; second, the mechanism by which the failure developed in the structure; third, the conditions responsible for the failure. Emphasis is placed on determining the spot at which the failure started.

A method of reading the rupture flow lines found on the surface of the fragments is described. The arrow points found in torn metal surfaces are shown as pointing to the origin of rupture. These arrow points and other surface characteristics furnish the time scale by which priority as to time may be established for tears or for ruptures which appear to be independent. Once the beginning of a failure is found, however, the laboratory investigation then becomes simple as it may be confined to a small area.

In this investigation the heat-affected zone of a weld was disclosed by acid etching. The design called for no welding at this point. Microscopic investigation showed that weld metal of an inferior quality was present, and that cracks existed in the heat-affected zone of the weld. A strip of metal of high Brinell hardness was found just outside the weld metal. The failure progressed from old cracks in this region of high hardness on the exterior surface of the gun. The tension and impact properties and the macroetch characteristics of the metal were determined and their influence upon the failure estimated. Finally, manufacturing records were checked and showed that a machine error on the surface in question had been repaired by welding.

THE design of a structure is based upon an analysis of applied stresses with provision for errors in the method of calculation and for deficiencies in behavior of materials applied under the factor of safety. Failures of structure may occur for any of the following reasons: (1) Stresses applied in excess of those for which the structure was designed; (2) highly localized stresses; and (3) unpredicted behavior of the material. Designs may be checked by various proof tests but primarily by service use. If structures fail under service conditions a complete analysis of the failure is essential to the perfection of design and processing practices.

In the study of failures of structures the first task is to find the origin of the failure; the second, the mechanism by which the failure developed in the structure. After this preliminary work the examination of the material and the analysis of stresses point to the conditions responsible for the failure.

Each structural failure is a special problem and involves different lines of approach. It is believed, however, that cases of examination of failed structures are of interest. Engineering literature is comparatively poor in this respect. There is a need for a more general disclosure of information regarding failures and their analysis for the improvement of design practice.

The gun is one of the earlier engineering structures for which careful stress analysis was made. It differs from most engineering structures in that the factor of safety is low and in that its life is limited by erosion of the bore rather than by the fatigue strength of the metal. This paper deals with the analysis of a failure which has taken place in a 240-mm howitzer of war production.

Howitzer No. 5 ruptured on the 283rd round on a half charge with a bore pressure of 15,400 lb per sq in. at the breech. The howitzer is designed for a bore pressure of 33,000 lb per sq in. with a minimum factor of safety of 1.25 in the powder chamber. The factor of safety of the muzzle section was not much over unity. Expansion of this section had been experienced under service pressures until a change in the contour of rifling was made.

Fig. 1 shows the gun and mount immediately after the failure. The fragment not shown was found 155 ft to the right rear. The muzzle was split in two sections, one of which is shown in Fig. 2. The two ruptured surfaces of this section are quite different in appearance. The lower surface is smooth in the middle region and fibrous at the ends, the coarseness of the fiber increasing toward the end. The top fracture has no smooth area except two very limited ones near the bore at *B* and *C*. The ruptures are characterized by fibers torn in the general shape of an arrowhead. In the lower surface the points of the arrows are directed toward the smooth area at the middle section. The fibers in the upper surface are coarser and the surface is rougher. The arrows of the fiber point toward *C* and also in the left section toward *B*. Fig. 3 shows the middle portion of the lower fractured surface. It will be noted that just below the center of the illustration is a very smooth area and that the apex of the arrows of the fibers point to that area. The lower edge at the picture is the outside surface of the gun. In Fig. 4 is shown one of the smooth areas of the upper ruptured surfaces of Fig. 2. The arrows of the ruptured fibers point to a small area at the lower (bore) surface of the fragment.

From general observation it has been noted that the apex of the arrows in a fractured surface point toward the origin of rupture. Fig. 2 shows three origins of rupture, one in the lower surface near the outside and two on the upper surface near the bore.

To establish priority of these origins, the nature of the surfaces must be considered. The lower surface of Fig. 2 (see also Fig. 3) is smoother and the center of propagation of rupture extends along the mid-section of the wall. There is a single system of rupture lines from one center. The upper surface of Fig. 2 (see also Fig. 4) shows the path of rupture extending along the bore surface. Fig. 4 shows that the flow lines change in appearance before reaching the upper (outside) surface. The rupture

Discussion of this paper was closed January 10, 1939.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

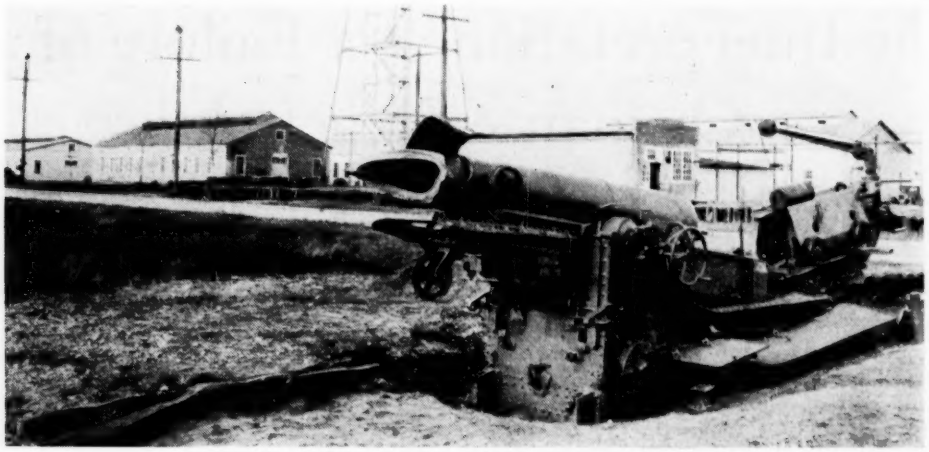

FIG. 1 FAILURE OF 240-MM HOWITZER

lines of the lower zone formed by about two thirds of width of section are traces of tearing. The upper zone has the appearance of having been pulled apart rather than torn. Near the upper edge of the upper fracture shown in Fig. 2 there is a difference in level of the fracture indicative of forces which did not exist in the rupture of the lower surface. There are at least two systems of rupture lines in this surface.

The smoothness of the ruptured surface varies directly with the speed of propagation of rupture.

The only conclusion that can be drawn is that the original rupture started near the outside surface at the point marked "start of rupture" in Figs. 2 and 3, proceeding in both directions. With the split on one side of the gun, the unsupported cylinder rotated about the outside edge of the opposite wall, causing failure to proceed from the inside surface outward. The initial fracture was more rapid. As the powder pressure was reduced, with loss of gases through the split and the increased volume of the bore, the violence of rupture decreased. Thus, the upper surface in Fig. 2 is rougher in appearance. As the two halves of gun opened out on the upper edge of Fig. 2 at a center, the rupture in this wall changed from a tear to a tensile break, as indicated in Fig. 4. In the second surface ruptured, the presence of two or more origins is natural. Both were due to stresses beyond the strength of the material induced by the failure of the opposite wall.

The appearance of the ruptured surfaces is consistent with hypothesis as to the origin of fracture. The position of fragments on the ground after the accident is also consistent with this hypothesis. The rupture flow lines shown in Fig. 1 definitely indicate the tearing proceeding from the near side, which checks with the hypothesis made from the examination of the fragment shown in Fig. 2.

A closer examination of Fig. 3 discloses a smooth, dark zone at the outer surface about $^1/_8$ in. deep and 4 in. long. An examination of this surface at low magnification, which is shown in Fig. 5, reveals a number of smooth dark areas which are interpreted to be independent crack systems of varying depth, the principal ones being near the two ends of the illustration. Near the middle of the upper edge will be noted a center from which rupture flow lines proceed in all directions and merge into the main rupture flow system. This is the localized origin of rupture at the bottom of an old crack system. It should be noted that this rupture system comes to the surface in some places and is indicative of the discontinuity and variable depth of the original crack system. Particularly to the left of the origin of rupture

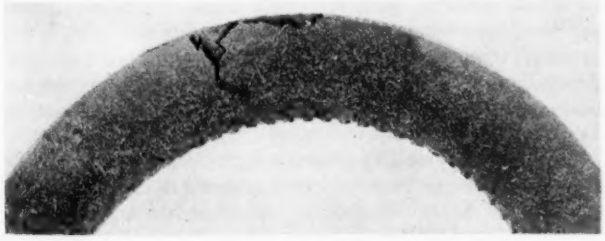

FIG. 7 MACROETCHED TRANSVERSE SURFACE

there will be observed independent flow-line systems. However, during the failure these local flow-line systems proceeded only a short distance before they met the main rupture system which was being propagated at a very high rate of speed.

Having definitely established the point from which the rupture proceeded, the next phase of the investigation is to determine under what conditions the original crack system developed and to examine the metal to ascertain why it has behaved so unexpectedly. Merely classifying the failure as one in fatigue gives no real answer.

Fourteen test specimens taken from metal of the fragments gave the results shown in Table 1, which are compared with original acceptance tests.

The lowness of proportional limits is explained in part by the cold work received by the metal in rupture and possibly in part to the use of more exact methods of test during the investigation. The difference in tensile strength indicates a difference due probably to location of specimens. The higher values for specimens originally tested may have been due to end effect in heat-treatment. That is, specimens near the end of the forging were hardened more in the quenching operation.

The average tensile impact strength is good; the low value is unsatisfactory. Two specimens gave fair values. Otherwise, the results were good. The ruptured surfaces of the tension-test specimens were characterized as laminated, with streaks of lustrous segregations and numerous checks on stems. These types of fracture and irregularity of tension impact tests are indicative of nonhomogeneity of structure.

The macroetched structure, illustrated in Fig. 6 for longitudinal surface and Fig. 7 for transverse surface, confirms the conclusions made from the appearance of fractures and the re-

TABLE 1 TEST RESULTS FROM FRAGMENTS OF THE RUPTURED MUZZLE COMPARED WITH ORIGINAL ACCEPTANCE TESTS

	Fragments	Original
Proportional limit, lb per sq in.[a]	37000–50000	63000–71000
Average	46700	.....
Tensile strength, lb per sq in.	90000–93000	95000–101500
Average	91800	.....
Elongation, per cent	20.5– 24.5	20.5– 22.0
Average	22.7	.....
Reduction of area, per cent	38.7– 49.6	37.3– 49.2
Average	45.3	.....

sults of physical tests. The metal was of the following percentage composition: Carbon, 0.38; manganese, 0.64; silicon, 0.19; sulphur, 0.045; phosphorus, 0.061; nickel, 2.24; and chromium, 0.11.

The structure indicates inadequate hot working to break up the coarse dendritic structure of the ingot and to disseminate the phosphorus and sulphur content which was high. The structures found are favorable for propagation of crack systems. No evidence was noted, however, to indicate that any original crack system existed because of conditions of nonhomogeneity of composition or structure.

Under metallographic examination the pronounced presence of dendritic structure near the bore is shown in Fig. 8 at a magnification of 5 after a copper-chloride etch. An unpolished specimen, shown in Fig. 9, reveals the size and distribution of nonmetallics. Fig. 10 shows the structure after etching with 1 per cent Nital, which may be classed as nonuniform sorbite of variable grain size. It will be noted that the grains are surrounded by a network of ferrite and that ferrite also occurs in the crystallographic planes. The structure found correlates with irregularities of ductility and impact properties and the appearance of fractures of tension specimen. Low ductility and an increased rate of propagation of failure of the structure might be postulated from these results. As yet, however, the results do not explain the failure.

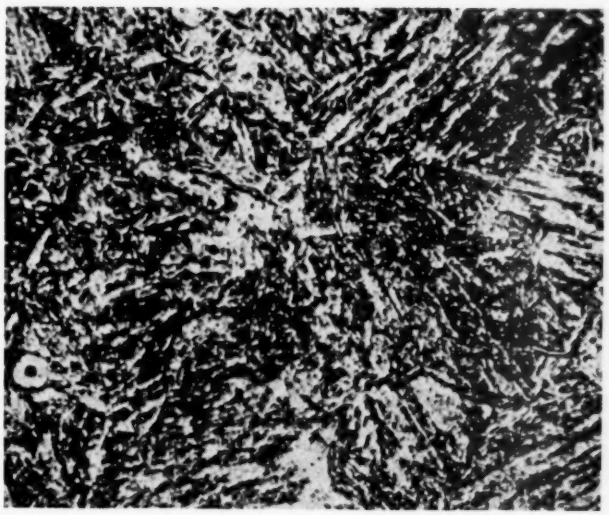

FIG. 13 SECTION NEAR THE FRACTURE ETCHED WITH 1 PER CENT NITAL. ×1000

(The structure has the acicular planes of martensite, but has been tempered by subsequent welding to troostite.)

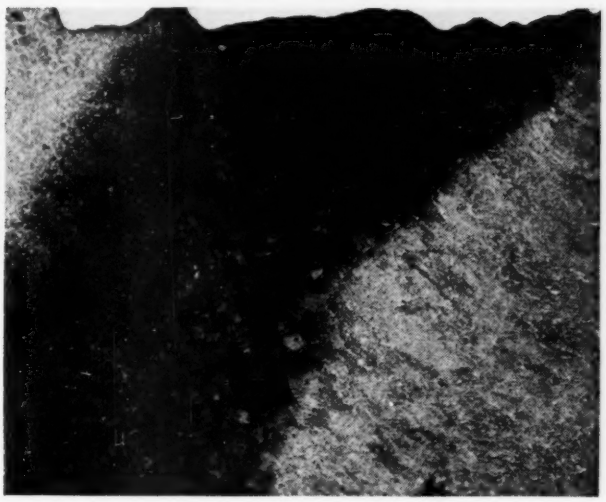

FIG. 15 VOIDS IN THE WELD METAL WHICH WERE ALSO THE STARTING POINT OF CRACKS. SECTION ETCHED WITH 1 PER CENT NITAL. ×25

(The path of rupture did not pass through the added metal at the upper right, but through the heat-affected zone in the lower section.)

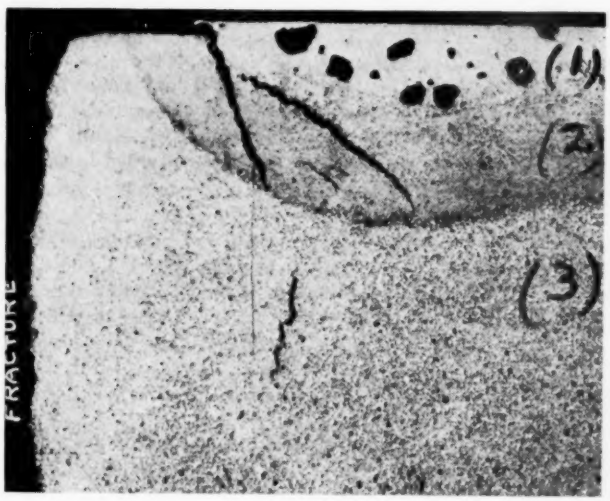

FIG. 14 PORTION OF THE WELD IN AN AREA NOT FAR FROM THE ORIGIN OF RUPTURE, AFTER ETCHING WITH 1 PER CENT NITAL. ×15

(Area 1 is the weld metal, area 2 is the heat-affected zone, and area 3 is the parent metal.)

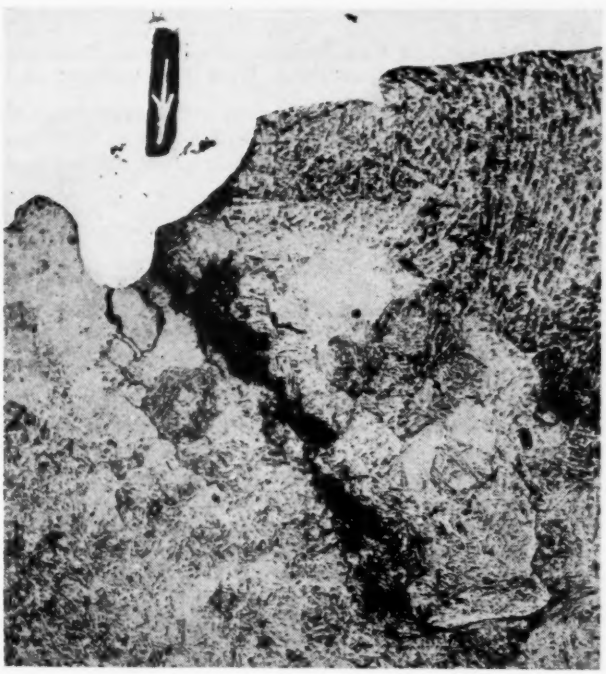

FIG. 16 ANOTHER TYPE OF DISCONTINUITY FOUND IN THE FUSION ZONE. SECTION ETCHED WITH 1 PER CENT NITAL. ×100

(The arrow points to undercut. The weld metal is in the upper right-hand corner. The crack system originated in the heat-affected zone.)

A section parallel to the rupture and about 1 in. from it was macroetched and is shown in Fig. 11. This section reveals a weld on the surface in which the rupture had its origin. A hardness survey disclosed hardnesses up to 550 Vickers Brinell in the heat-affected area. Fig. 12 shows two hardness plots—*B* taken parallel to the weld and 3 from the edge of the weld through the heat-affected zone into the parent metal. The microstructure in the heat-affected area, shown in Fig. 13, reveals acicular planes of martensite tempered by subsequent welding to troostite.

A microstudy of the weld in an area not far from the origin of rupture was made. In Fig. 14 the weld deposit is shown at (1), the heat-affected zone at (2), and the parent metal at (3). Of particular interest is the shoulder at the left edge of the weld, the crack system starting from this shoulder, and the intergranular-crack system in the parent metal.

Other intercrystalline cracks were found in the heat-affected zone near the fusion line. In some areas, weld undercuts were the starting point for intergranular cracks. Voids in the weld metal were also the starting point of cracks, as indicated in Fig. 16 which shows the weld metal at the upper right and the heat-affected zone in the lower section. In some areas cracks were transcrystalline. Most of the intercrystalline cracks are believed to have existed prior to rupture.

Another type of discontinuity found in the fusion zone is shown in Fig. 17. The fissures and voids shown are partially filled with oxides.

FIG. 17 FISSURES AND VOIDS IN THE ADDED METAL NEAR THE FUSION ZONE PARTIALLY FILLED WITH OXIDES. ×100

Fig. 15 is a view at 25 magnifications at the intersection of fracture, and the outside surface of the howitzer at the origin of rupture. It is to be noted that the rupture did not pass through the weld metal (upper-right-hand zone) but originated in the heat-affected zone just outside the weld metal. This is the region in which the ribbon of hard metal exists, as shown in Fig. 12, and which is prone to cracks and other discontinuities, as shown in Figs. 14, 16, and 17.

It is to be noted that the structure and hardness of the heat-affected zone pertains to metal which has not been stress-relieved. The defects are those expected in welding 0.40 carbon low-alloy steel of heavy cross section without preheating and with undeveloped technique. The welding does not represent current practice.

Proof is now complete that the rupture originated in the heat-affected zone just outside a weld.

The defects of the welded zone furnish the explanation of the failure of the structure. Cracks and other stress raisers were present at the outside surface where the rupture originated. The crack system gradually grew under the stress of firing until complete failure of the structure resulted. The fact that final failure took place on a half pressure round is not at variance with our knowledge of fatigue failures. All the facts related fit together in a single picture and justify the methods used in the analysis of fracture. One last check completes the story. The manufacturing records were consulted and disclosed that the area in question had been welded by metallic arc to correct an error made in machining.

ACKNOWLEDGMENTS

In preparing this paper the work of the following members of the Watertown Arsenal Laboratory Staff have been freely drawn upon: M. G. Yatsevitch, P. R. Kosting, H. C. Mann, W. C. Warner, and H. G. Carter, all of whom participated in the investigation of this failure.

The Use of the Piezoelectric Gage in the Measurement of Powder Pressures

By R. H. KENT[1] and A. H. HODGE,[2] ABERDEEN PROVING GROUND, MD.

The development of a piezoelectric gage for the measurement of powder pressures in guns is reviewed. A gage is obtained having a high natural frequency, insensitivity to shock, and accuracy. Details concerning the construction of the gage, the recording apparatus, and the method of calibration are given. Records are reproduced showing pressure waves in a gun and a closed chamber. Such records have been of value in the improvement of the design of powder charges and the determination of interior ballistic data.

NO DOUBT shortly after the invention of cannon in the middle ages, there must have been felt the need of a device for measuring pressures generated in such weapons to enable one to calculate the stresses produced by firings. However, it was not until 1857 that the first practical pressure gage was developed by General Rodman of the Ordnance Department of the U. S. Army. Rodman's gage consisted essentially of a piece of copper which was indented by a knife that was subjected to the pressure in the chamber. The pressure was deduced from the depth of the indentation.

Some time afterward Noble of England invented the well-known crusher-type pressure gage in the form which is now used. In this type of gage, the piston which is subjected to the gas pressure compresses a copper cylinder and the pressure is deduced from the amount of compression. Although such a gage should be capable of producing accurate measurements of pressures which are slowly applied and kept on, serious errors are encountered when it is used to measure the rapidly changing pressures in guns. The deformation of the copper cylinder exceeds the elastic limit and a flow of the copper takes place. It takes a certain time for this flow to be completed and thus in general, the maximum pressures indicated by the copper-crusher gage are too low.

The gages of Rodman and Noble measured only the maximum pressure in the gun. For a complete study of the generation of pressure, a gage is obviously needed which gives the pressure in the gun as a function of the time. For such a recording gage to be a satisfactory instrument for the study of powder pressures, it must satisfy the following requirements:

1 Its natural period must be small compared with the duration of the pressure-time curve. For the 14-in. gun, this duration is about 0.05 sec while for a caliber 0.30 rifle it is about 0.001 sec.

2 The gage must not be affected by the rather violent recoil and vibrations of the gun.

3 Its precision must be of the same order of magnitude as the precision of the velocity measurements.

Vieille made the first recording time-pressure gage about 1884 by the simple expedient of recording on a revolving drum the motion of the piston of the copper-crusher gage as it is compressed. Since that time a number of mechanical and electrical gages have been developed. Of these, the piezoelectric appears to satisfy the listed requirements in a much more satisfactory manner than any other.

The piezoelectric effect was discovered by J. and P. Curie in 1880. They found that certain crystals, e.g., tourmaline, quartz, rock salt, when compressed along certain axes, produce an electrostatic charge proportional to the imposed stress. Obviously such crystals by virtue of their high natural frequency are admirably adapted to the measurement of rapidly varying pressures of short durations such as occur in guns. To record the pressures one simply has to record as a function of the time the charge developed by the crystals. It was not until 1917 however, that the piezoelectric gage was invented by Sir J. J. Thomson[3] and used to measure the pressure in a gasoline engine. Shortly after this his associate Keys[4] used it in measuring the pressure of an explosion. The apparatus of Thomson and Keys consisting of tourmaline crystals and a cathode-ray oscillograph is shown schematically in Fig. 1.

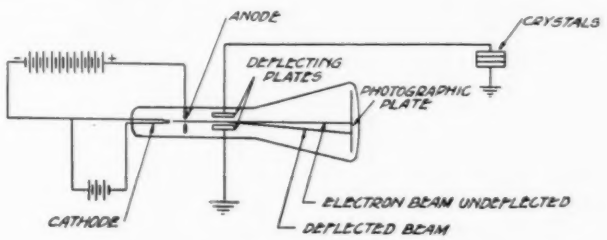

FIG. 1 APPARATUS OF THOMSON AND KEYS

As the crystals are stressed, the charges produced flow to the deflecting plates establishing a difference of potential between them. The electrostatic field thus arising causes the deflection of the electron beam which is recorded photographically by a plate at the end of the tube.

After the War, the Ordnance Department of the U. S. Army, aware of the experiments of Thomson and Keys, decided to undertake the development of a piezoelectric gage suitable for measuring pressures in cannon.

At that time, to record photographically by the cathode-ray oscillograph it was necessary to place the plate or film within the exhausted cathode-ray tube itself. To obviate this rather laborious technique various other methods were developed in turn for the Department by G. F. Hull, Karcher[5] and Eckhardt, and one of the authors (Kent).[6] Of these the methods of Hull

and Kent were essentially similar although differing in important details. The gage was connected to a condenser attached to the input of a direct-current amplifier, the output of which was recorded by a string galvanometer (Hull) or a Duddell electromagnetic oscillograph (Kent).

In 1932, Joachim and Illgen[7] developed for the Zeiss-Ikon

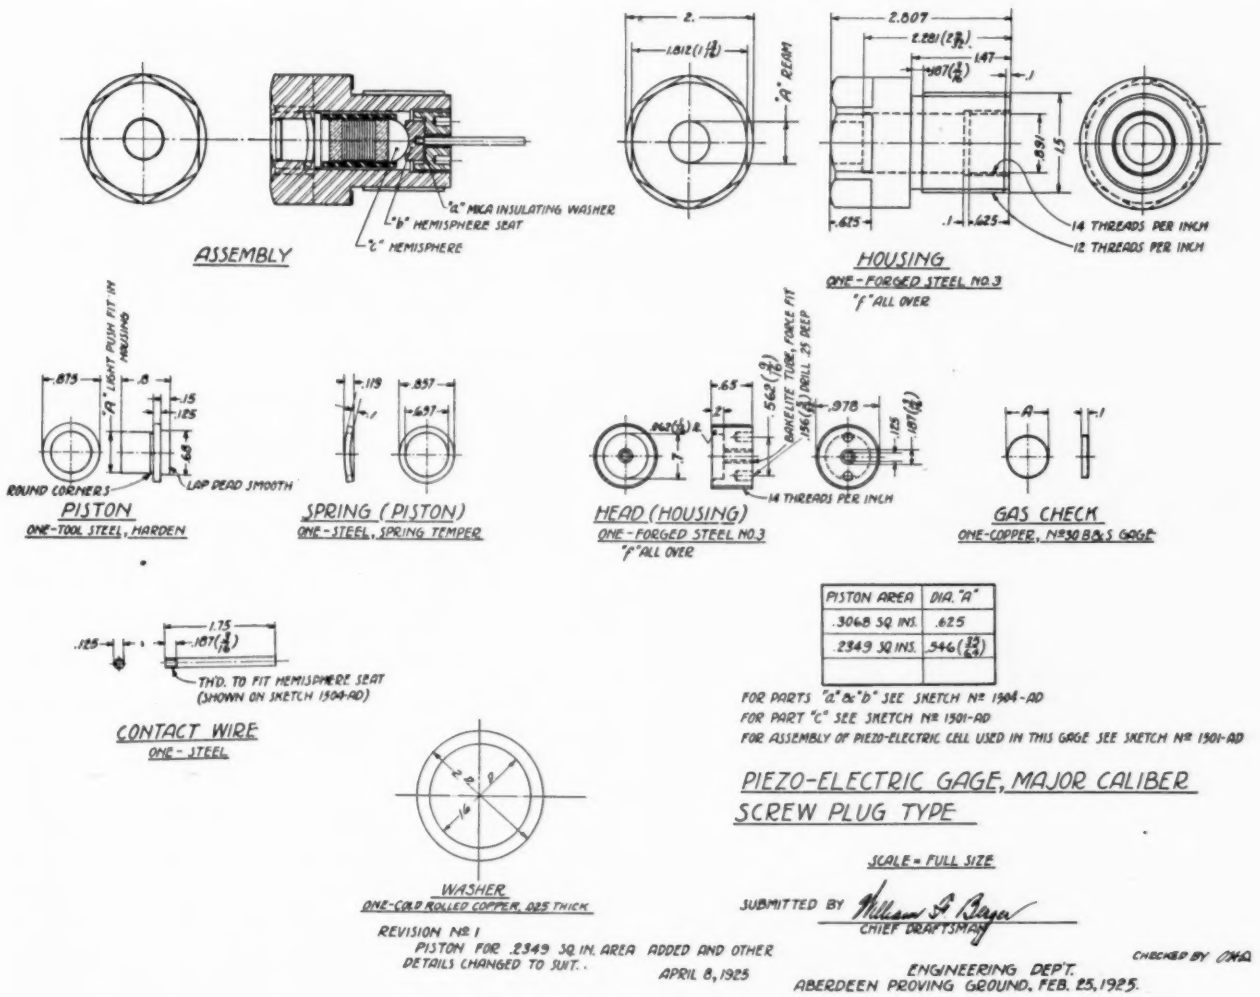

FIG. 5 DRAWING OF GAGE

Company a cathode-ray oscillograph of such characteristics that photographs of the moving spot caused by the impact of the electrons against the fluorescent coating could be taken outside of the tube. This was substituted for the electromagnetic oscillograph referred to. In this apparatus, the amplifier was retained to prevent the loss of charge that would occur with the small capacities required in the absence of amplification.

Since 1934, various other improvements have been made in the gage chiefly by one of the authors (Hodge). A schematic diagram of the apparatus as now most frequently used is given in Fig. 2. The gage consisting of a stack of quartz crystals with its housing is screwed into the chamber of the gun. It is connected to a condenser near by, which is in turn connected by an overhead line or underground cable to the input of a nonreactively coupled amplifier. The output of the amplifier impresses on the deflecting plates of the cathode-ray oscillograph a potential difference which is proportional to the potential difference of the condenser caused by the flow of electrostatic charge from the gage as the pressure changes. As the electrons impinge upon the fluorescent screen at the end of the cathode-ray tube, a luminous spot is produced. By means of a lens an image of this spot is obtained on the film or sensitized paper attached to a revolving drum. Timing lines are also placed on the sensitized paper by means of a tuning fork or other device. A photographic record is thus obtained of the pressure in the gun as it goes off. Fig. 3 is a sample record. It shows the pressure as a function of time in a caliber 0.30 Springfield rifle. The first break in the line to the left shows the time when the bullet reaches the muzzle and the second break shows the time when the bullet arrives at a screen placed in front of the muzzle. The timing lines indicate thousandths of a second. From the record it may be seen that the time from the beginning of the rise of pressure to the exit of the bullet at the muzzle is only slightly more than 0.001 sec.

DESCRIPTION OF VARIOUS PARTS OF THE APPARATUS

The gage proper consists of a piezoelectric cell and a housing in which it is placed. The cell consists of a stack of quartz crystals. The negative sides of the plates are connected together and grounded while the positive sides are connected to an insulated lead-out wire. A drawing of the cell is shown in Fig. 4.

Fig. 5 shows a drawing of the housing with the cell in place. Important features of this are the insulated stem which takes the charge from the positive sides of the plates and the Belleville spring which tends to keep the reaction between the cell and the housing constant during the small displacements of the cell allowed by the elasticity of the housing and the piston when it is subjected to the gas pressure. A photograph of the parts of the gage is shown in Fig. 6.

The gage is attached to a mica condenser of high quality placed near the gun. The capacity of the condenser is varied depending

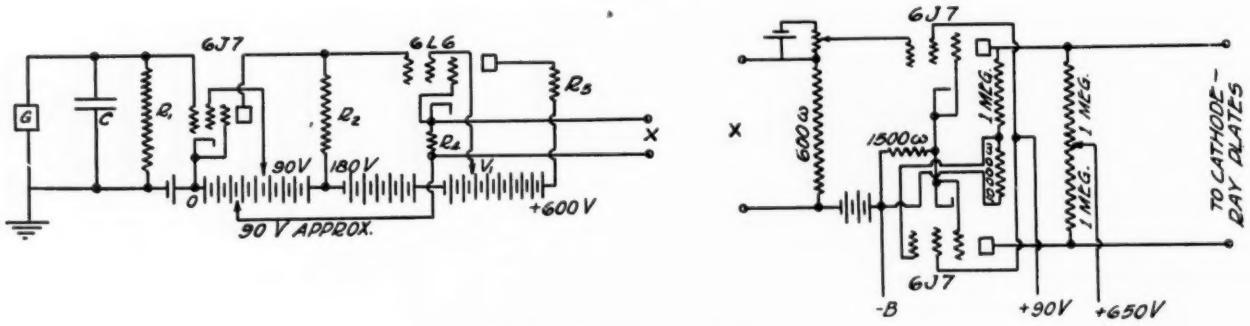

FIG. 8 AMPLIFIERS AND LINES

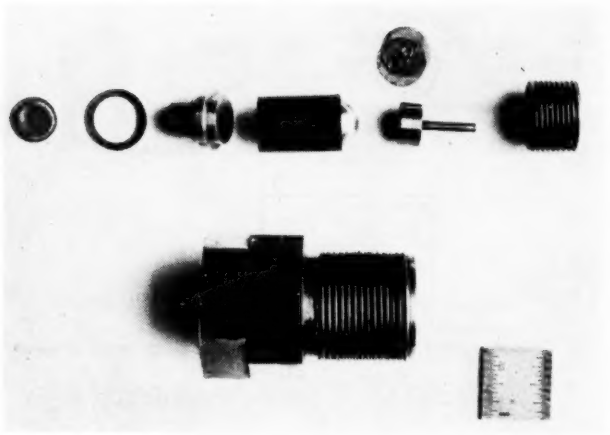

FIG. 6 PHOTOGRAPH OF PARTS OF GAGE

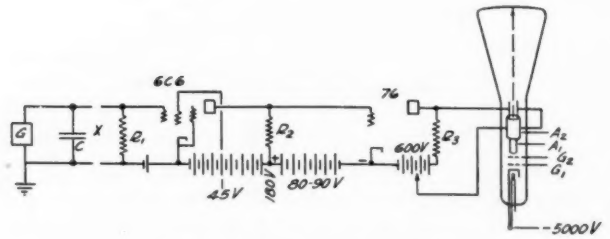

FIG. 7 DIAGRAM OF AMPLIFIER

upon the piston area of the gage used and the magnitude of the pressure to be measured. In measuring pressures in ordinary guns, the capacity is between 2 and 3 μf. The condensers are usually connected to an amplifier by means of a line or cable; in some cases a cable of a length of 2000 or 3000 ft is used without any great difficulty for all guns except small arms. In case it is desired to take pressures at more remote points, however, there is installed near the gun, an additional amplifier, which is connected to the amplifier in the laboratory, which in turn is connected to the cathode-ray oscillograph.

A schematic diagram of the amplifier currently used is shown in Fig. 7. In its design an attempt was made to keep the reactances as small as possible, since these cause distortions of the pressure-time curve, and to obtain a uniform amplification of voltages within its range of from 0 to 0.2 volt. No originality is claimed for it. The input tube is of the type 6C6 carefully selected to have a low grid current to minimize the loss of charge.

The batteries supplying the filaments and plate circuits are of such large capacity that the drift of the amplifier is slow. It can be used for a working day without appreciable change in calibration.

The cathode-ray tube is a special one having a blue short-persistence screen. In Fig. 7 the second anode of the tube is shown connected to the amplifier batteries but in case a long line is used between gage and amplifier it is better to use a separate battery for biasing the anode above ground potential.

By means of an f 1.8 lens of 1-in. aperture an image of the luminous spot of the cathode-ray tube is focused on sensitized paper attached to the moving drum.

Timing lines are placed on the moving paper by a tuning fork and an arc light.

The apparatus shown in Fig. 2 with the amplifier shown in Fig. 7 is satisfactory for the measurement of pressures in small arms and closed chambers fired near by in the laboratory and, unless the interference from power circuits and the like is large, for the measurement of the pressures in guns a half mile away. However, for the measurement of the pressures of guns situated several miles from the laboratory, the apparatus of Fig. 7 is inadequate because of the great amount of interference picked up by the long lines. To obviate this it is necessary to amplify the signal before it is transmitted.

Fig. 8 is a schematic diagram of a circuit which has been found to be reasonably good for use with these long lines. This circuit consists of two units, one of which is placed at the gun while the other is in the instrument building. The part of this amplifier which is placed at the gun consists of a high-resistance input tube directly coupled to a tube the cathode current of which passes through a 600-ohm resistor placed across the end of the line. The portion of the amplifier at the camera is a kind of cross between a single-ended and a push-pull circuit. Its input resistance is also about 600 ohms.

Some circuit constants and symbols for Figs. 7 and 8 are:

C	= 0.1 to 6 μf
G	= gage
R_1	= 5 megohms
R_2	= 0.115 megohm
R_3	= 0.1 megohm
R_4	= 600 ohms, R_5 = 5000 ohms
G_1, G_2	= control grids
A_1, A_2	= electrostatic focusing cylinders
K	= cathode
V_1	= 225 volts above cathode connection of 6L6
X	= transmission line.

The chief advantage of this circuit is that it provides an output voltage which is relatively large, 400 to 500 volts, and does not tend to cause defocusing of the cathode spot.

The 600-ohm resistors mentioned have this value to prevent reflections at the two ends of the line. Experience has shown that if these resistances differ greatly from 600 ohms, serious distor-

tions caused by reflections will occur in the recorded time-pressure curve. It is a bit difficult to obtain linear amplitude response over the useful range of this amplifier combination, but this defect can be overcome by a careful calibration.

Calibration

To enable the deflection on the oscillogram to be expressed as pressure in psi the apparatus must be calibrated. This is done as follows: (1) The gage itself is calibrated to give the relation between pressure and electrostatic charge, (2) the apparatus, consisting of the condenser, the amplifier, and the cathode-ray oscillograph, is calibrated to give the relation between the charge impressed on the condenser and the deflection of the oscillograph. The combination of the two calibrations gives an over-all calibration of the apparatus. It is possible but impractical to calibrate directly from pressure to deflection. To perform this correctly the dead-weight gage would have to be taken out to the gun. Furthermore, the calibration of the gage remains practically constant but the amplifier has to be calibrated every time records are taken.

The device which is used for calibrating the pressure gage proper is shown in Fig. 9. It is a dead-weight gage of the hydrostatic type and consists of a hand pump capable of producing 15,000 psi of oil pressure; a pressure intensifier which has a pressure ratio of 10 to 1 between the high- and low-pressure sides and an upper limit of 50,000 psi; an oscillating piston which is caused to rise off its shoulder seat by oil pressure and which raises a pan of from 50 to 500 lb weight; and a quick-release valve which is capable of releasing 50,000 psi pressure and of reducing the pressure against the gage piston to atmospheric in from 0.003

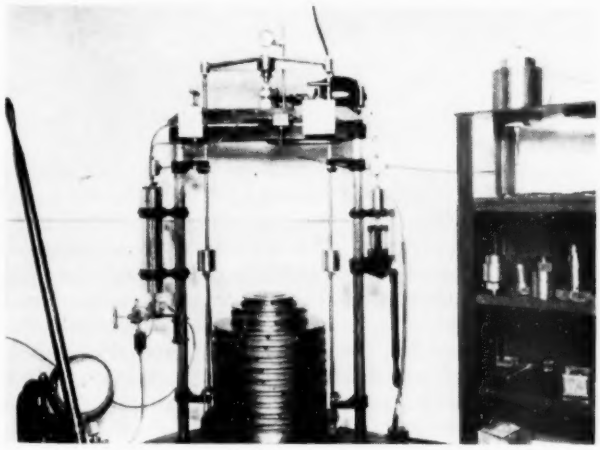

Fig. 9 Dead-Weight Pressure Gage

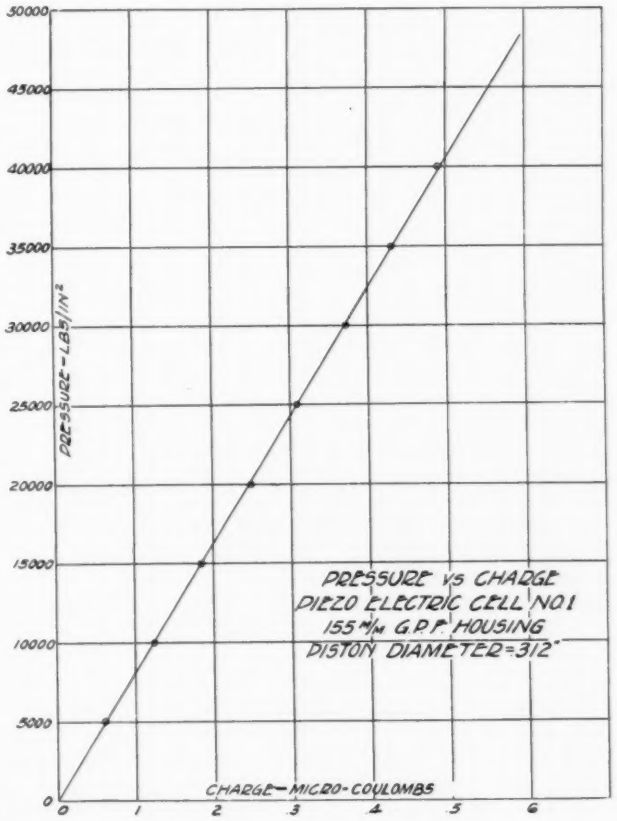

Fig. 11 Pressure-Charge Relation

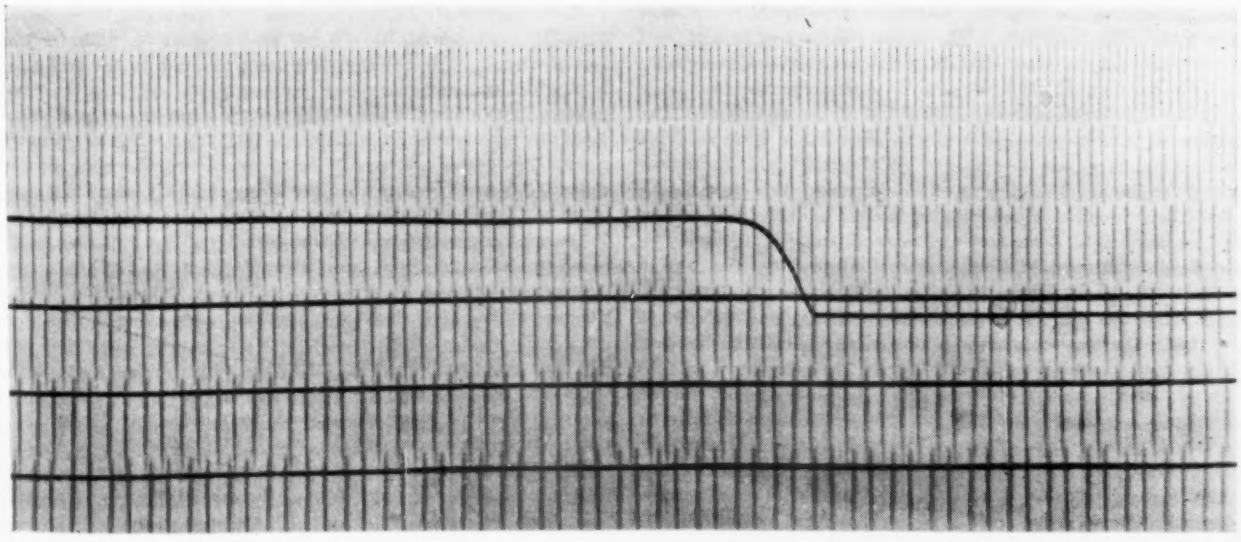

Fig. 10 Curve Showing Release of Pressure

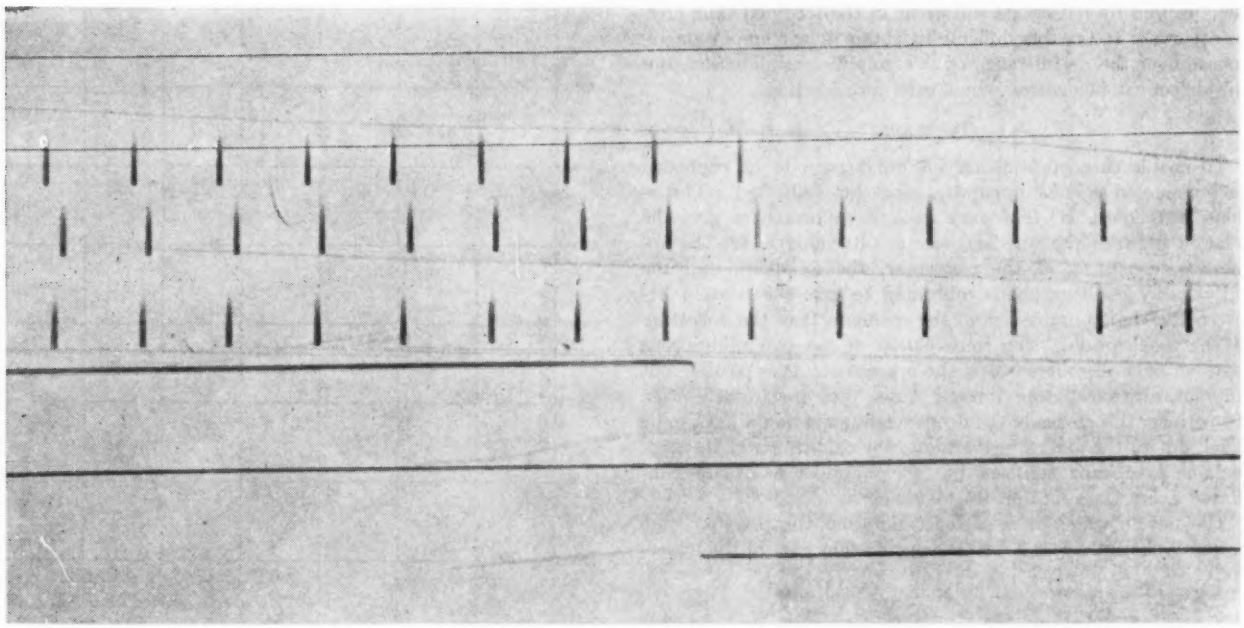

FIG. 12 CALIBRATION OSCILLOGRAM

to 0.010 sec. The charge produced by the gage on such a pressure release was used to obtain the pressure-time curve shown in Fig. 10. Thus the charge produced on the quick release of the oil pressure is used to calibrate the piezoelectric gage proper.

Fig. 11 shows the charge produced by the gage as a function of the pressure applied.

Fig. 12 is a calibration oscillogram showing the relation between the deflection recorded on the oscillogram and a charge suddenly impressed on the condensers attached to the input of the amplifier. The fact that the deflection is very sudden indicates that practically no distortion arises from the reactances of the circuits.

THE CHARACTERISTICS OF THE GAGE

As has been previously stated, a gage to be adapted for measurements of pressures in guns should have a high natural frequency, should be insensitive to the shocks produced by recoil, and should have satisfactory precision. The natural frequency of a typical piezoelectric gage is about 50,000 cycles per sec, which is amply high for most guns. If it were desired to do so the frequency could be raised considerably above this by a reduction in the number of quartz plates and in the size of the piston. This would of course reduce the sensitivity of the gage. In so far as sensitivity to the shock of the recoil is concerned, the gage has in general been found satisfactory. No trouble has been found when used in cannon of 3 in. and greater calibers. Some difficulty however has been experienced in a small-arms rifle if the gage is inserted in a weapon which is improperly balanced. The precision while not at the present time as great as desirable is tolerable. The probable error of the measurements is about 1 per cent under ordinary conditions.

In addition to meeting in a fairly satisfactory manner the requirements mentioned, the gage has some other valuable properties which should be mentioned. By reducing the capacity of the condenser, the sensitivity of the apparatus as a whole may be greatly augmented. It is thus possible to make quick shifts from an apparatus designed to measure 50,000 psi to one suitable for measuring 500 psi or less. However, as the capacity becomes smaller, the effects of leakage, referred to later, become more serious, interference increases, and the amplifier may become unstable.

The apparatus may be easily changed so that it will measure directly the rate of change of pressure dp/dt instead of p the pressure itself. For this purpose a resistor is inserted in place of the condenser shown in Fig. 2. With this form of the apparatus all of the charge has to flow through the resistor aside from the negligible amount required to charge the connecting leads. Hence if q is the quantity of charge generated, the current through the resistor is dq/dt and the potential difference between the terminals of the resistor is Rdq/dt if R is the value of the resistance. It is obvious that since q is proportional to the pressure the voltage impressed on the amplifier and hence recorded on the film is proportional to the rate of change of pressure dp/dt. This interesting and valuable use of the gage was developed by Dr. B. S. Mackey of the du Pont Company.

It has previously been mentioned that the input tube of the amplifier is chosen to have a low grid current to minimize the loss of charge. There is of course some loss due to the grid current and also some caused by leakage in the gage, in the condensers, and along the lines. However, when the gage is subjected to pressures of from 25,000 to 60,000 psi, such as occur in guns, it generates a relatively large amount of charge, approximately 0.6 microcoulomb. This large charge permits the use of a condenser of large capacity across the gage terminals. When used in connection with the amplifier of Fig. 7, the capacity is adjusted to keep the maximum input voltage to the line below 0.2 volt, which serves to keep the leakage current low. For pressure cycles which last for more than a few thousandths of a second the charge loss due to the low resistance of the input circuit may become appreciable. However, by the use of an input tube type 6C6 and of mica condensers of good quality it is possible to record pressure-time curves for all ordinary guns with negligible errors due to leakage.

Two of the most serious defects of the apparatus in its present form are: (1) Interference frequently occurs when lines half a mile long or longer are used and (2) the spot of the cathode-ray tube tends to defocus because, with the arrangement shown in Fig. 7, one deflecting plate is kept at constant potential while the

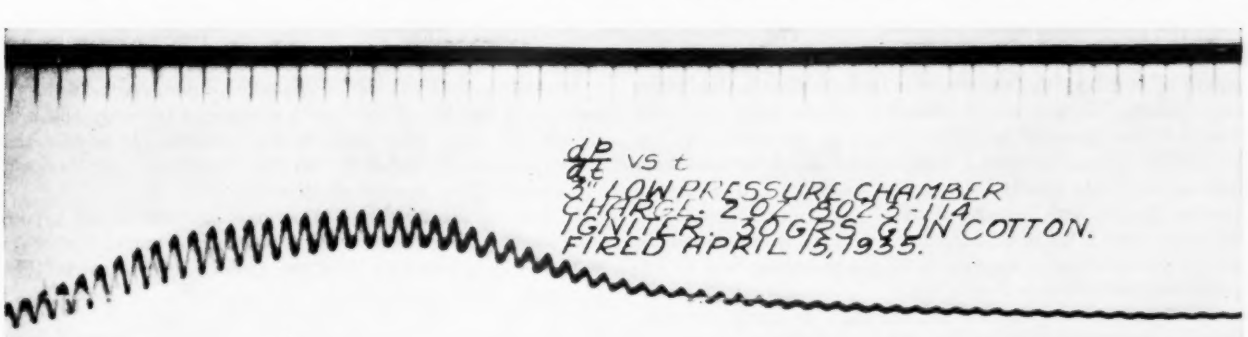

FIG. 14 SHOWING dp/dt FOR A CLOSED CHAMBER

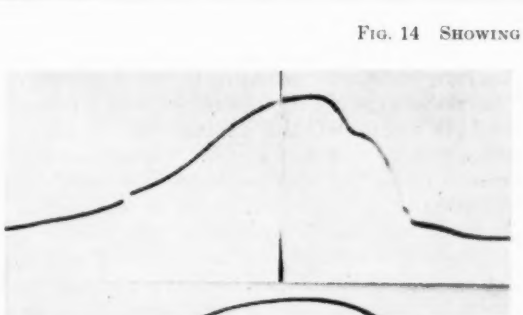

FIG. 13 PRESSURE-TIME CURVES OF 155 MM GUN

potential of the other is varied and this variation causes an appreciable change in the field accelerating the electrons. If push-pull amplification were employed the potential of one plate would be raised and that of the other lowered leaving the potential in the center of the tube unchanged. Push-pull amplification should also reduce the interference on the lines. This interference is partly caused by the unbalanced circuit. If the gage were designed to have both positive and negative terminals insulated a balanced input circuit could be obtained. With this and push-pull amplification most of the effects of interference should be eliminated. Work along these lines is now in progress.

EXPERIMENTAL RESULTS

The piezoelectric gage has been useful to the Ordnance Department in many ways. It has enabled maximum pressures in guns to be measured with much smaller systematic errors than was possible with the copper-crusher gages which had previously been used for this purpose. It has also been of great value in connection with the design of propelling charges for guns. While the possibility that there might be pressure waves of serious amplitude in guns has been known since the time of Vieille, it was not until records were obtained by the piezoelectric gage that it was known that such waves in the chambers of guns were a frequent occurrence, at least in guns using the American type of powder. Although the phenomena are really quite different, the pressure waves in a gun may be compared to the knock in a gasoline engine. If a suitable fuel and design of chamber are used, it is possible to eliminate the knock in the engine. Similarly in a gun, if the chamber, the charge, and the ignition are suitably designed, it is possible to eliminate the pressure waves and obtain a smooth pressure-time curve. Fig. 13 shows two cathode-ray oscillograms of pressures in the 155 mm gun G. P. F. For both of these oscillograms, the amount and kind of powder were the same but the arrangement of the charge was different. As may be seen, with the arrangement used to make the upper oscillogram, pressure waves of considerable amplitude are obtained while the arrangement of charge in the lower oscillogram eliminates the pressure waves completely.

When the apparatus is adapted to measure dp/dt, it is possible to get a sensitivity greatly increased over that obtained when p itself is measured. By the use of the dp/dt apparatus, it is therefore possible to record waves of an amplitude so small that they would probably escape detection if records were made with the ordinary apparatus. Fig. 14 is a copy of an oscillogram showing dp/dt in a closed chamber. From this oscillogram, the frequency of the waves may readily be obtained. From the frequency and the length of chamber the velocity of sound in the powder gas is determined. From the velocity of sound in turn, if the pressure and density are known, the ratio of specific heats γ may be calculated. It has been found that values of γ for the powder gas obtained in this way are in fairly good agreement with those calculated from the specific heats of the constituent gases based upon quantum mechanical theory.

ACKNOWLEDGMENT

In conclusion the authors gratefully acknowledge the assistance and cooperation of W. F. Berger and P. Ewing who designed many of the fittings and gage housings, R. C. Gerdom whose advice and mechanical skill have been invaluable, J. L. Sentman who has built practically all of the amplifiers and who has also taken the many records, and J. S. Durham who has cared for the gages at the guns and assisted with practically every phase of the pressure measurements.

The authors are indebted to the Ordnance Department, U. S. A. for supporting this interesting development and for permission to publish this paper.

Discussion

K. J. DEJUHASZ.[8] This paper is a valuable contribution to the literature on piezoelectric pressure indicators, which instruments have attained a considerable importance in the solution of engineering problems encountered in the measurement of rapidly changing pressures and forces. Though pressure indicators have been built also on other electrical principles (variation of resistance, inductance, capacitance, inverse Wiedemann effect, and photoelectric effect) and the last word has not been said as to which is the best principle, yet it appears at the present stage that piezoelectric indicators best fulfill the many engineering requirements.

[8] Associate Professor of Engineering Research, The Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

At the Engineering Experiment Station of The Pennsylvania State College electrical indicators have been used for the investigation of pressures in Diesel-engine cylinders and in fuel-injection systems. It was found difficult to obtain fully consistent results as to quantitative calibration, due presumably to the variability of amplification. Keeping the amplification under full control would greatly increase the reliability of these instruments. In previous piezoelectric cells one terminal is grounded while the other is led to the amplifier. Insulating both terminals as the authors suggest appears to be one promising way to improve the functioning in this respect.

Development on piezoelectric indicators is being advanced by several research institutions. By some workers, namely, by Meurer[9] at the Dresden Institute of Technology, and by Boerlage, Broeze, Van Dijck and Peletier at the Proefstation, Delft,

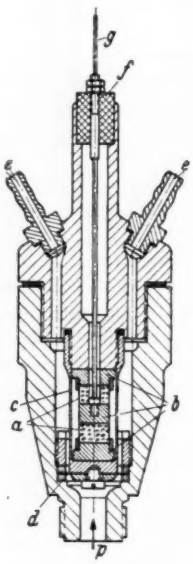

Fig. 15

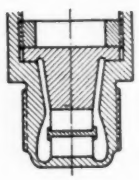

Fig. 16

FIG. 15 CELL USED AT DRESDEN

FIG. 16 CELL USED AT DELFT

Holland,[10] it has been found that mounting the quartz crystals between precompressing screws introduces hysteresis effects due to the minute slippage which occurs under stress between the male and female screw threads. Therefore the tendency is to eliminate the screw threads altogether and to mount the crystals between elastically yielding elements. Fig. 15 shows the cell used at Dresden and Fig. 16 that employed at Delft, both of which are built on this principle.

Another tendency in the construction of piezoelectric cells is to reduce the number of the quartz crystals to two only and most recent cells have been built in this manner. It is true that thereby the sensitivity of the cell itself is reduced but this can be compensated by a greater amplification.

In view of the increasing importance and use of this type of instrument, and of the progress in the construction of the cells, it would be of interest to learn the authors' experience in these respects.

B. H. MACKEY.[11] In my opinion, the importance of the instrument as described in this paper for research and development work cannot be overemphasized. The present method of measuring pressures with crusher cylinders will probably be used for routine work until the piezoelectric or some other form of pressure gage is simplified considerably, but it is quite obvious that the crusher gage has very limited value as a research tool.

It might be well to emphasize the importance of calibration in connection with the piezoelectric gage. The impression seems to exist in some places, that the piezoelectric constant of quartz is a definite quantity and that calibration is unimportant. Our experience has been that the constant for high-grade crystals can vary as much as several per cent and that each gage assembly must be carefully checked before use. It is also important that the quartz surfaces and those of the collector plates be almost optically flat in order that the gage may retain its calibration in use.

The piezoelectric gage has been used at Burnside Laboratory in essentially the form described in this paper for measuring pressure rises of comparatively long duration, i.e., 1 sec and also for pressure impulses given off by detonating explosives. In the first case, it is necessary to balance out the leakage currents with a separate supply voltage and in the second, it is necessary to damp the gage and the electrical circuit to eliminate extremely high frequency vibrations. The present paper has already indicated the wide pressure range through which this instrument gives satisfactory results.

AUTHORS' CLOSURE

As mentioned in the paper, it is necessary to place a Belleville spring between the head of the piston and the housing to keep the reaction between the housing and the piston approximately constant as the quartz crystals are compressed. This provides the elastically yielding element in the gage as developed at the Aberdeen Proving Ground.

With reference to the number of crystals, it is believed that most of the piezoelectric gages have contained not more than two plates. However, in our work, it is advisable to have many more plates because the gages as a rule are so remote from the amplifier.

The High-Pressure High-Temperature Turbine-Electric Steamship "J. W. Van Dyke"

By LESTER M. GOLDSMITH,[1] PHILADELPHIA, PA.

The author discusses the features of various steamship designs which were considered in the development and final adoption of the construction of the tanker S.S. *J. W. Van Dyke*. After data on steamship designs had been collected and analyzed an intensive study was made of hull form, propeller design, and power-plant requirements. The author describes the results of model tests conducted at model basins in Hamburg, Germany, and Washington, D. C.; the results of these tests were the deciding factor in selecting the propeller and hull designs. The paper includes a complete description of the steam-generating equipment, electrical equipment, high-pressure piping, controls, and miscellaneous electrical equipment which were finally selected for the ship. The author presents graphically the results of trial runs made with this turbine-electric steamship.

FOR a better understanding of the engineering development leading up to the construction of the tanker S.S. *J. W. Van Dyke*, an outline of some of the previous marine-engineering experience of The Atlantic Refining Company will first be given and may serve as a clarifying background for a ship carrying the highest steam pressure and temperature ever to go to sea from the United States.

Twenty years ago this company pioneered in the installation of Alquist or laminated type of double-reduction gears in five ships of 2600 shaft hp each, went through the entire period of this early development in reduction gears, and replaced them finally with compound turbines and single-reduction sets having solid gear wheels and embodying low tooth pressures in the design.

Fifteen years ago the company again pioneered by designing and building the first three Diesel-electric tugs and a 1200-ton Diesel-electric tanker, immediately followed by a 7500-ton tanker with the same system of propulsion. These installations were followed by others until this company had a fleet of fourteen vessels with Diesel-electric machinery, ranging in size from approximately 400 to 3000 shaft hp. At the same time, it was also operating on the same routes a number of the older steam-powered ships having both reciprocating and geared turbine machinery.

In view of this pioneering, and the experience and engineering development which followed it, together with the fact that the owners were manufacturers of petroleum products, it is evident that the company's engineers were absolutely unbiased from an engineering viewpoint, and had no other goal or object than to produce power for propulsion and transportation at the least cost per shaft horsepower, and per ton-mile.

By 1930, experience with, and observation of, Diesel-engine installations had convinced the company that this form of power had definite limitations. In other words, for horsepowers up to 3000, the Diesel engine is an undeniably economical prime mover, but above that size, doubtful, especially in view of the advent of the high-pressure high-temperature steam turbine. Having in mind that the company, within five years, would be faced with the necessity of replacing its then existing tonnage, the author inaugurated a study and thorough investigation of high-pressure and high-temperature steam plants. It was not until 1935, however, that the conclusion was reached that boilers and small turbines, using high-pressure and high-temperature steam, were suitable for marine applications. Keeping in mind the background of experience outlined, studies were made and tabulated of all available types of power plants, including Diesel-electric, direct Diesel, geared-turbine, and turboelectric.

While these data were being collected and analyzed, an intensive study of hull form and propeller design was begun. In order to correlate these studies of the power plant, propeller, and hull a description of the latter is first given.

The problem was to design a modern tank vessel to carry approximately 18,000 tons dead weight on a length of about 520 ft between perpendiculars and a maximum molded draft of 29 ft 6 in. at an average sea speed of 13¼ knots. This speed was considered the most profitable after a careful study of the conditions under which the ship was to run, and is the point at which a further increase in speed would reduce the margin between operating cost and gross profit.

A hull of the following dimensions was finally settled upon for tank testing and determination of propelling power: Length between perpendiculars = 520 ft; molded breadth = 70 ft; molded draft = 29 ft 6 in.; block coefficient (on between-perpendicular length) = 0.78; and displacement = 23,898 tons.

The Hamburg model experiment tank was chosen for model tests since it is well known to be the largest and best-equipped of its kind in the world and work on the previous ships had been done

---

[1] Chief Engineer, The Atlantic Refining Company. Mem. A.S.M.E. Mr. Goldsmith was graduated from Drexel Institute with a degree in electrical engineering in 1914, and after serving with the United Gas Improvement Company and the City of Philadelphia, became mechanical engineer with The Atlantic Refining Company in 1916. He was promoted successively to research engineer, engineer of tests, and superintendent of mechanical laboratory. In 1923 he was appointed technical assistant to the president, with the assignment of pioneering the application of Diesel-electric drive to ships. Soon thereafter he became the company's consulting engineer. In 1934, Mr. Goldsmith became manager of the engineering and construction department, and chief engineer in 1937. In addition, he is a director and vice-president of the Atlantic Pipe Line Company, a director of the Atlantic Oil Shipping Company, and chief engineer of the Atlantic Pipe Line Company, Keystone Pipe Line Company, and Buffalo Pipe Line Corporation.

Contributed by the Power Division and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in New York, December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in this paper are to be understood as individual expressions of the author, and not those of the Society.

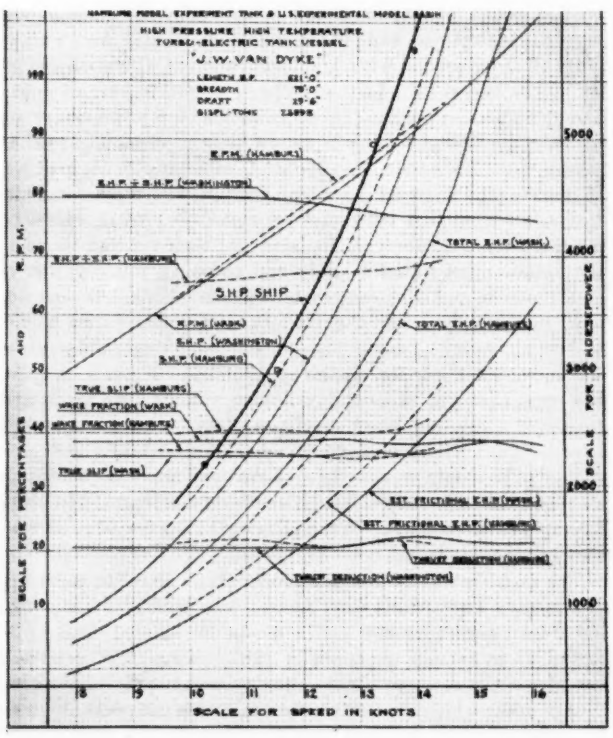

FIG. 1 COMPARISON OF MODEL EXPERIMENTS AND SHIP PERFORMANCE, WASHINGTON, D. C., AND HAMBURG, GERMANY, MODEL BASINS

there. At the time these experiments were started in March, 1934, there was still doubt in the minds of some shipbuilders as to the value of the so-called cruiser stern on the average commercial ship and, in order to obtain conclusive evidence on this point, the model was towed both with cruiser stern and the overhung counterstern, which is now almost obsolete. The results given in Table 1 leave no doubt as to the value of the former in cutting down eddy making and reducing the total resistance by an appreciable amount.

Self-propelled tests were next run with the cruiser-stern model, using propellers designed by the staff at the Hamburg model basin. Two different propellers were tried with results as given in Table 2. It can be seen from Table 2 that propeller No. 1275 gave the best results at the designed speed of 13.25 knots.

As stated previously, these tests were run in March, 1934, and it was not until January, 1936, that the company was ready to go ahead with the construction of the vessel. In view of this lapse of time and the fact that some higher propulsive efficiencies than shown in the Hamburg tests apparently had been obtained in one or two cases in this country, it was decided to have the same model experiments repeated at the U. S. model basin in Washington, D. C. This would serve not only as an interesting check on the results but would also provide opportunity for further possible improvement in efficiency. A model from the same lines was therefore tested at Washington at the same displacement, both for effective horsepower and self-propelled for shaft horsepower with a propeller designed by the staff at the Washington model basin. The results of these tests together with those obtained at Hamburg are shown in Fig. 1, and the principal characteristics of the two propellers are given in Table 3. From an inspection of the curves, it is readily apparent why the propeller developed in the U. S. model basin was adopted.

With regard to the structural plan of the vessel, the chief point of interest is the fact that her entire cargo tank and fuel bunker space, comprising a length of 353 ft, is electrically welded throughout. The bow and stern portions of the ship were riveted in the orthodox manner. The general arrangement otherwise follows more or less usual tanker practice. The ship is a poop, bridge, and forecastle type with one continuous deck and two longitudinal bulkheads and sixteen transverse bulkheads, the cargo space consisting of nine three-compartment tanks with a total capacity of 868,980 cu ft, or 6,500,000 gal. The modern tendency toward streamlining is followed to a moderate extent by rounding the fronts of bridge structure and poop and by giving the stack an ogival section. A general arrangement and profile plan of the ship are shown in Fig. 2, and her general appearance is shown in Fig. 3.

POWER PLANT

After all the analytical work was finally reduced to figures, it was disclosed that it would require 5000 hp to propel this vessel at the desired speed, as indicated by the model-basin work shown in Fig. 1. It was decided that for this horsepower, the form of power promising the lowest over-all operating cost per shaft horsepower was the turbine-electric drive. The reasons for selecting the turbine-electric drive embody more than just propulsion, for it was the request of the management of The Atlantic Refining Company that this vessel be outstanding in its ability to discharge cargo rapidly. In order to meet the requirements for discharging in less than 12 hr, pumps having a rated total capacity of 10,500 gpm at the desired pressure were selected. It was found that approximately 1000 hp would be required for these pumps when discharging in port. In addition, the trim of the vessel necessitated location of this cargo-pump room amidships. Therefore, it can be seen how simple it is to obtain this power from a standard turbine generator and operate the pumps electrically. It must also be kept in mind that not only economy of operation, but first cost and reduction of weight should be in the mind of every designer of any transportation equipment.

To meet existing rules of the American Bureau of Shipping, the Bureau of Marine Inspection and Navigation, and the require-

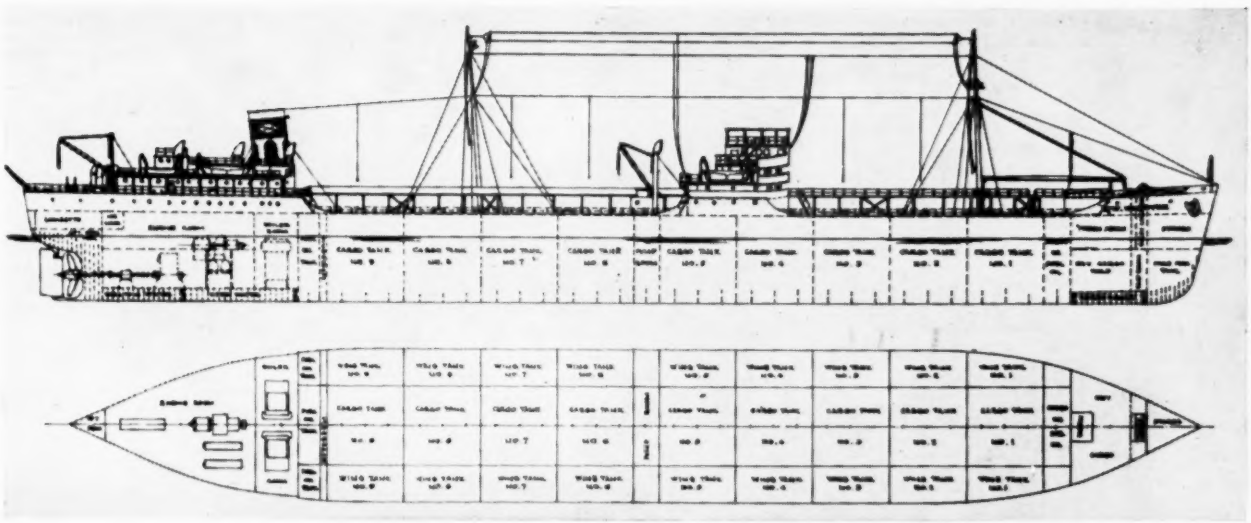

FIG. 2 GENERAL ARRANGEMENT AND PROFILE OF THE S.S. *J. W. Van Dyke*

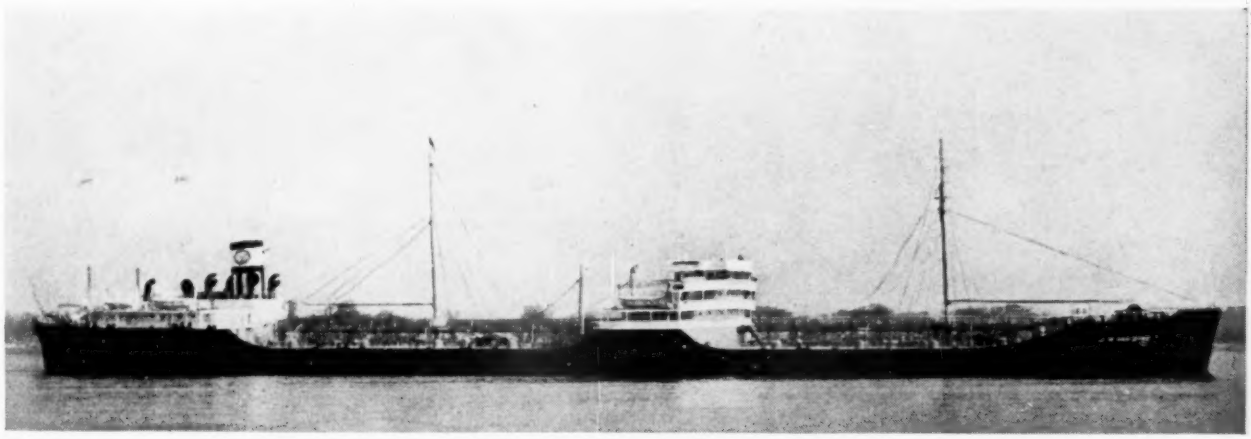

FIG. 3 THE S.S. *J. W. Van Dyke*

ments of economy in general, it was decided that the turbine should be designed for a pressure of 600 lb per sq in. and a steam temperature of 825 F. When the decision was made to go to this high pressure and temperature, one problem eliminated by the use of motor instead of gear drive was that of the reversing turbine and the question of keeping it cool.

In the tabulation of the engineering design of the previous turbine-electrically propelled vessels, both in this country and abroad, it was disclosed that none utilized a generator of standard voltage and frequency as we know them to be standard, thinking of land power plants in this country, nor did they employ the use of alternating current for auxiliary uses as is the case in all land plants. As no reason could be found why other than standard equipment should be used, engineering work was started with the idea of profiting by the principles in use in every modern land power station. A complete heat balance, as shown in Fig. 4, was first worked out in connection with the machinery manufacturers.

Three bleed stages were decided upon as giving the best compromise between the ideal and the practical complications of space requirements and piping. Another consideration borne in mind was that evaporation of feedwater should be reduced to a minimum and that every possible precaution must be taken to protect the boilers from impure water; therefore, all clean drains are collected and returned through a cooler into the main condenser while drains which are subject to possible contamination are reevaporated. The evaporators are planned to float on the line and normally only one of them, operating at much below its rated capacity, will be required. Under sea conditions, the heat of the evaporator vapor is used to supply such low-pressure steam as may be required for general heating purposes throughout the ship, and the remainder goes to the intermediate feedwater heater so that this heat is recovered. An emergency vapor line to the condensers is also provided for port use; but with proper operation this should not normally be necessary.

All three boiler feed pumps are turbine driven. Only one is required for normal operation. The exhaust is added to the second-stage bleed.

Therefore, it will be noted that under normal conditions the heat from the evaporator vapor and the feed-pump exhaust is either recovered in the feed or otherwise usefully employed.

No heat which can be put to use is rejected to the sea water except under unusual conditions.

Table 4 gives a comparison of the heat distribution as planned and as actually obtained. It will be noted that an over-all heat efficiency from burners to shaft of 22.5 per cent was expected.

LBS. FUEL/S.H.P.HR. (FOR PROPULSION ONLY)	.510		.502		.508		.511		.512				

During the trials, we obtained efficiencies as high as 22.6 per cent and in actual operation have obtained 22.7 per cent. It should be noted that these figures are that portion of the total heat supplied by the fuel to the burners which is used for propulsion, and not the gross steam-cycle efficiencies, which figures are 26.4, 26.1, and 26 per cent, respectively. Auxiliary sets do not enter into the normal heat-balance picture, since under usual load conditions they are electrically driven from the main generator.

Steam Generation

The design of the steam-generation plant is as follows:

Boilers are of the single-pass straight-tube header type as shown in Fig. 5, embodying four decks of superheat, stud-tube side walls, and air preheater.

Header-type boilers with air heaters, but without economizers, were selected with the thought in mind that the extreme simplicity of this design would be reflected in maintenance cost and, in particular, that with this type of boiler the tubes can be plugged off or even renewed without loss of ship time waiting for the boiler to cool down enough so that the drums can be entered.

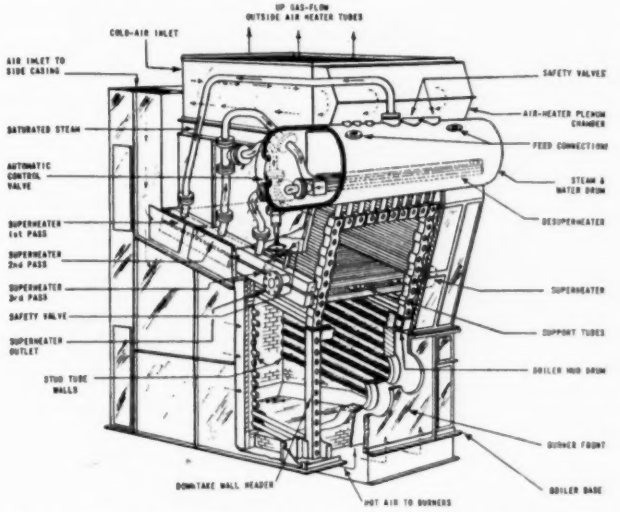

Fig. 5 Single-Pass Straight-Tube Header-Type Boiler Used on S.S. *J. W. Van Dyke*

It will be noted that the arrangement is further simplified by the fact that the boilers are so designed that the gases rise straight through, no baffles being required, thus further reducing internal maintenance.

The boilers have a rated capacity of 22,500 lb per hr each, at a pressure of 625 lb per sq in. gage and a steam temperature of 835 F, with feedwater at 300 F. They each have a total water-heating surface of 3222 sq ft, a superheating surface of 1094 sq ft, and an air-heating surface of 2412 sq ft. The furnace volume is 426 cu ft per boiler, giving a liberation rate of 66,000 Btu per hr per cu ft.

The lower two rows of tubes in both halves of the superheater are of 9 per cent chromium alloy and the boilers can be safely operated at 900 F final temperature.

They are fitted with automatic air-puff soot blowers.

The boilers are provided with complete automatic combustion control, including automatic superheat control, and the charts as shown in Figs. 6 and 7, will show how well this equipment functions. The charts in Fig. 6 are from one of the trial runs and show a continuous record of a 3-hr fuel test at constant load followed by three sets of runs at approximately full load, but under different ballast conditions. Note that no attempt was made to protect the boilers by gradual slowing or speeding up of the main turbine, but in spite of this, the superheat temperature falls off instead of rising when the load is dropped and is held at the set temperature when load is applied. At low loads the boilers are on hand operation; hence, the spread between the air-flow and steam-flow records.

When the low-load condition is to be maintained for any length of time, the burners can be changed to suit and the system again put on automatic operation.

The arrangement of the superheaters and their control is interesting. The superheater is divided into two sections, and a desuperheating coil is located in the drum which is so baffled that the entering feed passes along this coil. The saturated steam from the drum passes through the first half of the superheater and then is divided by a three-way valve so that a variable portion goes through the desuperheating coil before passing on to the second half of the superheater. The three-way valve is controlled automatically by the temperature at the superheater outlet.

It is interesting to note from precedent in this respect that today a land installation of a steam-generating plant, not embodying some form of automatic combustion control, would never be considered. Yet, in land plants, technical men, usually in the operating force and always in the supervisory force, are immediately available, while in the marine field, the supervision is only obtained at long distance. The successful operation of this type of equipment, as demonstrated on the S.S. *J. W. Van Dyke* will undoubtedly mean much greater application because of this demonstration. How well this control functions under sea conditions is shown by the charts in Fig. 7.

High-Pressure Piping

In the design of the high-pressure steam piping, the rules of the Bureau of Marine Inspection, which, at that time, not only prohibited welding, but were written without provisions for temperatures above 750 F, were somewhat of a handicap. However, through the cooperation of the bureau, rulings were obtained which permitted using stress-relieved welded joints. The main steam connections to the boilers, the boiler header, and the line to the main turbine are of 0.5 Mo, 0.2 C seamless-steel tubing with an inside diameter of 5 in. and an outside diameter of $6\frac{1}{2}$ in. This is heavier than necessary on account of the Bureau rules for thickness which did not permit taking full advantage of the greater strength of molybdenum tubing at high temperatures. In order to reduce radiation loss as well as the number of joints, the equipment was arranged to reduce the high-pressure steam piping to a minimum. The total length of the main steam lines, including expansion bends and valves, is as follows: Length of boiler risers, the 5-in. header, and main-turbine connection = 72 ft; length of the 3-in. Butterworth heater connection = 21 ft; length of the $2\frac{1}{2}$-in. boiler-feed-pump main = 22 ft; and the length of the 2-in. auxiliary-generator connections = 32 ft. All the high-pressure steam piping is of carbon-molybdenum steel. All flanges are recessed or tongue-and-grooved to give confined gaskets. All bolts, including those in the feed discharge lines, are of high-tensile class-C steel.

Main Turbine Generator

The main turbine generator is rated at 4500 kw, 60 cycles, 2300 v at 3600 rpm when supplied with steam at the throttle at 600 lb per sq in. gage and 825 F total temperature with the exhaust at 28.5 in. Hg vacuum.

The normal output for 5000 shaft hp was expected to be 4200 kw, 3850 kw going to the motor and 350 kw to the auxiliaries.

The turbine is of the impulse type, having 15 stages with bleeds after the third, seventh, and twelfth stages. The rotor is a solid forging with the wheels integral with the shaft, the first wheel carrying a double row of blades and all of the remaining wheels carrying single rows. The case consists of a high-pressure alloy fabricated steel section and a cast-iron low-pressure section, the division occurring between the tenth and eleventh stages. The case is also split horizontally to permit removal of the rotor. The blading of both wheels and diaphragms is of chrome-iron alloy; the first-stage nozzles are of steel with chrome-iron alloy partitions and the diaphragms are of cast iron or steel, depending on

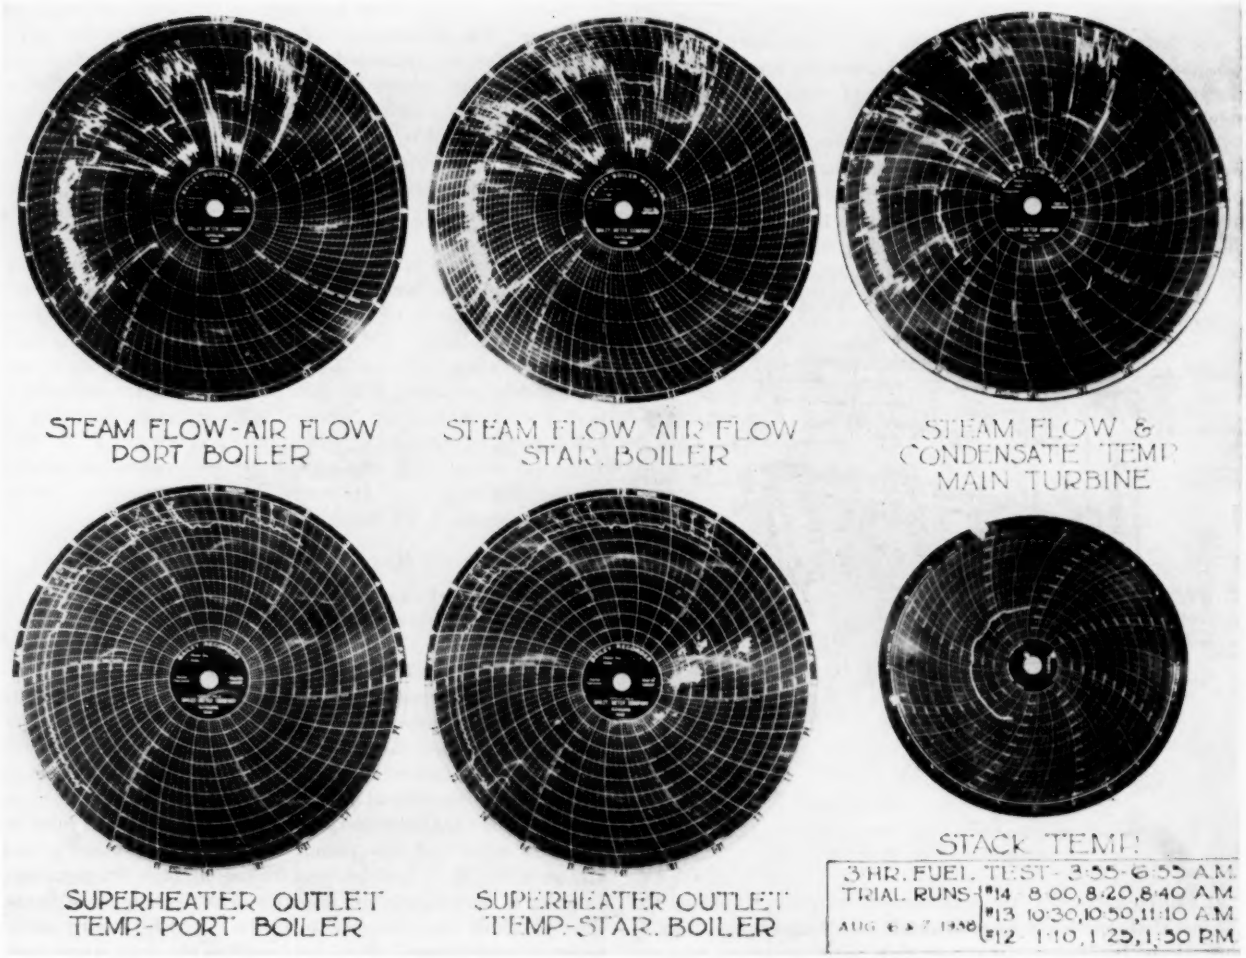

FIG. 6 CHART RECORD OF 3-HR FUEL-TEST RUN

the temperature. The packings are of the labyrinth type, and the glands are steam-sealed and provided with an automatic steam regulator.

Governing is accomplished by a valve chest containing six valves leading to the nozzle plate and so arranged that the nozzles are successively cut in or out as the turbine demand increases or falls off, thus avoiding the loss which would be caused by throttling the supply. The speed range which is obtainable is from 900 to 3780 rpm corresponding to 22.5 to 94.5 rpm of the propeller.

The generator, which is directly connected to the turbine, is of the rotating-field type. The stator consists of six coils Y-connected and brought out to six terminals. The rotor is ventilated by fans integrally mounted, which force air into its ends and out at the center; it then passes down through the air cooler, which is in turn water-cooled. This cooler is mounted directly under the generator and is housed in the same case. The bearings are of the plain babbitted type.

The combined turbogenerator set is only 22 ft 9 in. long × 10 ft 3 in. wide.

PROPULSION MOTOR

The propulsion motor is of the synchronous-induction type with 80 poles and is rated at 5000 shaft hp at 90 rpm, 2300 v, 3 phase, unity power factor.

It is only 17 ft diameter and 14 ft long over-all. This length includes the space allowed for sliding the stator aft to clear the rotor in case repairs are necessary. This arrangement avoids any need of disturbing the bearings or shaft alignment; this is the first time such an arrangement has been used.

The motor is separately cooled, but motor, fan, and air cooler are all enclosed in a tight duct system so as to give practically the effect of a totally enclosed motor.

Both the generator and motor are equipped with CO_2 connections for fire protection.

CONTROL

Figs. 8 and 9 show the main control panel with the operating levers. The method of control is extremely simple. Referring to Fig. 8, the left-hand lever (30) as you face the controls has three positions for both ahead and astern movement. As it is moved from the off position, it first closes the line contacts to the generator, then the generator field contacts so that the motor starts as an induction motor, and finally the motor field contacts, which causes the motor to pull into step and run as a synchronous motor.

Beside this lever is the turbine-governor lever (31) which permits varying the speed of the generator from 900 to 3780 rpm by adjustment of the governor setting.

In addition, there is an emergency throttle lever (32) which permits operating the generator on hand control up to 75 per cent of normal speed and an emergency trip (27).

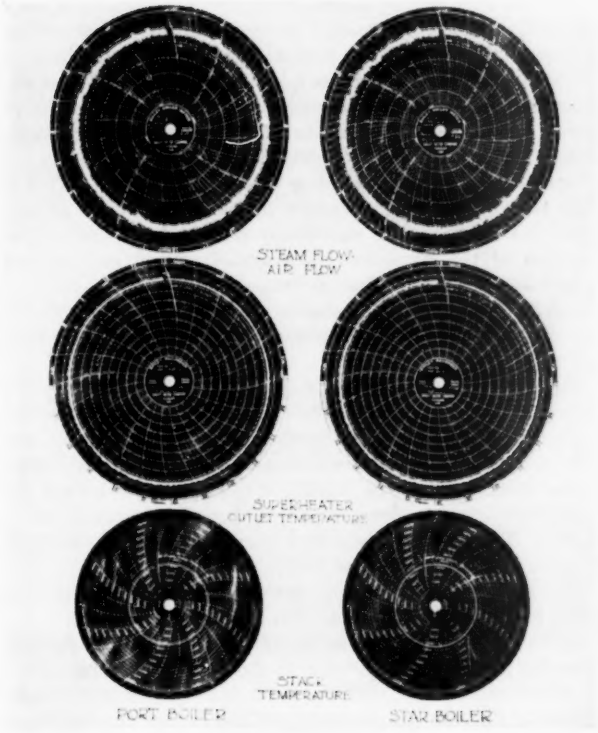

FIG. 7 CHART RECORD OF BOILER OPERATION UNDER NORMAL SEA CONDITIONS

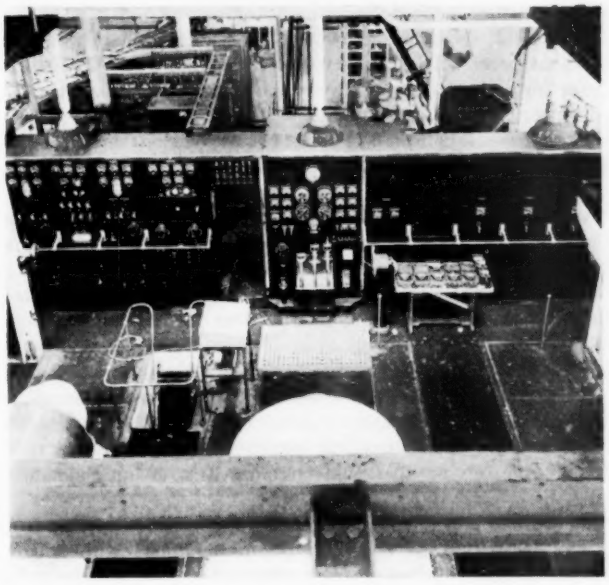

FIG. 9 CONTROL PANELS OF THE S.S. *J. W. Van Dyke*

All these levers are mechanically interlocked to prevent incorrect operation.

AUXILIARY SETS

There are two auxiliary sets, one to run and one for a stand-by unit. Each consists of a 5568/1200-rpm geared turbine driving a 350-kw 60/50-cycle 450-v synchronous generator, a 65-kw 110-v d-c exciter for the main units and a 20-kw 120-v d-c generator for excitation of the 350-kw auxiliary generator and supplying miscellaneous direct-current requirements.

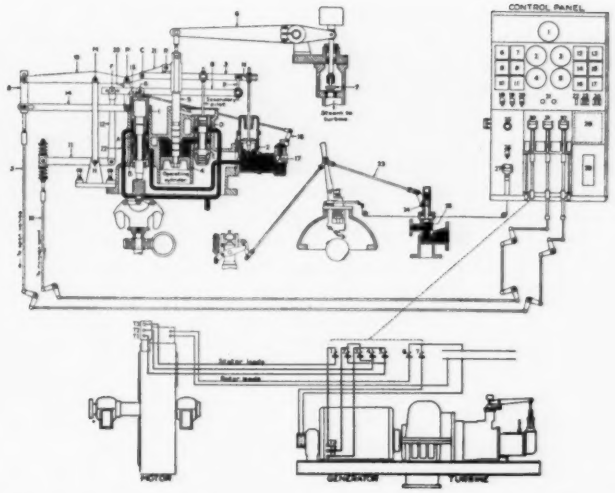

FIG. 8 SCHEMATIC DIAGRAM OF THE PROPULSION EQUIPMENT

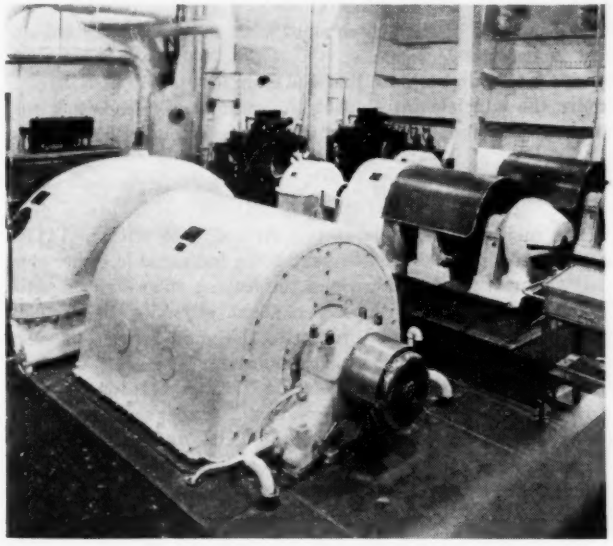

FIG. 10 THE MAIN GENERATOR AND TWO AUXILIARY SETS

The auxiliary units are so arranged that under normal conditions (60/50 cycles) the 350-kw unit operates as a motor, taking current from the main generator to drive the direct-current machines and drag the turbine. (No cooling of the turbine is required as vacuum is maintained through a connection to the main condenser.) When the speed of the main generator drops to approximately 52 cycles, the speed governor of the auxiliary set automatically starts to open the steam-admission valve so that the auxiliary turbine assumes the full auxiliary load by the time the main unit has slowed to 50 cycles. The circuit breaker between the two generators opens automatically to prevent the auxiliary generator attempting to motor the main generator. When the auxiliary turbine is to operate for any length of time, it is then brought up by hand to 60-cycle speed. When the main unit is again above 52 cycles, the auxiliary generator can be returned to motor operation as follows: The main and auxiliary generators are synchronized by means of a synchronizing device on the auxiliary-turbine governor. The circuit breaker is then

closed and the speed governor reset at its lower limit (52 cycles) which cuts off the steam, but leaves it ready to open and causes the turbine to reassume the load automatically when the main generator speed again drops below 52 cycles.

The compactness of both the main and auxiliary units and the convenience and "shipshape" arrangement of machinery made possible by electrification are clearly shown in Figs. 9 and 10.

Fig. 10 is a view from above the switchboard looking forward and to starboard across the main generator and the two auxiliary sets.

Fig. 9 is a view from the bridge across the forward end of the engine room and looks down and aft. In this view the main generator is in the center foreground with the auxiliaries to the left and the steam-gage panel board to the right. Across the center is the switchboard with the main control panel in the center, the three cargo pump panels at the right, and the auxiliary panels at the left. At the extreme left beyond the auxiliary panels may be seen the control panel for all the various motors throughout the ship. In this connection, note that equipment cannot be started from this panel, but only by means of push-button stations located at the equipment. Behind the switchboard on the left may be seen the relays and on the right the 2300-v–440-v oil-filled transformers. The table full of instruments in front of the switchboard is a temporary installation of test instruments.

It is interesting to note that the main motor is almost directly under the panel board so that the main power leads are only about 15 ft long from generator to switch panel and down to the motor.

Condensers

The main condenser is of the divided type with a divided hot well so that in case of leakage being indicated in either side, that side can be shut down and the leaking tube plugged while operation continues with only a slight reduction of vacuum. This condenser is bolted directly to the main turbine, most of its weight being taken by spring supports.

It has 4775 sq ft of $^3/_4$-in. 70–30 Cu-Ni tubes, 14 ft long between tube sheets, solidly rolled at both ends. Expansion is provided for by bellows joints in each side of the shell. It is rated at 35,300 lb per hr at a vacuum of 28.44 in. Hg with sea water at 76.8 F which is the average for the conditions under which this ship is to operate.

The auxiliary condenser has only a single bundle of 800 sq ft effective surface. The tubes are of the same material, size, and length as the main unit so that only one set of spares is required. As in the main unit, the tubes are rolled in at both ends and expansion is provided for by a bellows in the shell.

This unit has a capacity of 6000 lb per hr at a vacuum of 28.44 in. Hg with sea water at 76.8 F. This corresponds to the output of one auxiliary unit at 105 per cent load.

It can also handle the output of both units at 70 per cent load (8000 lb per hr) at a vacuum of 28.1 in. Hg.

The auxiliary condenser is connected by a header to the main condenser, and the auxiliary turbines exhaust into this header. Valves are provided to shut off either auxiliary unit and to permit the operating unit to exhaust either into the auxiliary or the main condenser.

The arrangement of the circulating-water system is unique and merits some explanation.

It has long been recognized that the principal cause of condenser-tube corrosion is entrained air. Many attempts have been made to eliminate the trouble by such means as water-box vents, streamlining of water passages, and flaring of tube ends, all of which have helped, but have not solved the problem.

Therefore, an attempt has been made to arrange the sea suction so that the entrained air is removed before the circulating water reaches the pumps. In order to accomplish this, a chamber has been provided between the tank top and the skin of the ship. The sea connections are made into this chamber. Baffles and vents are provided so that any entrained air is separated and removed before the water reaches the intakes of the circulating pumps, which are at the bottom of this chamber.

Examination of the condenser tubes in the S.S. *J. W. Van Dyke* after 6 months of operation indicates that this is proving effective as there was no sign of any pitting of the tubes. The impellers of the circulators were also examined and likewise showed no signs of corrosion or erosion.

It is believed that this arrangement will prove to be an important contribution to the protection of both condensers and circulating pumps.

The circulating pumps are of the so-called "deep-well" type, having mixed-flow type impellers at the lower end of vertical shafts driven by hollow-shaft vertical motors. Each pump normally supplies one side of the condenser, but they are manifolded so that both sides of the condenser can be supplied from one pump (when this is done, there is a loss of vacuum of about $^1/_2$ in.). These pumps also supply the generator and motor air coolers and the lubricating-oil cooler.

The remaining engine-room machinery is not described in detail, but a summary list is given in Table 5.

For those who may fear that the use of turboelectric equipment instead of gear drive adds unduly to the machinery weight, it will be of interest to note that the main turbine generator weighs 91,000 lb; the main motor weighs 107,000 lb; the air coolers and motor-cooling fan weigh 6100 lb; and the propulsion control equipment weighs 7600 lb. The total weight of this equipment is 211,700 lb.

The total dry machinery weight of the entire ship is only 423 tons, including deck machinery and cargo pumps.

The total weight of the power plant and auxiliaries only is 405 tons (wet). This equals 0.08 tons per shaft hp. The usual figure for a geared-turbine ship of this power is from 0.11 to 0.12 tons per shaft hp (550 to 600 tons); for direct Diesel, or Diesel-electric drive, it is from 0.11 to 0.14 tons per shaft hp (550–700 tons).

This low machinery weight is reflected in the unusually high ratio of dead weight to displacement obtained for the ship, the figure being 0.758, which is considered very good, especially in view of the extra-large cargo-pumping equipment installed.

Expressed in another way, the lower machinery weight alone permits the carrying of from 1000 to 2000 bbl more cargo.

Cargo Pumps

As stated earlier, it was necessary to provide cargo-pumping equipment of sufficient capacity so that the ship could be unloaded between tides. This required pumps of a total capacity of 10,500 gpm, giving an actual pumping time of approximately $10^1/_2$ hr.

In order to take advantage of the ship's generating equipment, it was decided to use deep-well pumps equipped with 2300-v motors as with this arrangement the motor room can be completely separated from the pump room except for the shafts which pass through stuffing boxes at each end of the cover pipe with bleedoffs to the suction side between them.

The pumps are three-stage centrifugals rated at 3500 gpm at 1750 rpm versus pressures of 80 lb per sq in. on gasoline and 90 lb per sq in. on crude oil, and requiring 220 and 245 hp, respectively. At maximum load on salt water, the power requirement is 300 hp. No stripping pumps are used, but instead, the cargo pumps are set in suction boxes which in turn are connected to vacuum priming pumps through float boxes so that as long as a

suction box is filled with liquid, the suction to the vacuum pump is closed by the float. If air enters, it passes into the float chamber, the valve opens and the air is drawn off through the vacuum pump, thus restoring suction to the cargo pump. The intakes of the cargo pumps being close to the bottoms of the suction boxes, the pumps continue to operate at full capacity until the tanks are practically empty as is evidenced by the fact that the *Van Dyke* has discharged her cargo in as short a time as 10 hr and 6 min, and normally discharges in less than 11 hr. Her sister ship, the S.S. *Robert H. Colley*, established a record of 9 hr and 21 min to discharge her cargo of 138,069 bbl of crude oil.

Miscellaneous Electrical Equipment

Motors. All pump and fan motors are of the class-2 marine type and are totally enclosed except (*a*) the main motor which is ventilated by a separate motor-driven fan and (*b*) motors in locations classified as hazardous, which are of the class-1 type and are explosion proof. This latter group includes the cargo pump, the cargo priming pump, and pump-room bilge-pump motors. The deck-machinery motors are also of class-1 explosion-proof construction.

All motors except the steering-gear motors are provided with overload relays.

The steering-gear motors, and the lights and galley service are

Fig. 11 Fore-and-Aft Gangway Has Solid Sides

on an automatic transfer between the two auxiliary units. Certain other motors are equipped with sequential relays to restart automatically after a power failure in the following order: (1) main lubrication oil pumps, (2) main circulators, (3) forced-draft fans, (4) main condensate, and (5) fuel-oil service.

In connection with the electrical equipment, the problem of carrying the cables forward to the cargo pump room and the midship house was given considerable thought, and it was finally decided to provide the fore-and-aft gangway on deck with solid sides instead of open railings and to run the cables along the inside of these where they are not only amply protected but are easily accessible. This gangway, with its cables, is shown in Fig. 11. The 2300-v cables are further protected by a box cover which can barely be seen where the cables turn down to enter the cargo-pump motor room in the foreground.

Steering Gear

The steering gear proper is of the conventional electric-hydraulic type with horizontal opposed rams connected to a tiller on the rudder stock and with power furnished by duplicate Hele-Shaw type oil pumps driven by 20-hp, 875-rpm induction motors. The steering control, however, is somewhat unusual in that there is no mechanical shaft or hydraulic telemotor connection between the bridge and steering-gear compartment, either for normal or emergency steering. The system used consists of two entirely independent electrical controls using Selsyn motors, and separate circuits from bridge to steering gear. One of these controls is arranged for either hand or automatic steering through the usual gyropilot and is a full follow-up self-synchronizing system. The alternate control is a nonfollow-up type operated by means of a small lever on the right-hand side of the steering stand. Any one of these three steering methods, automatic, hand, or emergency nonfollow-up is instantly available to the helmsman without moving from his position by simply shifting the three-point selection lever on the left side of the steering stand. At the afterend of the ship, for operating the steering-gear hydraulic valve, are

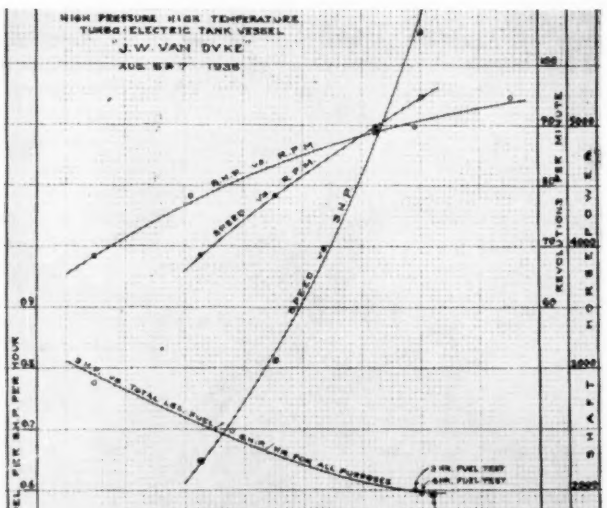

FIG. 12 PERFORMANCE CURVES FROM TESTS OF THE S.S. *J. W. Van Dyke*

two Sperry power units, one connected to the automatic and normal hand-steering control just described, and the other to the alternate nonfollow-up control. Each of these power units is connected on its output side to the hydraulic valve mechanism through a magnetic clutch operated by the selector lever on the bridge steering stand so that the unit not in use is disconnected.

In addition to the described steering controls from the bridge, the ship also has two emergency steering stations aft, one on the aft end of the poop deck house and the other on the poop deck close to the stern. The former is a mechanical rotating shaft control directly to the hydraulic valve on the steering gear and the latter is the usual hand gear operating directly on the rudder stock through spur and worm gearing and a quadrant.

Trial Results

General. On August 6 and 7, 1938, after having been in service about 5 months, the ship was put through a series of speed, horsepower, and fuel-consumption tests over a measured mile at the Delaware breakwater and off the Delaware capes. The results of the horsepower and speed tests are shown by the heavy curve in Fig. 1 and the performance curves in Fig. 12. Fig. 1 also shows the model-basin results. It can be seen that the ship-performance curve comes within the usual allowance of 12 to 15 per cent added to effective horsepower as obtained on the model, to allow for such effects as sea conditions. It should also be noted in this connection that the ship was fitted with bilge keels while the model was tested without them and the depth of water over the trial course was not as great as is generally considered desirable if speed is not to be affected. The empirical formula

$$\frac{10 \times \text{draft in ft} \times \text{speed in knots}}{\sqrt{(\text{ship length in ft})}}$$

gives a close approximation to the minimum desirable depth and, in the present case, the actual depth was about 60 to 70 per cent of the 180 ft given by this formula.

Minimum turning-radius tests were made both to port and to starboard at full speed and showed a diameter of turning circle of 0.47 nautical mile to port and 0.45 mile to starboard; the time to turn through 180 deg was 3.6 min in each case.

A test of the steering gear showed that, with the ship at full speed, in full-loaded condition, the helm could be put from hard-over to hard-over in 17.8 sec with a maximum load on one of the two 20-hp steering-gear motors of not much more than half its rated capacity.

With the ship in full-loaded condition and going full speed ahead, a full-speed-astern bell stopped her headway in 5.08 min in a distance of 0.40 nautical mile.

A similar test, in which the propulsion motor was stopped instead of being reversed, gave results in which the ship drifted for approximately 1 mile in 14.05 min before stopping.

Both of the last two tests were made against a moderate wind with a velocity of approximately 13 knots per hour and against a tidal current of possibly 1 knot per hr.

Power Plant. It was of course impractical to arrange for the measurement of every quantity and temperature throughout the entire steam and water cycles as indicated on the heat-balance diagram shown in Fig. 4, but boiler meters were provided, as was a recording and integrating flowmeter for the steam to the main turbine. Thermometers and pressure gages were installed at all important points so that it has been possible to determine fairly closely and without any unwarranted assumptions how close the actual results came to theoretical expectations.

Boilers. It was possible to determine the output and efficiency of the boilers quite closely. Fig. 13 shows the expected performance from which it will be noted that the boilers were designed to give an efficiency of 85.5 per cent at the rated load of 22,500 lb

per hr actual output at a pressure of 625 lb per sq in. and a temperature of 835 F; this corresponds to an equivalent evaporation of 26,260 lb per hr. During the trials, two fuel-test runs were made, one of 4 hr and one of 3 hr duration. During the first of these runs, the boilers were operated at a pressure of 620 lb per sq in. and a temperature of 855 F, producing 21,810 lb per hr each, or an equivalent evaporation of 25,100 lb per hr. The feed temperature was 351 F. The stack temperature was 324 F, CO_2 was 14.7 per cent, CO was 0, and oxygen 1.8 per cent. These results gave an efficiency of 86.6 per cent, a stack loss of 11.3 per cent and an unaccounted-for loss of 2.1 per cent.

The second run was at almost exactly the same rate and conditions, and showed an efficiency of 86.9 per cent with stack losses of 11.3 per cent and unaccounted-for losses of 1.8 per cent.

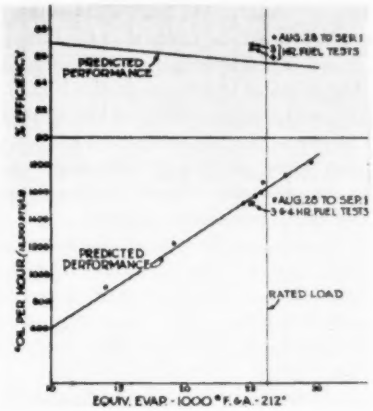

FIG. 13 BOILER-PERFORMANCE CURVES

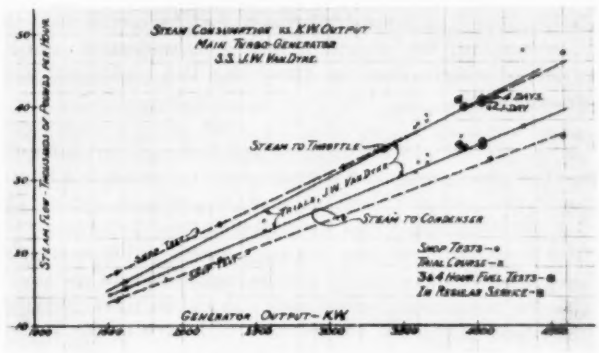

FIG. 14 STEAM CONSUMPTION VS. KILOWATT OUTPUT OF THE MAIN TURBOGENERATOR

Since these tests were made, the results under normal operating conditions have shown that these efficiencies are easily maintainable. Data taken from the log of the homeward (loaded) leg of voyage No. 12 show that an efficiency of 87.3 per cent was maintained for the four consecutive full days of this run. We believe that such efficiencies can only be obtained and maintained by the almost perfect combustion conditions made possible by automatic combustion control.

Turbogenerator. The performance characteristics of the main generator are shown by the curves in Fig. 14. The two pairs of curves show a comparison between the shop tests of the turbine and the trial results on the S.S. *J. W. Van Dyke*. In studying these curves, it should be borne in mind that the figures for the trial runs were taken over periods varying from 4 to 10 min and that the amount to the condenser was calculated from the amounts of stage bleed which in turn were calculated from the rise in feedwater temperature. However, there were sufficient data taken during the 3- and 4-hr fuel tests to permit determination of the generator performance during these runs and, in addition, points obtained by averaging the four full days of voyage No. 12 of the *Van Dyke*, as mentioned previously, are also shown. In view of the close agreement of all of these points, it is believed that the curves, as shown, are a fair representation of the turbine performance.

Table 4 gives a summary of expected results compared to those actually obtained. There are two columns under each heading, the first giving the pounds per hour, the second the amount of heat added or removed at each point in thousands of Btu per hr. Below these columns is also shown the shaft horsepower (by torsionmeter), the pounds of total steam generated for all purposes per hour per shaft horsepower, and the pounds of 19,000-Btu fuel oil used per shaft horsepower.

CONCLUSIONS

For the purpose of our conclusions, we are selecting from Table 4 the figures for four days of voyage No. 12, as we believe these to be the most accurate data. From these it will be noted that the consumptiom of fuel per shaft horsepower for propulsion is 0.511 lb and this figure is to be compared to 0.510 lb predicted; however, it can be seen from Table 4 that consumptions as low as 0.502 have been obtained. We, therefore, think it fair to say, in consideration of all the data, that the power plant in its entirety has met the economy of the design.

It will be particularly noted that in arriving at the foregoing figures from Table 4 the portion of the fuel required for auxiliaries has not been included. The reason for this is that, generally speaking, all quoted figures for engines and other types of prime movers are on a shaft-horsepower basis, due to the fact that no two owners have the same requirements for auxiliaries for a given type of vessel. Therefore, it would be misleading to compare unless we can compare like things, and so the foregoing fuel figures are based on the propulsion requirement only.

It is believed that the foregoing will reveal power-plant efficiencies not previously approached in this country in marine installations, and that when one considers the price differential between the fuel burned in these vessels and the fuel required by Diesel engines, there should no longer be controversy relative to the most efficient type of power for this size of power plant. It is altogether fitting that the results of the engineering disclosed in this paper be presented before this Society, because it is only an adaptation of well-known principles, designs, and developments previously published through the A.S.M.E. that have been applied here. It is the earnest wish of the author that more study be given and more interest shown in ship propulsion by A.S.M.E. members in the future, so that the latest developments in power-plant equipment may be available to the marine field.

ACKNOWLEDGMENTS

It is only fitting, at this time, that the author express his appreciation and admiration for Mr. J. W. Van Dyke, chairman of the board of The Atlantic Refining Company, for his extreme foresight in fathering this forward development, for his countless contributions to the engineering of these vessels, and for his continued patience and encouragement given the author; to Mr. R. C. Tuttle, manager of transportation of The Atlantic Refining Company, for his tolerance and cooperation; to the members of the engineering and construction department of The Atlantic Refining Company for their unfailing cooperation, loyalty, and devotion for the success of these ships; and to the suppliers of equipment, as a group, who have never tired of trying to make their equipment the best possible.

Discussion

E. G. Bailey.[2] The excellent performance of the tanker *J. W. Van Dyke* in regular service is a tribute to the farseeing and detailed research Mr. Goldsmith gave to every item in the power equipment of this vessel before the keel was laid.

In discussing the automatic control, the statement is made of the trials, "At low loads the boilers are on hand operation, hence the spread between the air-flow and steam-flow records." This was true at the time the steam-flow air-flow charts were made, but it has been standard practice for the last few months to continue on the automatic control when maneuvering in pilot waters, as well as in the open sea. The automatic control properly adjusts the fuel oil and air flow to meet the demand for steam. Burners are cut in and out for the major steps for large variations in steam demand, with the automatic control properly adjusting fuel and air within the oil-pressure range, which gives efficient atomization.

Mr. Goldsmith mentions the fact that one reason he selected the single vertical-pass gas-flow-type boiler was the entire absence of gas baffles which this design assures. Of equal importance from a maintenance and external corrosion point of view is the entire absence of shelves or ledges for soot to lodge. Any such ledges or other soot pockets are always potential fire or corrosion hazards with modern boiler-fuel oils with their frequently high sulphur content and minute particles of carbon which are frequently impossible to burn completely, even with relatively hot furnaces.

The use of air heaters as the medium for reducing the temperature of the gases well below that of the boiler tubes, not only assures desired high efficiencies with a minimum of high-pressure parts, but also is an important factor in providing optimum combustion conditions at all rates of operation.

The point is brought out in the paper that, with the type of boiler selected, prompt plugging or renewal of boiler tubes may be made without loss of ship's time waiting for a boiler to cool down enough for the drums to be entered. This is a particularly important feature in ships fitted with only two boilers, where the outage of one for a day or so may seriously affect the ship's ability to maintain her schedule.

Practical experience together with extensive tests and research work on both navy and merchant-marine installations have proved that, when burning bunker fuel oil, excessively low furnace-release rates have no commercial or thermal advantages. Mr. Goldsmith is to be congratulated in not handicapping his ship by utilizing excessively large furnaces under the boilers in the *J. W. Van Dyke*. The consistently excellent combustion results obtained in this installation serve to emphasize the commercial advantage of not wasting valuable floor and cubic space in the ship with unnecessarily large furnaces.

David Dasso.[3] The writer wishes to comment on the statement in the fifth paragraph, namely, "In other words, for horsepowers to 3000, the Diesel engine is an undeniably economical prime mover, but above that size, doubtful, especially in view of the advent of the high-pressure, high-temperature steam turbine." It is my belief the author is stating there the truth, the whole truth, and nothing but the truth, but only as applied to the steamship *J. W. Van Dyke*, operating on comparatively short runs between points in which cheap residual oils of the type called bunker fuels are available.

Beyond these restrictions, the author's statement is hardly in accordance with present-day experience. A large percentage of ship construction in all foreign countries is Diesel propelled. Many large navigation companies which previously bought nothing but steamers are buying more and more Diesel ships. There must be a reason why large Diesel ships in horsepowers ranging between 3000 and 30,000 are being ordered in increasing numbers. Are the purchasers making a mistake, according to Mr. Goldsmith's statement? They are not, and the reasons are fairly simple to elucidate.

The choice of the best type of propelling power depends on many factors. It is generally admitted today that the fuel consumption of an up-to-date Diesel plant does not exceed 0.38 lb per shp per hr, against a minimum under the best conditions of 0.5 lb per shp per hr for steam. While it is true that in some ports the steam vessel may avail itself of very cheap bunker fuel prices, this does not hold true for all ports of the world. Especially in the Far East, it will be found that the differential between the price of Diesel oil and the price of bunker oil is much less than it is on the Atlantic Coast and in the United States. The saving in fuel consumption in a vessel of the up-to-date type with a speed well in excess of that mentioned in this paper is very considerable and, taken on a run of 6000 miles or more gives to the motorship an additional freight-carrying capacity which in many cases makes this advantage decisive.

The best proof of this is the case of the large Dutch shipping companies which are building simultaneously steamships and Diesel ships, the former being allocated for medium runs between ports with favorable bunker-oil prices, and the latter for long runs between ports in which the differential in price between the two fuels is not great.

The foregoing conclusions have been affirmed in this country. Several years ago Robert L. Hague of the Standard Shipping Company, presented a paper[4] before The Society of Naval Architects and Marine Engineers discussing the subject in a similar manner. His conclusions were that, for service along the Atlantic Coast, the steamship was more economical, and for service in foreign waters the Diesel ship had been found more advantageous.

R. H. Davis.[5] In the design of any tanker, determining the type and arrangement of the cargo pumping system is a matter directly involved with the selection of the propulsive drive. The ideal condition from a fire- and explosion-hazard standpoint is a pump room, divorced from the engine room and located amidship, in which there are no wiring, electric current, or steam. With the pump room located amidship and no power available this immediately limits the selection of pumps to the vertical type, with the driving elements located on the upper deck.

The so-called deep-well type vertical centrifugal pump lends itself admirably to such an application. While a unit of such type had never been used previously for cargo pumping in a tanker of this size, it was selected in this case because of its many advantages.

The units are driven by 300-hp vertical explosion-proof motors, located on the upper deck, with the entire thrust load of the unit carried in the upper motor bearing, thus permitting complete freedom to the long length of intermediate shafting, cover pipe, and drop pipe. The pump bowls themselves are located at the bottom of the pump room in the so-called suction wells or boxes. The outside drop pipe is connected to these suction boxes through a flexible expansion joint, which also in-

[2] Vice-president, The Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

[4] "Performance of Standard Oil Tankers," by Robert L. Hague, Transactions of The Society of Naval Architects and Marine Engineers, New York, N. Y., vol. 40, 1932, pp. 357–368.

[5] Assistant manager, Marine Division, Worthington Pump and Machinery Corporation, Harrison, N. J.

corporates stops to prevent too great a movement. The drive shaft operates in a cover pipe which is filled with oil, supplied by an automatic lubricator above. The cargo flows between the cover pipe and the outside drop pipe and is discharged at the deck above. The lower portion of the drop pipe and cover pipe is made in the form of a split section so that the pump may be inspected or dismantled, if necessary, without disturbing the intermediate shafting above.

The important element in the ability of a ship to discharge its cargo rapidly is the method of stripping the tanks. In the case of the *J. W. Van Dyke*, no separate stripping pumps are used and yet this ship, together with its sister ship, the S.S. *Robert H. Colley* has established a record that never before has even been approached in the unloading time of a vessel of this size. The main cargo pumps are used as stripping pumps with the aid of vacuum priming pumps, which are connected to the suction boxes and so arranged that the cargo pumps are always completely primed regardless of the amount of air pulled through from the tanks. It can therefore be seen that the rate of stripping the tanks is greatly increased and the time required for stripping becomes a small proportion of the entire pumping period. Not only is the stripping time greatly reduced but this method produces amazingly dry tanks.

The characteristics of these main cargo pumps are such that the capacity increases with slight reductions in the head, in much the same manner as the conventional centrifugal pump with a relatively flat capacity-head curve, except that this capacity-head curve rises rapidly as it approaches shutoff. The shape of the brake-horsepower curve is such that it increases in practically a straight line until it reaches a maximum just before the design condition and then falls off rapidly at the outer end of the curve, thus providing an ideal horsepower characteristic for a unit which is called upon, not only to pump cargo, but to handle salt water during ballasting periods at relatively low heads. The units are powered to provide ample margin for any peak horsepowers when these units are used for ballasting when handling salt water.

The pump room is also equipped with a small 160-gpm unit of the same type as the main cargo pumps for bilge service, driven by a 3-hp motor on the deck above.

In connection with the feed system, it is interesting to note that the deaerating marine feedwater heater installed has made it possible to operate this vessel under all sea conditions with practically zero oxygen content at the feedwater as obtained by tests. This unit not only acts as a feedwater heater and deaerator, but provides approximately 2500 gal storage capacity.

E. H. Markley.[6] The writer's comments will be confined to the condensing plant which has some unusual features and which has had an excellent performance record. When the power plant of the S.S. *Van Dyke* was considered, the owners did not issue definite or detailed specifications for the condensing plant. The condenser manufacturer was requested to submit his recommendations on the best possible plant to meet the operating conditions, with the understanding that the final design would be determined after owner and condenser builder had studied all of the conditions; efficiency, reliability, space, weight, details of ship design, etc. The idea was to install the plant best suited to the operating requirements and the machinery to be served by the condenser. Results have proved the effectiveness and soundness of this cooperation.

As Mr. Goldsmith mentioned, the main condenser is of the divided type, having a total surface of 4475 sq ft, rated at a capacity of 35,900 lb at 28.44 in. vacuum, when circulated with 6775 gpm of cooling water at an inlet temperature of 76.8 F. It will be noted that these proportions take advantage of the benefits secured from the patented deaerator in that a 7.5 fps water velocity through the tubes, with its attendant economies, could be selected without fear of abnormal tube corrosion or erosion. So far there has been no sign of tube corrosion or erosion on the *J. W. Van Dyke*, which certainly justifies the installation of the deaerator. Another result of the use of the deaerator is that all condenser tubes are filled with solid water, thus raising the over-all heat-transferring capacity of the condenser.

It should be mentioned that the condenser tubes incorporate inlets belled into a hydraulic radius; water boxes are streamlined and proportioned for direct flow at exceedingly low velocities.

Another interesting point, particularly as it affects spare parts, is that the condenser-tube diameter and length are the same for the main and auxiliary condensers. The main and auxiliary air ejectors employ the same size elements.

Recognizing that a frequent and preventable cause of poor vacuum is air leakage into the condenser, the owner took precautions to prevent such leakage. The condenser is bolted directly to the turbine exhaust flange without an expansion joint, thus eliminating one vacuum joint. The expansion strains are taken up by providing a spring mounting for the condenser. Air ejectors are located on the condensers adjacent to the air offtake connections, thus eliminating the customary long air-suction pipe with its multiplicity of vacuum joints.

The benefits, derived from the careful engineering consideration given the problems surrounding the condenser installation, are evident in the following performance data which are average for one of the latest voyages: Steam load, lb per hr, 34,600; vacuum, in. Hg, referred to 30-in. barometer, 28.6; sea temperature, 76 F.

J. J. Nelis.[7] While this ship is an example of many progressive hull and engineering developments, there are some features of its power plant that differ from many of our newer ships. It has the highest pressure and temperature in the American merchant marine. The United States Navy is using approximately the same pressures and temperatures in some of its new ships. As regards pressure and temperature, the marine man is naturally conservative, as his equipment is confined in a small space, where failure of the pressure parts will endanger human life. That is one of the reasons why he has been slow to install high pressures and temperatures.

The straight-tube-type boiler, installed on this ship, has been in use for a great many years, both ashore and afloat. In the new ships now being built for the American merchant marine and for the Navy, more than 80 per cent of all the boilers installed and on order are of the bent-tube type as this type fits into the limited space conditions aboard ship to better advantage than the straight-tube type. The final-stage feedwater heater of the countercurrent flow type, commonly called an economizer for want of a better description, has also been installed on over 80 per cent of the new merchant-marine and naval vessels. The arrangement of the boiler room in this ship, requiring several frame spaces which could be used for additional cargo space, is different from other recent American tankers, where the boilers are placed aft of the turbines on a flat, thus saving the fore-and-aft space required for a separate boiler room.

Bent-tube boilers, coupled with economizer installations recently installed in new merchant and naval vessels, have shown stack temperatures averaging close to 280 F. These average

[6] Engineer in charge, Condenser Department, Ingersoll-Rand Company, Phillipsburg, N. J.

[7] Vice-president, Marine Department, Foster Wheeler Corporation, New York, N. Y. Mem. A.S.M.E.

temperatures are lower than on the few new ships fitted with air heaters. There is an increase of nearly 2 per cent in the boiler efficiency, due to the lower stack temperatures with economizer-fitted boilers.

Modern ships are fitted with closed feed cycles which give an air-free feed. With rolled-tube condensers and air-free feedwater, few, if any, boiler repairs are required in the newer vessels. The bent-tube boiler eliminates the necessity for long repair periods, as it has only two gasketed joints for the manhole plates, as against the many small gasketed joints of the straight-tube-type boiler.

The boiler shown gives a liberation rate of 66,000 Btu per cu ft of furnace volume at full power. It would be interesting to learn what the Btu release is when the ship is washing holds at sea. In many modern tankers of from 3000 to 4000 shp, when cleaning the holds at sea, the steam required for cleaning tanks is equal to that for the power plant. Consequently, the Btu release in the furnace is then more than double the full-power conditions, due to a slight drop in boiler efficiency at the higher ratings.

With a straight-tube boiler and convection superheater to obtain superheat control requires considerable extra control equipment and a desuperheater in the drum. Marine drums are necessarily small. It is desirable to provide adequate superheat control without a drum desuperheater. A straight-line temperature curve may be obtained with the by-pass as shown in the paper, but a control of superheat at any temperature above saturation can be obtained without the complications of the desuperheater and the extra piping shown.

It is desirable to bring a marine turbine into service with a minimum temperature rise and to increase the temperature as the turbine is slowly warmed up. This requires complete superheat control which is now being used on other tankers.

In addition to complete superheat control, combustion control is now becoming standard on American ships. The new wide range oil burners, coming into use in conjunction with combustion control, give a steady efficiency without manual oil-burner operation both at sea, when maneuvering, coming in and leaving port, and when lying at the dock in port. Combustion control at sea is not so important on a ship as in a land plant, as a ship is essentially a base-load plant when at sea, the variation in steam demand being minor changes in some of the small auxiliaries. Many ships at sea are operating just as efficiently without combustion control as with it on account of their steady base-load conditions.

In connection with combustion, it is not necessary to design furnaces for high temperature to burn the fuel, particularly in marine work where the average fuel is oil having about 12 per cent hydrogen. Marine furnaces are small and instead of being heated by additional heat from the air heaters, they require cooling. In this case, the air is heated and additional heating surface is installed in the sides of the furnaces for cooling which is hardly logical.

There may be maneuvering and other advantages in an electric-drive arrangement. An interesting comparison of the heat-balance data, Table 4, of the paper can be had with that of a paper entitled "Heat Balance Calculations for Marine Steam Plants," presented at the 1938 annual meeting of The Society of Naval Architects and Marine Engineers, by A. S. Thaeler and D. C. MacMillan, where for approximately the same steam pressure and temperature, practically an equal fuel rate per shaft horsepower is shown with a mechanical gear drive and the same general heat balance.

The condensing system has several unique features. The air-removal chamber is new and may do the work expected of it. A well-designed marine condenser, having 70–30 per cent cupronickel tubes, properly designed water boxes, inlet and outlet piping, will operate without serious air corrosion for many years, if not for the life of the ship. The division of the condenser is an idea that has been tried many times and, for ships operating in tropic waters, has considerable value. It is not installed in many ships and has not yet become standard in marine practice.

In the past, marine operating engineers have seldom been technically trained men, but more of the mechanic class. Today with living conditions aboard ship greatly improved and with high-pressure, high-temperature, high-efficiency plants demanding expert attention, engineers of ability, many of them college-trained, have been attracted to the merchant-marine service. Eventually we may expect the staffs of our ships to be composed of high-grade engineers. Time only will tell which of the new and progressive ideas tried out in this ship are important enough to become standard in the future. There are other tankers recently built incorporating progressive ideas and for the pressures and temperatures used give a comparable fuel consumption per shaft horsepower. Comparisons of this with other new developments will in the end lead to better marine power plants.

MASON S. NOYES.[8] The extent of the engineering information in this paper is considerable and of great interest and value to those who are concerned with similar design work on government vessels.

The most notable items in the design are: (*a*) The slight step-up in average sea speed over present United States practice; (*b*) the selection of electrical speed reduction in place of the customary mechanical method between turbine and propeller; (*c*) the very short discharge period permitted for the ship's cargo; (*d*) the use of motor-driven cargo pumps; and (*e*) the employment of main steam conditions which, although no longer unusual for power plants ashore, are quite beyond the ordinary in present-day merchant vessels. Only in the merchant fleet of the progressive Germans can be found equal or higher steam conditions utilized for new ships.

Nevertheless, the boilers reflect conservatism, as well as the dictates of maintenance cost and time indicated by the author. The heat release, presently available in reliable marine boilers under the same steaming conditions, is several times larger than that quoted for the boilers on the *J. W. Van Dyke*. The $^{3}/_{4}$-in. (or more) thickness of the main steam piping seems definitely excessive and provides an element of danger. Such stiff piping imposes higher expansion thrusts on boiler and turbine connections, unless a more extensive piping arrangement is used to increase flexibility to the proper degree. The resulting low stresses reduce the creep rate below the neutral (or flat) value so that actually a decreasing creep rate may exist. Information is requested as to whether any "cold-spring" or pull-up was used in installing the main steam piping. What type of gasket and what gasket material were used? What is the actual pressure drop between superheater outlet and the main turbine?

The use of 2300-v cargo-pump motors is noted, together with the means provided to replace the usual stripping pumps and piping and to protect the 2300-v cables along the weather-deck gangway. Were any other special precautions taken to protect such cables from the effects of free water?

In his conclusion, the author mentions the very low fuel consumption obtained. This is due to the excellence of the heat-balance arrangement in rejecting the minimum amount of heat to the sea and to the high efficiency of the machinery items selected. Unfortunately, Table 5 does not give complete data, so that the exact extent of motor-driven units is not revealed. On the other hand, the effects of an advanced steam pressure and temperature

[8] Engineer, Design Division, Bureau of Engineering, Navy Department, Washington, D. C. Mem. A.S.M.E.

are reflected in the low machinery weights and spaces and the correspondingly high deadweight displacement ratio.

H. L. Seward.[9] With the experience of the author and his organization in high-temperature, high-pressure apparatus ashore, it was no extraordinary effort for them to decide to use the steam conditions, standard apparatus, and modern designs, which make these tankers so important and commendable at this time. Economy is important but dependability is more important in these vehicles, which are but a part of the machinery and equipment necessary to carry on the principal business of the company.

Those of us, whose sea experience goes back to the days when almost all of the auxiliary pumps were beam-connected onto the main engine, recall what an event it was when we got under way and started the main engine with its attached boiler feed pumps, air pump, and bilge pumps. On these tankers with a central electric-generating plant, the application of power to the propeller motor is but an incident in operation no more to be considered than the application of power to the cargo pumps or other ship's services. Aboard one of these vessels for a short trip, the writer noticed many details of design which deserve favorable comment, although not all were mentioned in the paper: Accessibility of machinery for inspection and repair; quarters for officers and men; location and type of electric cables; location of cargo-pump motors and controls; release of entrained air in circulating water; position of all motor starters on a high and protected level in the engine room; in addition to the well-known Btu savers, described in the paper, which if misapplied, may save some thermal units at the expense of over-all cost. With three fourths of the total weight of the loaded vessel as pay load, the marine industry will appreciate the achievement made in design and should watch the operating results of the next few years with great interest.

W. F. Schultz.[10] The marine industry is particularly interested in this paper, since the author not only has described in much detail the machinery installation but has also presented the highly important propulsive-design information which, in the case of privately owned ships, is somewhat rare. It is noted that, in comparing the propulsive performance predicted by the Hamburg tank, and that by the Washington tank, there is considerable divergence, although the predicted power-revolution curves are practically coincident for both tanks, and with the actual ship performance on trial. It is noted that the actual ship shaft horsepower is about 16 per cent higher than the Washington tank prediction at the designed speed of 13¼ knots. This is not unusual since the trial course off the Delaware capes is not as suitable for comparing model test data with actual ship performance as is the Rockland course. It is probable that sea and wind conditions together with depth of water and the effects of current have increased the power requirements above ideal trial conditions.

In discussing the power plant, however, there is considerable difference of opinion as to the most economical installation possible, and it is in this connection that the writer wishes to discuss the paper.

The author is to be commended for his selection of steam conditions. It is the first instance in which an American-built merchant ship has been fitted with steam pressures and temperatures above 400 lb and 750 F. These conditions are even somewhat unusual in shore plants in the same power range, although there are several. To the progressive engineer, however, the attractive features of higher pressures and temperatures make such adaptation worth while. It may be interesting to consider the economies possible through their use.

Table 6 gives a brief summary of the pertinent features of four hypothetical installations, each having different steam conditions; and each progressively higher. In this case the installation is for 6000 shp, employing multistage feed heating, all-electric auxiliaries, double-reduction-geared turbines, and boilers fitted with air heaters and economizers. An attached generator, driven from one of the low-speed pinions, furnishes the electric power for sea operation, similar to the equipment fitted in fourteen ships built by the company with which the writer is associated.

TABLE 6 SUMMARY OF STEAM CONDITIONS, TYPICAL PLANTS

Installation	A	B	C	D
Pressure, superheater outlet lb per sq in., gage	460	600	900	1200
Temperature F, superheater outlet	750	850	900	950
Feed temperature F, economizer inlet	318	332	365	400
Feed heaters, number of stages	3	3	3	4
Steam flow to condenser, ratio	1.0	0.91	0.83	0.80
Boiler heat output, ratio	1.0	0.97	0.91	0.88
Fuel, lb per shp per hr, all purposes	0.588	0.568	0.534	0.517
Fuel rate, ratio	1.0	0.967	0.908	0.88

It will be noted that the machinery installation on the *J. W. Van Dyke* is in some respects similar to installation B (Table 6). There are, however, differences that make comparison with this installation somewhat difficult. Therefore, the writer has prepared Table 7, showing the differences between an installation similar to B and that of the *Van Dyke*. Both plants have the same steam conditions and will deliver the same shaft horsepower, but for the proposed installation the writer has made certain substitutions.

The main propulsion machinery is of the cross-compound turbine double-reduction-geared type, without attached generator. The boiler plant consists of two 2-drum units fitted with air heaters and economizers. The feed system is of the three-stage type, with surface-type heaters and deaerating-type surge tank. The main feed pump is electric-motor-driven, as are the feed-heater drain and booster pumps. The electrical load requirements are provided for in two 350-kw, 230-v, d-c generators, one of which will carry the normal sea load at about 50 per cent rating. The two units would be sufficient for cargo pumping requirements in port. A contaminated steam system is included similar in design and purpose to that of the *Van Dyke*.

Based on the information given in the paper, the estimated fuel rate for 5000 shp, based on 19,000 Btu oil, is 0.596 lb per ship per hr for all purposes. Service performance has proved the author's estimates to be very accurate, speaking well for his own ability, and for the reliability of information from the suppliers of his machinery.

We are accustomed to base our performance on 18,500 Btu oil, which is a fair average value for the fuel supplied today. Referred to this value the fuel rate of the *Van Dyke* is about 0.612 lb per shp, say 0.61 lb per shp per hr for average service conditions.

Comparing this performance with an installation similar to B in Table 6, we find that a gain in economy of approximately 7.5 per cent is possible. Analyzing this gain, it is found that the reasons are generally as set forth in Table 7.

In explaining the apparent reasons for the increased economy, noted in Table 7, the writer wishes to discuss the various principal items of machinery in their order of importance.

The cross-compound turbine, as furnished by the principal machinery builders, either impulse or combined impulse-reaction

[b] Estimated from test data given in paper.
[c] Effect of operating ship auxiliaries at sea from main propulsion unit.

type lends itself particularly well to obtaining relatively higher efficiencies than the single-cylinder unit such as used on the *J. W. Van Dyke*. Higher speeds are possible, smaller shafts and smaller-diameter wheels can be used, thus reducing internal friction and bearing losses, and generally lighter units are possible. In the paper, the weight of the main propulsion unit, complete, is 211,000 lb. Recent 6000-shp turbine proposals for cross-compound 18-stage double-reduction-geared units varied from 174,000 to 180,000 lb, a saving in weight of more than 30,000 lb. It is obvious of course, that this difference in weight would indicate a substantial reduction in cost. This difference is more pronounced based on the evaluated cost, in consideration of efficiency due to higher speeds and greater number of stages. It should be noted, however, that the reduction gears proposed were of the modern single-case type, and not the extremely heavy three-case type of five years ago.

A modern double-reduction gear of the single-case type, with two bearing pinions, and tooth pressures of the order of 60 lb per in. of face per in. of pinion diameter will give a mechanical efficiency of not less than 97.25 per cent and in most cases 97.5 per cent or better, as compared with a combined efficiency of from 93 to 93.5 per cent for generators and propulsion motor. In addition, the space required for the geared-turbine unit is less than that of the electric drive for the same power.

In discussing boilers, the writer will not attempt to criticize the type used. It is generally a matter of opinion as to the type best suited for the purpose. However, it is believed that an economizer in combination with the air heater may have been used to advantage and the efficiency raised to 88 per cent, at a relatively low increase in cost, and with no appreciable increase in weight.

It is the writer's opinion that wider use of the completely water-cooled furnace, as is rather common practice in shore power plants, will prove of considerable economy to the marine field. The elimination of brickwork, especially in furnaces designed for high rates of heat release, will reduce furnace maintenance to a minimum.

The author is to be congratulated on the method of temperature control applied in this installation. It is believed to be superior to other forms, and lends itself particularly well to shipboard use. We have contemplated a similar arrangement for use in high-temperature installations for desuperheating steam to the astern turbines during maneuvering. We have introduced feedwater into the main steam line for this purpose in the past, but this method is relatively crude compared with the excellent arrangement used on the *Van Dyke*. By this method, the one principal disadvantage of the geared-turbine installation may be overcome without great difficulty.

The application of automatic combustion control is of great interest. The writer fully concurs with the author that the use of higher pressures and temperatures will further increase the use of this equipment beyond its growing application today. It is now possible to obtain from at least two sources in this country, a wide-range oil burner that will greatly augment the value of the controls for all-purpose operation. A recent installation in a tanker provides us with a very instructive case in point; the ship was able to get under way, maneuver, drop anchor, and perform all the necessary tasks including docking without use of towboats, with all burners in use and under full automatic control.

Concerning the type of current used by auxiliary drive, the author had available the main propulsion generator for supplying power at sea and, with the selection of this type of drive, the best arrangement would be the simplest, namely, alternating current at a standard voltage. However, with geared turbine drive it is believed that direct current is more suitable since the problem of speed regulation is relatively simple. It is questionable in my mind, when the cost of the controls necessary to provide speed regulation for fuel and feed pumps, forced-draft fans, and cargo pumps is included with motor costs, whether there is any appreciable difference in cost. The space required by a-c controls is considerable and would probably minimize the gain in space inherent with smaller sized alternating current motors.

Among the interesting features of this ship are the cargo-pumping arrangements. Excellent judgment has been used in adopting explosion-proof motors, since tanker practice requires the ultimate in safety. This ship is engaged in the gasoline trade and handles great quantities of this fluid at high pumping rates, requiring extreme care. All the demands of this service seem to have been amply met. It would be interesting to obtain the author's reaction to having this same type of pump installed in the pump room below decks, and providing forced ventilation from fans on the deck, with elevated intakes.

Author's Closure

In his comments Mr. Bailey has referred to the combustion-control features of the *Van Dyke*. The record of the use of the automatic combustion control on this vessel followed exactly the predictions made for it. At first it was only used when under full or nearly full load and not in pilot waters. The next step was to leave the fuel under automatic control at all times and to regulate the air supply by hand at low loads or when maneuvering. As stated by Mr. Bailey, the automatic control is now used at all times but, at low loads or when maneuvering, the air flow is set up to avoid the possibility of smoking when the load is suddenly increased.

In reply to Mr. Dasso, the author's ideas as to the relative merits of turbine versus Diesel drive are obviously based on the conditions which he has to meet. He agrees that for other conditions the selection might have been different. It should be noted, however, that, using Mr. Dasso's figures, the ratio of fuel consumptions of turbine versus Diesel machinery is 1.32 to 1, whereas the ratio of fuel cost of Diesel to bunker C oil at present varies from 1.6 to 2.07 to 1, which is a fairly wide margin in favor of steam. It should be borne in mind also that the European preference for the Diesel is to some extent due to the fact that most of the shops and shipyards abroad are unable to build modern high-pressure, high-temperature turbines. Also it is an easier step for an engineer who has been trained on a reciprocating steam engine to change over to the Diesel type.

Mr. Nelis refers to the wide adoption of the bent-tube boiler in new merchant and naval vessels in the United States. In the author's case the lighter header-type, straight-tube boilers enable more cargo to be carried than if multidrum, bent-tube-type boilers were installed, regardless of space arrangement. This is due to the fact that, while the *Van Dyke* has a tank capacity for 18,600 tons of 60 deg Bé gasoline, the cargo allowed is only 17,125 tons with a deadweight tonnage of 18,105.

Clean and uncorroded boilers are admittedly possible with proper feed preparation but this cannot always be assured, as witnessed by the recent difficulties with the boilers of a modern tanker, which might have been avoided if the tubes could have been inspected. No difficulty has been experienced in keeping

handhole covers tight. It is the author's belief that there is but slight difference in the number of gasketed joints between a header-type boiler with an air heater and a bent-tube boiler with an economizer.

The relative boiler efficiencies obtainable with an economizer as compared to an air heater depend entirely upon the size of the air heater. On a number of recent ships, stack temperatures as low as 280 F have been obtained with air heaters. During the fuel-consumption trials, the stack temperature on the *Van Dyke* averaged 323 F. In this connection it should be noted that a gain in boiler efficiency may be made at the cost of a greater loss in over-all efficiency, as is witnessed by the figures given in the paper by A. S. Thaeler and D. C. MacMillan, to which Mr. Nelis refers. It will be noted that columns A and C in Fig. 5 of that paper compare almost identical setups, except that the boiler of column A has an economizer only, with a feed temperature of 235 F. In contrast the boiler of column C has an air heater and an economizer which permits three heating stages instead of two with a feed temperature of 300 F, resulting in a fuel reduction of 110 bbl per hr, or 2.3 per cent.

The heat-liberation rate in the *Van Dyke* boilers (66,000 Btu per cu ft per hr) is extremely conservative in the light of present practice (note Mr. Noyes's comments). Even if doubled it would still be well under what has proved to be possible. This, of course, depends on the burners used and the arrangement of the combustion space and surrounding cooling surfaces. In general, it is not the combustion space but the capacity of the downcomers which limits the capacity of a boiler.

With regard to superheat control, the author fails to see that there is essentially any greater complication in controlling a by-pass valve to the desuperheating coil than there is in controlling another oil burner.

No difficulty has been experienced in obtaining all necessary control of steam temperature when starting the turbines on the *Van Dyke* cold.

It is agreed that, for perfectly steady loads, it is theoretically possible to operate efficiently without automatic control. Evidently this generally is not done, since as Mr. Nelis states: "Combustion control is now becoming standard on American ships."

The author is in agreement with Mr. Noyes, concerning the excessive thickness of steam piping, but is happy to say that the Bureau of Marine Inspection and Navigation has recently issued a ruling which will permit advantage to be taken of the higher creep strength of carbon-molybdenum tubing on the third ship now under construction. In this case the thickness of the 5-in. main will be reduced from $^3/_4$ in. to $^1/_2$ in., approximately.

In answer to specific questions by Mr. Noyes, the following information is given:

Piping was "cold sprung," approximately 50 per cent of the expansion.

Gaskets were originally of soft (Armco) iron, but these were found to be unsatisfactory due to the temperature changes incident to shutting down at weekly intervals. "Flexitallic" gaskets have successfully replaced the solid soft iron.

The pressure drop from superheater outlets to turbine throttle is 10 to 15 lb at full load.

Cables of 2300 v on the catwalk are 106,000 cir mils with 2400-v lead and armored, basket-weave marine insulation. They are fastened to the inner surface of the catwalk side by lead-covered brass clips and covered by a brass housing bolted to the side panels.

Table 2, given in discussion by Mr. Schultz, compares a hypothetical power plant with that on the *Van Dyke* and shows a gain of 7.6 per cent in efficiency, partly due to the assumption that higher turbine and boiler efficiencies might be obtained. This is no doubt possible but the author's original investigations, preparatory to selecting the equipment for the *Van Dyke*, led to the conclusion that the extra cost of so doing would n t be justified in a plant of this size. The remaining gain is based on the higher transmission efficiency of a gear drive. Granting this gain to be possible, it was felt that the advantages of the electric drive, as outlined in the paper, more than offset this difference. However, it may be noted in passing that the oil coolers generally specified for geared installations have capacity to remove a heat equivalent of more than 5 per cent of the rated power of the unit.

Regarding Mr. Schultz' request for the author's reaction to the use of deep-well cargo pumps, having vertical motors below decks with forced ventilation, it is that this greatly increases the fire hazard, requires the added cost and complication of forced ventilation, considerably increases the work of the pumper, and only gains a reduction in the length of the shaft and cover pipe, which hardly seems worth while.

Rollcurve Gears

By H. E. GOLBER,[1] CHICAGO, ILL.

In automatic machinery the movements of the various bodies are usually obtained from the motion of a follower compelled by a driver. The driver is usually assumed to rotate at a uniform speed and the follower is given some definite motion, ordinarily a definite rotation. When the follower motion is to be a rotation at uniform speed, the driver and follower are usually connected by ordinary circular gears. When the follower motion is to be a rotation of nonuniform speed, elliptical gears are sometimes used. When the follower is to move in a more complicated manner, all kinds of devices, such as cams or planetary levers, are used. Very frequently the designer does not know of any means for producing the desired follower motion. Therefore, he is compelled to use an undesirable motion which he knows how to produce, and abandons what he considers the best.

This article discusses rollcurve gears. It shows that by using such gears, the follower can be given practically any desired motion, thereby enabling the designer to produce the follower motion desired and obtain the best condition in the new machine. The article first illustrates actual rollcurve gears installed and in use on actual machines. It discusses their durability and applicability, and gives a short history of some of them. This is to assure anyone that these gears are reliable and that their production is practical.

The article next shows the production of the "speedgraf," which is a standard method developed by the author to make the desired method perfectly definite. It is then shown how to convert the speedgraf into rollcurves which may then be drawn and tested on the drawing board. The rollcurves can then be used to obtain patterns for the gear blanks. These gear blanks then have the teeth cut into them, converting them into a pair of gears. When the driver moves at uniform speed, the follower moves in the desired motion. The result is positive and reliable.

Certain features that occur in connection with the rollcurve gears are explained. Also, to show the broad applicability of the gears, a few speedgrafs, for which gears have already been made, are shown and are commented upon.

THIS article is submitted by the A.S.M.E. Graphic Arts Division because the subject matter was developed in connection with the design of printing machinery and the applications shown are upon printing presses. However, the subject is really one of applied mechanics and is equally applicable to all classes of automatic machinery.

This article deals with means and methods for producing motions that hitherto have been either impossible or impractical. The motions now capable of production are of the greatest variety; they are produced by means that the writer calls "rollcurve" gears.

Years ago it was possible to design spur gears the axes space of which was standard. The pitch diameter of the spur gear was always the number of teeth divided by the diametral pitch. If the designer were asked to make a nonstandard axes space or nonstandard pitch diameter, he would be in trouble. Finally, however, there was introduced the hobbing machine and the Fellows gear shaper, with which the designer can readily make gears before thought to be impossible. For instance, the author has made three coaxial gears, one with 8 teeth, a second with 10 teeth, and a third with 12 teeth, all simultaneously geared with a common rack. The previous cramping limitations have vanished.

Again in bevel gears, previously the two axes had to intersect and could not pass each other. Now with hypoid gears the axes may pass each other. The cramping limitations have vanished.

Similarly, designers have made use of cams and roller arms. For a reciprocating irregular motion, of say 30 deg, there was no trouble. For a reciprocating motion of, say, 90 or 180 deg, auxiliary mechanism had to be introduced. For irregular continuous rotation the difficulties were large and so the designer avoided them. It will be found that in the rollcurve gears, these cramping limitations are gone, and the designer is able to produce in a simple and positive manner almost any motion desired, regular or irregular. The possibility of design has automatically vastly expanded.

A rollcurve gear is one that has a rather uncommon rolling curve as its pitch line. In ordinary spur and annular gears, the pitch lines are rolling circles. Also gears have been made with ellipses as their rollcurves. Some suggestions have been made to use equiangular spirals as rollcurves. The most extensive treatment of the subject known to the author is the one by Robinson,[2] who gives a rough method to find the mating rollcurve to any given rollcurve. So, to a given rotation of the first, the second must rotate in a definite manner. No attempt is made in that book[2] to treat the accelerations, velocities, or displacements of the driver and follower.

About 1931 the author developed some methods for making rollcurve gears, and they were applied in practice. His method was not derived from any previous method, although at places there necessarily must be some resemblance since the subject "rollcurve gears" is the subject in common.

The basic difference between say Robinson's methods[2] and the author's is that Robinson assumed one rollcurve and then tried to find the other, while the author first assumed the motion of both the driver and follower and then found the pair of rollcurves at once. Robinson thus obtained a motion of the follower

[1] Research Engineer, Miehle Printing Press & Manufacturing Company. Mr. Golber was graduated from the University of Chicago in 1896, and was a Fellow in mathematics and chemistry at that University from 1896 to 1899. He was employed with the Standard Oil Company for one year, with the Wahl Company for 19 years, with the Riterite Company for five years, and has been associated with the Miehle Company for the last 15 years. He has been the recipient of the Octave Chanute Medal of the Western Society of Engineers, and of the John Scott Legacy Medal of The Franklin Institute.

Contributed by the Graphic Arts Division and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] "Principles of Mechanism," by S. W. Robinson, John Wiley & Sons, Inc., New York, N. Y., 1910.

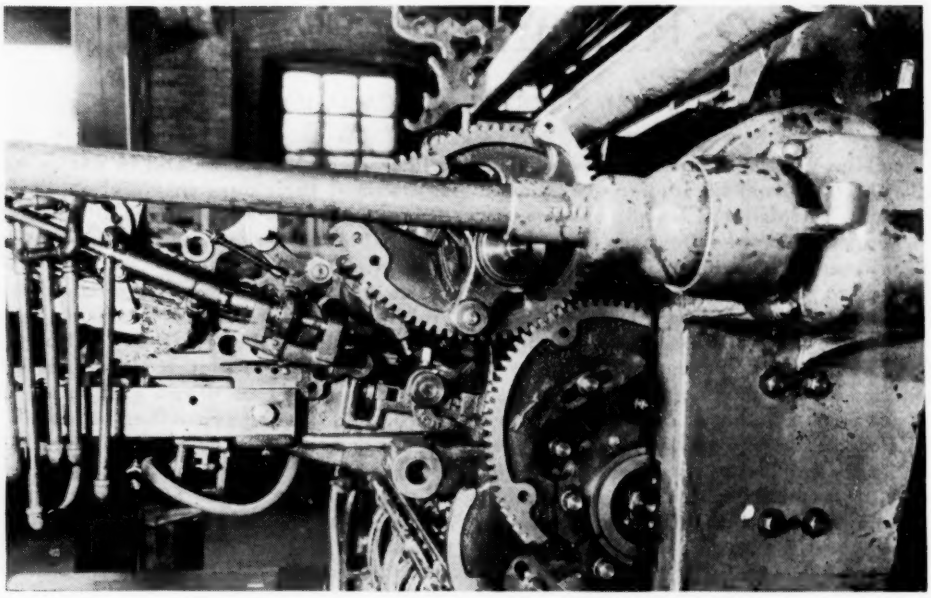

FIG. 1 THE FIRST ROLLCURVE GEARS

which depended on the properties of the assumed rollcurve. The author started with the desired motions and thereby made the rollcurves depend upon the motions. The result was that Robinson used well-known curves, say the circle, the ellipse, and the equiangular spiral. His curves were simple but his motions were complex. The author uses the circle and curves that have no names as yet. He thus obtained unusual curves, but his motions are simple. The simplicity of the motions has allowed them to be used extensively in machinery.

Observe the various illustrations of rollcurve gears. Some of them show the gears mounted upon and forming parts of machines. All are of gears for actual machines, not for models or experimental mechanisms. Many sets of gears have been made, installed, and used. They are still in use.

Immediately the questions arise: (1) How long have they been used? (2) How well do they wear? (3) How costly are they to manufacture? (4) Where should they be used? The answers in the order asked are as follows:

(1) The earliest pair was built about 1931. It is still in use. (2) They wear about the same as other gears made of similar material, cast iron or bronze. As yet there have been no replacements. (3) A first pair of gears is rather costly. They can then be reproduced quite commercially. (4) Where shall they be used? This must be left to the judgment of the designing engineer. Here he might take into consideration that by these gears, he has a tremendous broadening of the possibilities of design. He is able to produce in a positive simple manner practically any motion. Motions that otherwise are impossible or very difficult are easily made by rollcurve gears. Moreover he is able to reduce the number of links in the driver-follower chain, and thus reduce backlashes and improve register.

The author is continually called upon for more and more new rollcurve gears desired by the firm where the gears were first used. Some calls have also come in from outside.

CONSTRUCTION OF THE GEARS

We start with the driver and the follower. How these are to move depends of course on what they are to do in the machine. We assume that the designing engineer knows what he wishes to accomplish. From his knowledge he finally produces a description of the desired motion of both the driver and follower. This description the writer always finally reduces to a designer's "speedgraf."

Speedgraf. In books on kinematics we find various diagrams called "displacement diagram," "velocity diagram," and "acceleration diagram." The author refers to these as "sitegraf," "speedgraf," and "celgraf," respectively. Of these the speedgraf (or velocity diagram) is much more useful than the others and in practice he finds it is sufficient for his needs. Only very seldom does he need some additional diagrams.

In various books he has seen given a displacement diagram for the follower displacement, a velocity diagram for the follower speeds, and an acceleration diagram for the follower acceleration. Three diagrams are given. With very little training the engineer can obtain all this information at one glance upon the speedgraf only, and he needs no others. Thus looking at the speedgraf the observer finds the follower displacements, as the areas by the speedgraf; the follower velocities, as the ordinates of the speedgraf; the follower accelerations, as the slopes of the speedgraf; and the follower impulse, as the bent of the speedgraf.

From now on we shall consider the speedgraf as the fundamental graph—the start is with the "designer's speedgraf."

Speedgraf Segments. If the pair of gears is a pair of ordinary circular gears, the speedgraf is a line parallel to the speed-line zero. This is usually a horizontal line. Thus a horizontal line represents uniform rotation for both the driver and follower. When the speedgraf line is above the zero line, the driver and follower rotate in opposite directions as in a pair of spur gears. When the speedgraf line coincides with the zero line, the follower rests or dwells. When the speedgraf line is horizontal but below the zero line, the follower and driver rotate in the same direction.

It is usually assumed that the driver rotates at a uniform speed. The follower rotates at the speed and in the direction desired. When the follower speed changes, its speedgraf curve is not a horizontal. When the speedgraf curve is an oblique (straight line), the speed changes at a uniform rate. The follower motion then is like the motion of a body falling under gravity.

At first, each speedgraf was made as a polygon of oblique and horizontal lines. By such a polygon, varying motions and uni-

form motions were very nicely represented in a simple manner. But every cusp or point of the polygon spoiled the smoothness of the motion and caused trouble, first in the making of the gears and later in the finished machine itself. As these troubles were serious, they will be gone into more fully.

It was found that every speedgraf cusp produced a corresponding rollcurve gear cusp. This can be readily seen from Fig. 1. This pair of rollcurve gears is the first chronologically, being built early in 1931. The upper gear is the follower; the lower gear is the driver. The gears were made out of pieces of elliptic gears fastened together. Note that the follower gear segments are in several planes. The driver segments are similarly arranged but are covered over.

Note the rollers on the follower. One is clearly in sight, while the other at the top is half hidden. To cooperate with them is a cam, only part of which is visible at the lower left.

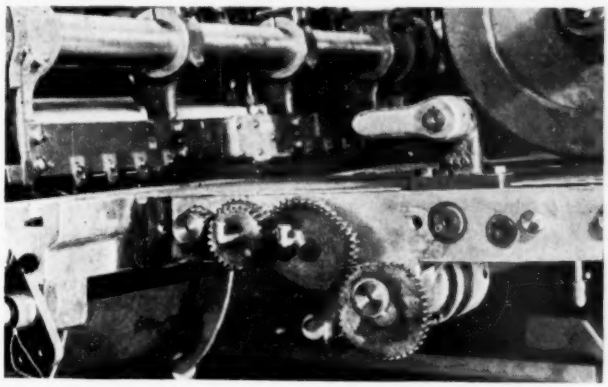

FIG. 2 TWO SMALL CONTINUOUS ROLLCURVE GEARS

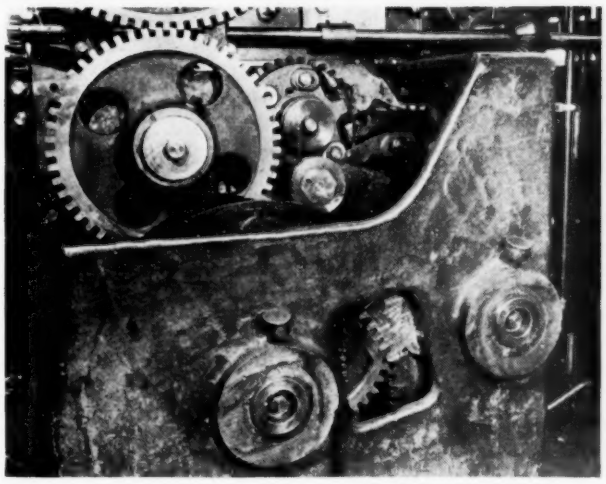

FIG. 3 ROLLCURVE GEARS, THE DRIVER AND FOLLOWER OF WHICH HAVE A CONVEX AND CONCAVE CUSP, RESPECTIVELY

This pair of gears was made before the development of the speedgraf method. In fact, it was the difficulties encountered in this pair that drove the writer to the consideration of the speedgraf and finally to the development to be described.

As the next example, consider Fig. 2. Here the two little gears are continuous and all in one plane. They are made of bronze cast with the teeth. The lower right gear is the driver. Each gear has three cusps. This spoiled the continuity of the gear rollcurve, making the cutting of the original master gears quite

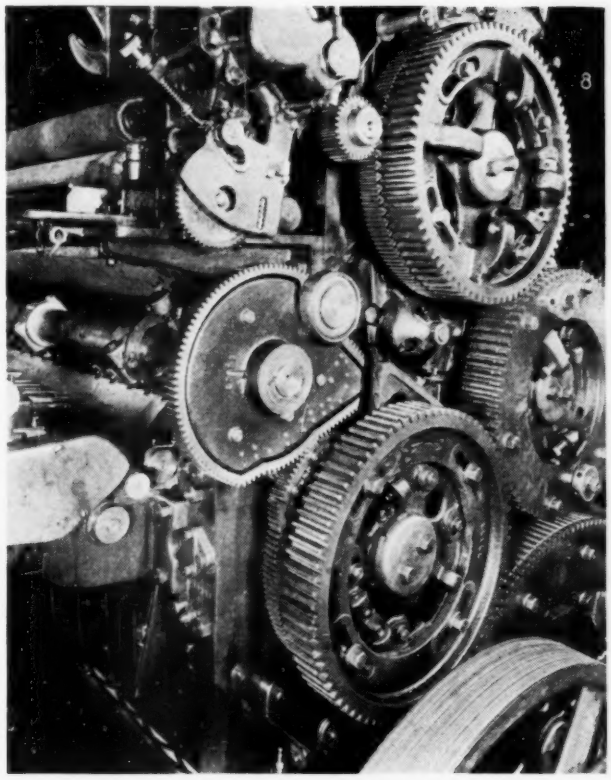

FIG. 4 ROLLCURVE GEARS, THE TEETH OF WHICH ARE ALL IN THE SAME PLANE

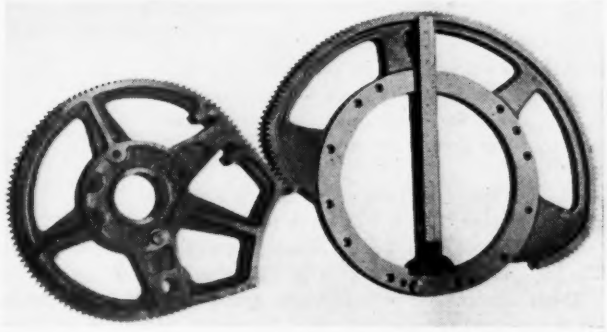

FIG. 5 ROLLCURVE GEARS WITH CUSPS ELIMINATED WHICH PERMITTED THE GEARS TO BE CUT WITH A FELLOWS CUTTER

difficult. These gears were by far the smallest, being about 3 in. in the axes space.

As the next example, consider Fig. 3. Here most of the mechanism is invisible but a portion of the driver (at the left) and the follower (at the right) are visible through the window. Note that the driver has a convex cusp and the follower a corresponding concave cusp. Here is also seen that the apex of the convex cusp has a gear space and the apex of the concave cusp has a gear tooth. This rule was found to be indispensable. Note that the follower had to be built in pieces to permit the cutting of the gear teeth. The mechanism was strong and heavy, the teeth having diametral pitch of four.

We next come to Fig. 4, in which the follower is very prominent. A portion of the driver is visible and in mesh with the follower. Note that the follower rollers have been very much

enlarged. The gear segments are still made in different pieces fastened together. However, unlike Fig. 1, the teeth are all in one plane. The teeth of the driver and follower have a pitch of eight, the big gears have a diameter of 20 inches and a pitch of four. Fig. 4 shows that the driver has quite a hump.

This was the last pair of rollcurve gears to be built in that manner. Strenuous efforts had been made to devise some scheme for the elimination of the cusps, so that teeth could be cut continuously. This was finally done successfully and the

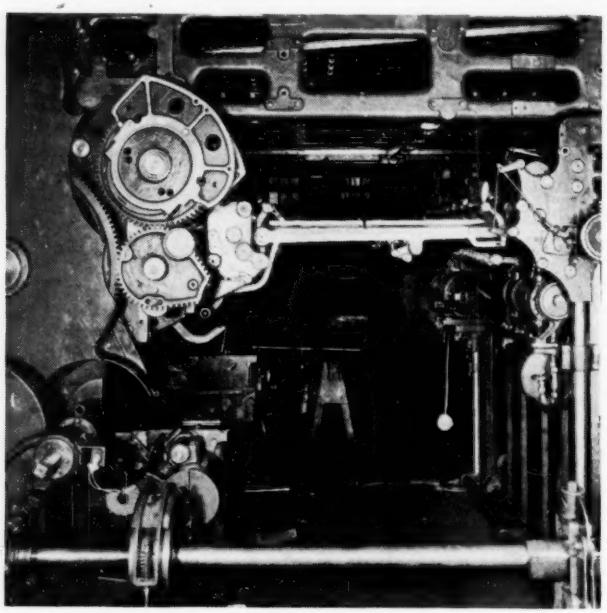

FIG. 6 LARGE ROLLCURVE GEAR

gears henceforth were cut by a single Fellows gear shaper cutter. As an example, see Fig. 5. The cusps are gone, the gears are continuous all in one plane, and easily manufactured. Moreover they are accurately machined, say to 0.001 in.

There is really nothing more that is novel to show; however, Fig. 6 will serve to exhibit the extent of the use of such gears in a large machine. The big gear at the left is 36 in. in diameter.

These illustrations will serve to prove that rollcurve gears are in practical commercial use. Moreover, attention must be called to the fact that each machine shown was not an individual machine but one of a line of machines marketed.

Returning now to the speedgraf and its cusps. One reason for objecting to cusps is the consequent cuspiness of the rollcurves, and resultant difficulty in making the gears. There are, however, other objections. Thus, upon examining the speedgraf at a cusp, we see that the slope or grade suddenly changes. That is, the acceleration suddenly changes. Now machines are assumed to be built of rigid material, say, cast iron. But there is no material absolutely rigid. Every body bends when forces are applied to it. Assuming Hooke's law that "strain is proportional to stress," then every body in a machine bends an amount proportional to the stress on it. As in a machine, the forces are proportional to the square of the machine speed; therefore, in a machine the bends of the bodies are proportional to the square of the machine speed times acceleration. At every speedgraf cusp, the theoretical bending of the bodies have two different bendings corresponding to the different grades. It frequently happened that the bodies were springy and bent sufficiently to cause a misplacement of the parts, and at high speed the machine "knocked" and did not "register." All these troubles were cured by eliminating the speedgraf cusps.

So the speedgraf polygon cusp was rounded over by a filleting arc. Here many choices could be made for the arc. It could be a portion of a circle, an ellipse, an harmonic, or a parabola. The choice finally fell upon a parabola with a vertical axis. This was because in computation it was simpler to deal with a parabola, than with a circle. True, in drawing, the circle was easier, but the parabola was never drawn except very roughly. The vertical parabola won out and is the filleting curve now used.

To summarize the foregoing, the speedgraf curves used are: (1) The horizontal straight line for uniform motion of the follower; (2) the oblique for nonuniform motion; and (3) the vertical parabola either U or $\cap$ for uncusping the speedgraf. How these are to be combined depends of course on the machine needs and the designer's best judgment. The final result is the designer's speedgraf.

Designer's Speedgraf. The designer's speedgraf takes many shapes. Fig. 7 shows a comparatively simple one. Here we see that the speedgraf is $ABCDEFGH$. As this is a full cycle, A and H are the same point. The speed-line zero is $A_0B_0C_0D_0E_0F_0G_0H_0$, so $A = A_0$, $B = B_0$, $G = G_0$, $H = H_0$. In the speedgraf, AB and GH show speed zero, the portion $G(H=A)B$ showing a follower dwell. The horizontal DE shows a follower uniform rotation in a direction opposite to the driver. The obliques BC and FG show follower increasing and decreasing speeds. The curves CD and EF are parts of a $\cap$ parabola. The points D and E are therefore vertices of the parabolic arcs.

To show that the speedgraf covers a complete cycle, the column of zone angles is given. The total $AH = 360.0000000$ deg. The column of ordinates is given, having been determined in some manner by the designer. There are other items, such

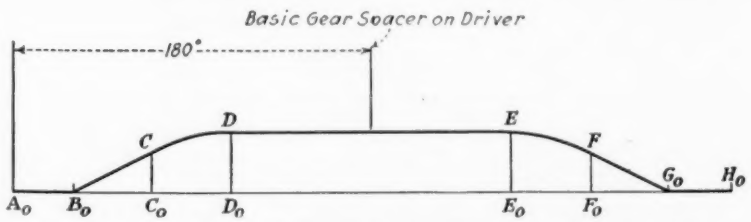

FIG. 7 DESIGNER'S SPEEDGRAF FOR A GRIPPER DRIVE

A_0B_0	= 29.6388885 deg	A_0A	= 0
B_0C_0	= 40.0000000 deg	B_0B	= 0

Roller cam equal steps = 1 deg

as 180 deg = basic gear space on driver, which are also given.

As the drive part $GHAB$ is a dwell, it is necessary to provide for it in some manner. For it, a follower tooth would have to be kept at the center of the driver axle, and this would be very unsatisfactory for several reasons. Therefore, the dwell part is made not by rollcurve gears, but by cams and roller arms. Moreover, the gear portions on BC near B, and on FG near G, are not satisfactory because they unmesh, and so the cam drive is made to extend and cover the unsatisfactory parts of BC and

FG. The required data for the cam drive are given in the lower column.

It has been stated previously that all cusps are to be removed from the speedgraf and yet there are two left, *B* and *G*. But these two occur not on the gear portion but the cam portion, and the follower speed is very low. In some speedgrafs even the speed-zero cusps are rounded out.

The designer might have been very careful. But did he make a mistake in his computation? To some extent this can be tested from the data given and implied. It was understood that while the driver made a complete rotation, so did the follower. The driver rotated uniformly and made 360 deg per machine cycle. The follower rotated always in the same direction while starting, speeding up, speeding, slowing down, or resting. But in one machine cycle it also made 360 deg. We have already stated that in a speedgraf the area represents the displacement. For the driver the area would be 360 deg $\times$ 1 = 360 deg. For the follower, the cycle displacement must be the area by the speedgraf or the area *ABCDEFGH*, which we see is equal to the values given in Table 1.

The result for the follower area we call the area angle. It should be exactly 360 deg. It is 360.0000008 deg. We assume the agreement to be accurate enough; that is, the follower rotates once for every rotation of the driver. Our first check is satisfied.

The above accuracy seems to be silly. But as we proceed, the errors that occur, because of the inability of the author to integrate accurately for the length of the arcs, reduce the above from ten significant figures to seven, which is about right to make rollcurve gears correct to 0.001 in. on an axes space of 36 in.

We next examine the tangencies. The grade at *C* of *BC*, and the grade at *C* of *CD*, must be the same. The grade at *C* of *BC* is

$$\frac{C_0C}{B_0C_0} = \frac{1.00628931}{40.0000000} = 0.0251572327$$

The grade at *C* of *CD* is

$$\frac{D_0D - C_0C}{(1/2)C_0D_0} = \frac{1.50943396 - 1.00628931}{(1/2) \times 40.0000000} = 0.0251572325$$

Again the agreement is close enough.

At *D* the parabola is tangent; similarly at *E*. We see also that *F* is symmetric with *C*. Thus far the speedgraf checks. We assume that it is correct in all details.

The Rollcurves

Having now an accepted and tested speedgraf, the next step is to obtain the rollcurves. In Fig. 8 let *C* and *F* be the driver and follower axes, respectively, with the rollcurves *V* and *W* contacting at their tangent point on the axes line *FD*. Let *r* and *R* be the driver and follower "rays," respectively. Note the word used is "rays" and not "radius," the latter term being limited to the distance from the center of a circle. Let $d\theta$ and dw be the respective small rotations of the rollcurves. Then

$$r + R = DF = L = \text{axes space} \quad [1]$$

and because of rolling

$$r\,d\theta = R\,dw \quad [2]$$

From Equation [2] we obtain

$$\frac{dw}{d\theta} = \frac{r}{R} \quad [3]$$

However

$$\frac{dw}{d\theta} = \frac{\text{speed of follower}}{\text{speed of driver}} = \text{speedgraf ordinate}$$

Therefore, we obtain Equation [1] ($r + R = L$), and

$$r/R = \text{speedgraf ordinate} = S \quad [4]$$

Combining Equations [1] and [4], we obtain

$$r = \frac{LS}{1 + S} \quad [5]$$

and

$$R = \frac{L}{1 + S} \quad [6]$$

As *L* is the axes space for the two gears it is a known constant. And as the speedgraf is known, *S* is known for every value of θ or for every driver displacement. We can therefore find as many different values of *S* as may be required. In a drawing, the angles θ are usually taken say every 5 deg. In computation for machine work, θ is taken for every 2 deg for gears say up to 10-in. axes space and for every 1 deg for larger gears.

The computation of *S* for every θ, of course, varies in the various segments of the speedgraf. In *AB* and *GH* the *S* is 0.0. In *DE*, *S* is constant. In the oblique *BC* it is equal to $(CC_0/B_0C_0) \times$ abscissa, measured from B_0. Similarly in the oblique *FG* it is equal to $(F_0F/F_0G_0) \times$ abscissa, measured back from G_0. In the parabolas *CD* and *EF* we use a computation as in a body falling under gravity.

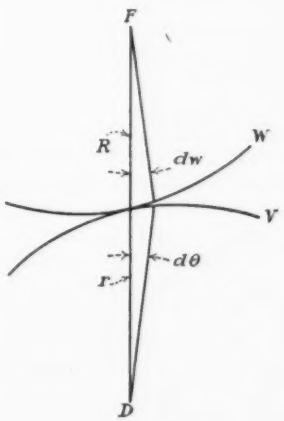

Fig. 8

We thus finally have the *S* value for every θ value and make a table for every θ, say from degree to degree.

Driver Rollcurve. We can now substitute in Equation [5] and obtain the value of the rollcurve ray for every θ. This gives the driver rollcurve mathematically accurate. The angle θ varies by equal angular steps.

Follower Rollcurve. By substituting in Equation [6] we obtain the set of follower rays corresponding to the follower sites for the driver places. The driver steps are equal. The follower steps usually are not equal and must be computed. These steps, of course, correspond to the corresponding area obtained by the speedgraf. We see that in the speedgraf the follower steps *AB* and *GH* are equal to zero. In *DE* they are constant. In *BC* and *FG* the areas

are easily obtained as they are the areas of trapeziums. In CD and EF they are the areas by parabolic arcs, and can be computed say by Simpson's formula.

Thus, finally for every driver angle θ, there is found a corresponding angle w for the follower. This combined with R of Equation [6] gives the polar coordinates of the follower rollcurve.

Production of the Driver and Follower Blanks

Patterns and rough castings can be made from drawings made from the values previously computed herein. When it comes to accurate machining the shop facilities must be taken into account. The most direct method would be to use a turntable capable of being rotated and set to 0.001 deg. The ray length can then be measured to 0.0001 in. and a hole with a definite radius be bored. This would give a blank with a series of holes whose centers are exactly on the rollcurve.

In the establishment with which the author is associated there is no machine kept up to do the accurate boring as just outlined. There is, however, a very accurate jig boring machine with slides at right angles and it is kept in fine condition. Therefore, the polar coordinates previously obtained for the driver and follower rollcurves are now converted into rectangular coordinates. These are used on the jig borer and the rollcurve blanks are bored with centers exactly on the rollcurves.

Thus, by one machine and polar coordinates, or by another machine and rectangular coordinates, a first pair of blanks are obtained. The boring is carefully done and then the ridges between borings are filed off. A careful workman leaves very faint marks showing the bottoms of the original borings. This filed master will be called master cam No. 1. It is smaller than the rollcurve by the radius of the bore, or master cam No. 1 = rollcurve — bore radius of master cam No. 1.

The master cam No. 1 is now mounted on a cam reproducing machine. Of these, there is an excellent one in the shop. It really reproduces a cam. From master cam No. 1, by means of a proper sized roller and cutter, there is now produced master cam No. 2 whose periphery coincides with the rollcurve. Similarly by another operation on the same machine, there is produced a gear blank for the actual rollcurve gear. It has the addendum of the teeth added thereto.

For another set of gears, only a new gear blank has to be machined. Master cams Nos. 1 and 2 serve for all sets.

A similar procedure is now gone through for the follower rollcurve, and its master cam No. 1, and its rollcurve or master cam No. 2 are produced. From these as many blanks as desired with the teeth addenda added are milled out.

Computation of Arc Length

At first, attempts were made to approximate the rollcurves by circle arcs and to cut the teeth as circular segments. Here great difficulties were encountered. The approximations were made on the drawing board and it was immediately found that to obtain any acceptable result, the drawings had to be larger than natural. And there always was danger. It was very easy to go outside of the rollcurve and obtain a jam, or to go too far inside of the rollcurve and obtain undesired backlash. Finally, the author, discouraged with his ill success on the drawing board to obtain usable circle approximations, attacked the problem mathematically, and evolved the method now used.

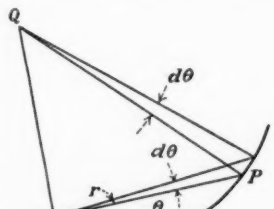

Fig. 9

In Fig. 9, let P be a point of a curve (rollcurve). Let $OP = r$, $AOP = \theta$. Let OQ be perpendicular to the ray OP, and PQ be a normal to the curve at P. Then PQ will be called the norm, and OQ the rayper(pendicular). In this place we call OQ the rayper, as being a short, expressive term.

We know from differential calculus that when θ is measured in radians (not degrees), dr and $rd\theta$ represent the ray increments along its length and transversely, respectively. This results immediately in the equation $dr/d\theta = OQ$. Moreover, the length of the arc, say AP is obtained thus

$$\text{arc } AP = \int_0^\theta \sqrt{(OP)^2 + (OQ)^2}\, d\theta = \int_0^\theta PQ d\theta$$

As the rollcurve AP was obtained from the speedgraf, and as the speedgraf was composed of horizontals, obliques, and parabolas, it seemed hopeful to obtain the polar equations of AP and to integrate for the length AP. There was no difficulty in obtaining the polar equations. The integration for the length of arc was something else. The horizontal segments gave simple integrals, the obliques gave elliptic integrals, and the fillet parabolas gave hyperelliptic integrals.

The author devoted much time to the study of the computation of elliptic and hyperelliptic integrals In this connection the best book he knows is "Simplification of Integrals," by Söderblom.[3] It is the best but is not simple enough. Therefore, the author was driven to the standard methods of approximation and used the well-known formulas, namely the Simpson $^1/_3$, the Simpson $^3/_8$, and the Weddle. These are given in various books.[4] Using these he was able to obtain the approximate values of the arcs. By computing first with the Simpson formula and then with Weddle's the author was able to make a check on the accuracy of the results. Making the original computations on a ten-place computing machine, his Simpson and Weddle results agreed to seven significant figures. These he assumed to be accurate. Moreover, they proved so in practice.

In this manner he obtained the length of the rollcurve arc of the driver from one step to another, say from degree to degree. As the lengths of the rollcurve arcs are the same for both driver and follower, he thus obtained also the length of the follower arc for degree to degree of the driver (not the follower). A table of the driver degrees and rollcurve arc lengths was then made.

The next was to select some satisfactory diametral pitch for the teeth of the rollcurve gears. This, of course, had already been done long ago when the proper addenda were added to the rollcurves to make the gear blanks. In practice the little gears in Fig. 2 had a diametral pitch of 16. For the bigger gears, there were used 8 pitch, 6 pitch, and 4 pitch, $14^1/_2$-deg involutes.

When the diametral pitch P was known, the pitch arc was known as $\frac{\pi}{P}$ and could be used as a measure to determine the number of pitch arcs.

Look again at Fig. 7. It shows the basic gear space on the driver. The start was therefore given, and all the other pitch points could be located therefrom.

Gage Points

Not all the pitch points were necessary. Only a few were required and the rest were derived from them. These were called the gage points and they had to be computed. These gage points almost never came at an exact step of the driver angle so did not fit in the table of arc lengths that had been computed. However, as the exact location of the gage points was required, the exact driver angle was computed by inverse interpolation.

PEARSON QUADRATIC

After spending a considerable time experimenting with various interpolation formulas, the author selected the Pearson quadratic as being the most suitable for this work. It can be found in "Tracts for Computers," No. 2, University of London, 1920. It is the simplest he knows of, for both direct and inverse interpolation. Moreover, both Simpson and Weddle formulas can be derived from it.

By means of the quadratic, all interpolations were made, and finally the ray lengths and ray angles were converted into rectangular coordinates by means of trigonometric tables. The values were then entered on the detail drawings.

CUTTING OF TEETH

It has been stated that a Fellows gear shaper cutter was used to cut the teeth on the gears. This was done by making a special machine in which the master cam No. 2, already described, was used. As a roller for it, rolled around the master, the cutter shaped out the teeth of the gear blank.

It was soon found that sometimes the roller had to be increased or decreased in diameter. Here the gage points came in. The cutting was started at the start gage point. If the finish gage point were hit accurately, it would be assumed that the intermediate points were correct. In practice it always worked well enough.

This first gear cut was seldom used in the drive. It was installed in the gear-cutting machine. In it then rolled a toothed circular gear, nonrotatable with the Fellows cutter. All subsequent gears were thus "fellowsed" without the possibility of slipping.

Refer now to Fig. 5. Note that the gears are both cut off. This was usually done at a place where the ray-norm-angle (of both the driver and follower) was 45 deg. If the angle were larger, the gears would unmesh. The complete drive for the speedgraf was thus unfinished. The drive for the gap was made by two cams on the driver and two rollers on the follower. These are seen in several of the gear illustrations. However, the making of roller cams for a given drive is nothing new and so it is not gone into further.

As it has been stated before that by means of the rollcurve gears almost any desired motion of the follower may be obtained for example, the author adds Fig. 10 showing a more complicated speedgraf. In making the rollcurve gears therefrom the work was slightly more extensive but no new principles were encountered.

Also, finally, the author shows an even more complicated speedgraf Fig. 11. Here the cusp J was in the cam part, not in the rollcurve gear part. Moreover, the designer checked both the driver and follower angles himself.

The foregoing gives a general description of the subject. In practice it was necessary to systematize it, and to reduce it to a method that could be used say by an intelligent high-school graduate. The details of this, however, would require an article much larger than the space taken herein, and it has been thought that sufficient has been given for the present.

Discussion

J. W. HUCKERT.[5] Spur gears having pitch curves other than circles have been in demand for a long time. One obstacle is the mathematics. It is too complicated for practical use. The rectification of the noncircular curves, as the author points out, involves elliptic and hyperelliptic integrals, and much labor is required to evaluate them either by the methods of the calculus or by the methods of approximation. If the methods of the author are simple enough so that he can compute the chordal thicknesses of all the teeth on a rollcurve gear, it may be enlightening to compare the theoretical against the measured thicknesses as a check on the spacing of the teeth.

In order to have accurate spacing of the teeth, the angular-speed ratios proper between the tool and the blank must be maintained throughout the generation of the gear. It is doubtful whether the author has met this requirement so that gears may be generated which will be suitable for all classes of machinery. In the ordinary setup of the Fellow's gear-shaper, the tool and the blank are positively rotated with respect to each other by means of a gear train. The author replaces this gear train with a friction drive during the cutting of the first gear. If slippage occurs, the spacing of the teeth on the first gear cannot be accurate. Since the first gear is employed in the drive between the tool and the blank during the cutting of subsequent gears, its

[5] Associate Professor of Mechanical Engineering, University of Maryland, College Park, Md. Mem. A.S.M.E.

inaccuracies will be reflected in all the others. Maybe accuracy in spacing is not necessary on gears for printing machinery. Neither is it so important on gears for agricultural, textile, and wrapping machinery. However, accuracy of spacing is important on gears for high-speed machinery and for machine tools, where not only the total angular displacements but also the instantaneous angular speeds must be preserved.

A. L. Ruiz.[6] This paper presents the practical aspects of a topic the writer has examined at various times in the past from a theoretical point of view. The investigations were never carried through to the stage of constructing noncircular gears, principally because of lack of an immediate application. It was with interest therefore, that the writer read the author's exposition of his method of manufacturing rollcurve gears. It is requested that the author explain further certain points and an alternative method of using these gears under certain circumstances is proposed.

With regard to cutting rollcurve gears on the Fellow's gear-shaping machine, it is rather clear that the cutter is moved in and out with respect to the blank by means of a roller bearing on a master cam. It is not so clear to the writer how the proper rotations of the cutter and the blank are obtained. In cutting the first of a particular type rollcurve gear, it appears that the cutter alone is rotated, and this, as it cuts into the blank, causes it to rotate. When one successful gear has been produced, it is used in the machine with a proper-size gear to cause succeeding blanks to rotate at a definite variable rate with respect to the cutter. Is this interpretation of the process correct?

Mention was made in the paper of the calculation of arc lengths of the rolling curves for the determination of gage points. Is this calculation extended to determine the size of the rolling curves so that an integral number of teeth is obtained in a complete circumference of each gear?

The author is apparently interested primarily in using the rollcurve gears to obtain a variable rotational velocity from a constant rotational velocity. With what degree of accuracy do the gears produce the velocity for which they were designed? For other applications one might be interested in obtaining a variable position of the follower shaft as a function of the position of the driving shaft. To what accuracy do rollcurve gears perform this service? The problem of backlash is of prime importance in any system designed to reproduce positions. This was touched on during the verbal discussion of the paper at the Annual Meeting. At that time the author stated that his rollcurve gears had backlash which increased as the ray-norm angle increased, although no magnitudes were given. The thought immediately arises as to whether methods for reducing the backlash have been tried, such as, decreasing the center distances of the gears, or using slightly enlarged blanks, or cutting thicker teeth.

The paper states that for low velocity ratios or for zero velocity of the follower gear, roller cams were used; the curved gears were designed to unmesh at a proper place, at which point the roller cam assumed the duty of transmitting the variable rotary motion. It would appear that the design and manufacturing requirements for constructing cams and gears so as to give a smooth transition with a minimum of lost motion would be rather fussy. The writer suggests the following scheme as a possible antidote for these difficulties.

Assume the designer wishes to construct a pair of rollcurve gears for a speedgraf some of whose ordinates are zero or negative. Add a constant to each ordinate so chosen that the entire speedgraf becomes positive. All ordinates may then be scaled down in proportion so that the area under the graph will be 360 deg. If the constants have been chosen properly, a pair of rollcurve gears may be constructed for this resulting speedgraf. For this pair of gears, as the driver is rotated at a constant velocity, the follower never reverses, but always rotates in a direction opposite to that of the driver, with a velocity which varies between predetermined maximum and minimum values. Then, connect the driving gear and the following gear together differentially with some form of planetary gearing, so that a portion of the driver velocity is subtracted from the follower velocity. If the gear ratios are chosen properly, the output of the differential will rotate at a velocity proportional to the ordinates of the original speedgraf. (Adding a constant to every ordinate of the speedgraf means adding a constant to the velocity of the follower gear at each point. This constant velocity is subtracted out by the planetary gearing.) The advantage of this method of construction is that the roller cam could be eliminated. The motion would be transmitted entirely by rollcurve gears and straight gearing, with a probable decrease in lost motion and an increase in smoothness of operation.

Author's Closure

The author wishes to clear up some questions asked in the oral discussion of the paper at the time of its presentation. One was in reference to the backlash where the ray-norm angle is increased. The author answered that the backlash was increased. Somehow this answer led some to the idea that thereby a good deal of backlash was introduced. This is a false conclusion. If the gear is cut with a backlash of 0.0000 in. where the ray-norm angle is 0, and with similar accuracy at other places, then the backlash would be 0.0000 in. everywhere even at 45 deg. If the backlash were, say, 0.001 in. where the ray-norm angle is 0, then when the angle is 45 deg (at the limit) the backlash would be only $\sqrt{2} \times 0.001$ or 0.001414 in. The author's meticulous truthfulness and accuracy seem to have misled the listeners. For all practical purposes there is no backlash at all, anywhere. In ordinary spur gears, we work with backlash of, say, from 0.000 to 0.010 in. The rollcurve gears have been made equally tight.

A second point raised at the meeting was that in the rollcurve gear, the line of pressure of the gear tooth changes all the time and, therefore, the theory cannot be right. However, in cycloidal gears, the line of action is not straight and nevertheless the action is correct. The same is true with rollcurve gears.

The third point raised at the meeting was that the use of a friction drive at one point, obviously made the process inaccurate so that it could not be exact. Here of course the question arises as to what is meant by "exact." Must gears be correct in every dimension to an accuracy of 0.000001 in. before they are called *exact?* If so, then these rollcurve gears are not exact. But there never has been any exact gear made by anybody at any time in this world so far as the author knows. In commercial spur gears in the chord over, say, five teeth, the variations will amount to say 0.005 in., and the rollcurve gears are equally accurate.

The author does not know of any better test than by the accurate fitting of the plug in the predetermined space of the rollcurve gear, giving a location to the plug accurate in both abscissa and ordinate. It is actually correct to about 0.0005 in. and that is close enough for even the fine work such as is required for printing presses.

Professor Huckert states "Maybe accuracy of spacing is not necessary . . . . . on gears for printing machinery." Actually, printing presses require an accuracy of spacing that is beyond the commercial output of even the best of machine gear cutters. The teeth have to be corrected as by the Maag gear-tooth grinder.

The author does not understand the meaning of ". . . where not

only the total angular displacements but also the instantaneous angular speeds must be preserved." The author always assumed that if the angular displacements are always right, the instantaneous angular speeds must always be right. In any case in so far as the rollcurve gears are concerned, both the instantaneous angular displacements and also the instantaneous angular speeds are always preserved.

That the mathematics is "too complicated for practical use" raises quite a discussion. It would be spendid to find simpler mathematics for the solution of the problem. The author does not know any simpler. The fact remains, however, that it is being used by the Miehle Company to make gears on their lines of printing presses. If that is not practical use, what is?

Mr. Ruiz seems to have concluded that the rollcurve gears are cut on a Fellows gear shaper. They are not. The author nowhere said so. He did say that a Fellows gear-shaper cutter was used. The gears are cut on a special machine designed for the purpose, which it would take far too long to attempt to describe.

Complete gears, with an integral number of teeth, have been made, as in Fig. 2, and are being made regularly. There are now cuspless, continuous rollcurve gears, driving each other as desired. There is no difficulty.

It is true that the author described the driver rollcurve gear as rotating at a uniform rate, and the follower as having a predetermined variable rate. But this is simply a mathematical convenience. After the gears, have been cut and meshed, then obviously the driver may be moved and at any rate, constant or variable.

Again Mr. Ruiz also raises the question of accuracy. The gears are machined to 0.001 or 0.002 in. on the rollcurve arc and they perform their function to this degree of accuracy. No special means for decreasing the backlash is required since, when desired, the gears are cut to run metal to metal without backlash.

Mr. Ruiz intimates that it is difficult to make the node cams join the gears smoothly. "It must be a fussy job." It is a commercial job, as the line of machinery marketed by the firm shows. It gives a fine job with a minimum of backlash.

Mr. Ruiz inquires whether by the use of an auxiliary planetary gear, it would not be possible to produce a dwell and even a negative rotation. Certainly it would be possible, but the author abandoned that idea because in his opinion it would introduce not a minimum of backlash but an increased backlash. Moreover the machine, Fig. 3, produced both positive and negative rotations of the follower. To accomplish this result an intermediate (but not planetary) gear was used, and is being used today.

Moreover, when the gears need to be on a dwell in printing-press work, there should be a dwell and not a constant quiver.

Finally, the author does not doubt that improvements can be made in the mathematics and in the method of cutting. He himself has shown that it is both possible and practical to produce rollcurve gears. He assumes this is but the beginning and sees no reason why rollcurve gears should not become quite common.

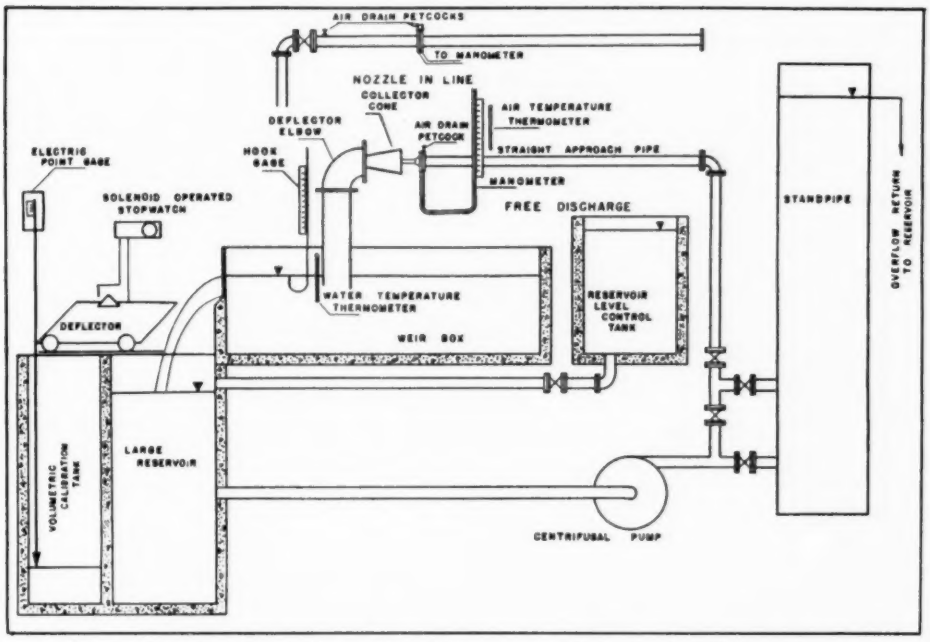

FIG. 1 ARRANGEMENT OF TEST EQUIPMENT AT THE UNIVERSITY OF CALIFORNIA FOR THE CALIBRATION OF NOZZLES PLACED IN AND AT THE END OF A PIPE LINE

Nozzle Coefficients for Free and Submerged Discharge

BY R. G. FOLSOM,[1] BERKELEY, CALIF.

This paper presents in brief form a summary of investigations made at the hydraulic laboratory of the University of California, in cooperation with the A.S.M.E. Special Research Committee on Fluid Meters, to determine nozzle coefficients for free and submerged discharge. A description of test facilities and procedure is included. The results given concern a series of A.S.M.E. long-radius nozzles for 3-in., 4-in., and 8-in. pipes tested with pipes of different wall roughness, various upstream piping arrangements, and different pressure-tap locations. Some data on I.S.A. nozzles which have been manufactured at the University shops are added.

THE INVESTIGATION reported in this paper is one of many conducted at different laboratories throughout the country with the support of the A.S.M.E. Special Research Committee on Fluid Meters to study the characteristics of the A.S.M.E. long-radius nozzle. Earlier papers have dealt with the general program as well as some particular results (1, 2, 3).[2]

The work at the University of California involves calibration of the nozzles placed in a pipe line in the normal manner, and also placed at the end of the pipe line. The latter condition of free discharge is of importance in various testing arrangements, particularly in tests of irrigation and dredge pumps. A previous paper (4) presented results of tests with orifices for free discharge.

During the investigations, it was found that if the nozzles were left in the pipe line for a few days in contact with water, material forming a sand-like surface was deposited on the nozzles. A similar phenomenon has been observed at the National Bureau of Standards (3). This deposit has an appreciable effect on the coefficient. Unless otherwise noted, all tests considered in this paper refer to nozzles with clean smooth surfaces.

EQUIPMENT AND PROCEDURE

Fig. 1 shows the arrangement of the equipment in the Hydraulic Laboratory at the University of California for calibration of nozzles placed in and at the end of a pipe line. Water was drawn from the large reservoir by the centrifugal pump and discharged to the standpipe or directly to the nozzle as desired. An additional reservoir was provided to maintain constant suction condi-

[1] Assistant Professor of Mechanical Engineering, University of California. Jun. A.S.M.E. Mr. Folsom received the degrees of B.S., M.S., and Ph.D. from the California Institute of Technology in 1928, 1929, and 1932, respectively. Since his graduation in 1928 he worked one year as part-time research assistant at the Riverside Cement Company, Riverside, Calif.; four years as teaching fellow at the California Institute of Technology; and one year as engineer for the Water Department of the City of Pasadena, Calif. He has been at the University of California since 1933.

Contributed by the A.S.M.E. Special Research Committee on Fluid Meters and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tions on the centrifugal pump when it discharged directly to the nozzle, thus keeping the discharge rate constant during the test.

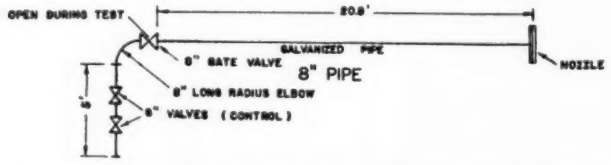

FIG. 2 ACTUAL ARRANGEMENT AND DIMENSIONS FOR TESTS WITH 8-IN. GALVANIZED PIPE WITH FREE DISCHARGE

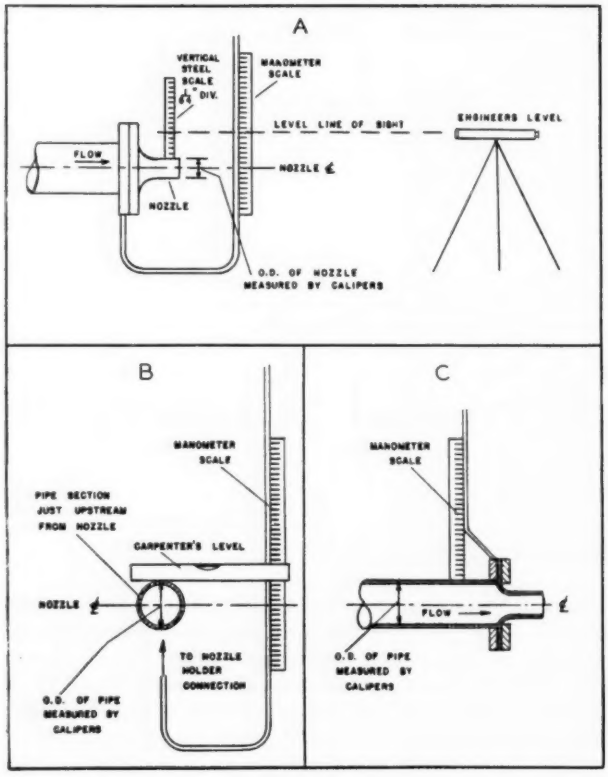

FIG. 3 VARIOUS METHODS FOR DETERMINING THE ZERO READING OF MANOMETERS

The dimensions and actual piping arrangement for a typical test setup are shown in Fig. 2.

Nozzles. The long-radius nozzles supplied to the laboratory were manufactured from brass or bronze and possessed smooth surfaces except as indicated in the following:

Nozzle No. 8.300.2 was built up by brazing parts together and then machining the meter. Since the material was not homogeneous from the standpoint of hardness, the tool tended to chatter and left a series of waves on portions of the nozzle converging section.

Nozzle No. 8.375.1 was similar in construction to that of nozzle No. 8.300.2. Blowholes were evident at the junction of the parts which also left a prominent line around the upstream face.

Nozzle No. 8.562.1 was made of steel.

Nozzle No. 8.506.1 had indentation areas in the surface, which were due to insufficient metal in the casting.

Quantity Measurements. The rate of discharge was determined from the volume of water collected in a measured period of time.

The gravimetrically calibrated volumetric tank had a capacity of about 400 cu ft and a cross-sectional area of about 46 sq ft. The rise of water level was measured with an electric point gage reading to the nearest 0.001 ft. The water-collection period was determined from a solenoid-operated stop watch with contacts for the solenoid placed on the hand-operated deflector. The stop watch was checked daily against a clock known to keep correct time within a few seconds per month.

The hook gage was read at the start and finish of each run to determine the storage or depletion of water in the weir box. The weir was not used as a flow-measuring device.

Head Measurements. All nozzles were mounted in holding rings having centering devices and with corner taps which corresponded to I.S.A. standards (5, 6). Additional pipe taps were placed at various distances upstream for the free-discharge measurements. For the nozzle-in-line position, corner taps, and pipe taps, one pipe diameter upstream and one-half pipe diameter downstream, were used.

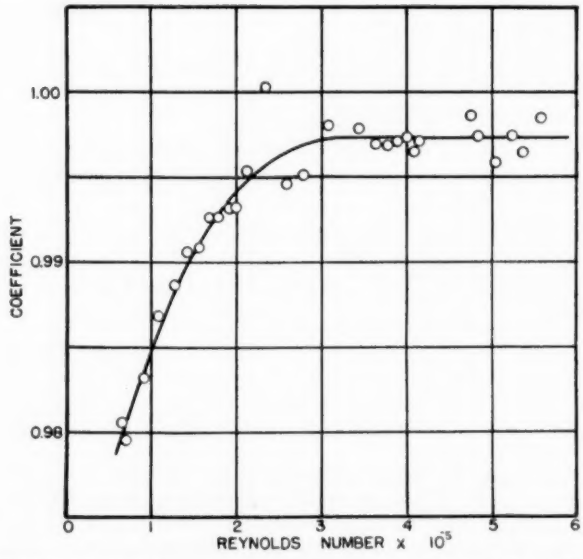

FIG. 4 TYPICAL NOZZLE-CALIBRATION CURVE PLOTTED FROM TEST DATA ON NOZZLE NO. 57195*R* WITH GALVANIZED PIPE AND FREE DISCHARGE

Vertical water columns, slant and vertical mercury-filled U-tubes were used for manometers. The scales were graduated to 0.01 ft and all readings were estimated to the nearest 0.001 ft. The inside diameters of the manometer tubes were of sufficient size to make the effects of surface tension negligible (7).

With free discharge, it is necessary to measure the elevation of the manometer scale with respect to the center line of the nozzle. Fig. 3 illustrates some common methods used for this determination. The method shown in Fig. 3*A* was employed for the tests reported in this paper.

In many cases, the room or air temperature was appreciably different from the water temperature, the discrepancy reaching as high as 30 F. For these tests, the manometer fluid was assumed to be at room temperature. Corrections were applied to express the head in terms of the fluid flowing through the nozzle.

EXPERIMENTAL RESULTS

Discharge Equation. As indicated elsewhere (4), the form of the discharge equation is largely a matter of convenience. All coefficients reported in this paper were computed from

$$Q = CA\sqrt{(2gH)} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

[a] The coefficient did not reach a well-defined constant magnitude. The value given is an approximate one toward which the coefficients approach.
[b] Ratio of coefficients for nozzle at free discharge to the coefficient in-line for galvanized pipes.
RN = Reynolds' number.

where Q = discharge rate, cfs; C = a dimensionless coefficient; A = area of nozzle throat, sq ft; g = weight per unit mass = 32.15 ft per sec per sec; and H = differential head across the nozzle (in-line) or head at the center of the nozzle (free discharge) expressed in feet of water corresponding to pipe-line conditions.

The coefficient C is primarily a function of the diameter ratio, upstream-velocity distribution, and the pressure-tap location and type. As the upstream-velocity distribution is often difficult to measure, the factors which influence the distribution are usually indicated as the variables. These are the Reynolds number, roughness and length of approach section, and piping arrangement upstream from the straight approach section. Other factors also influence the coefficient, e.g., roughness of nozzle, submerged or free discharge, and eccentricity of the nozzle with respect to the pipe. The linear dimension in the Reynolds number was selected as the throat diameter of the nozzles.

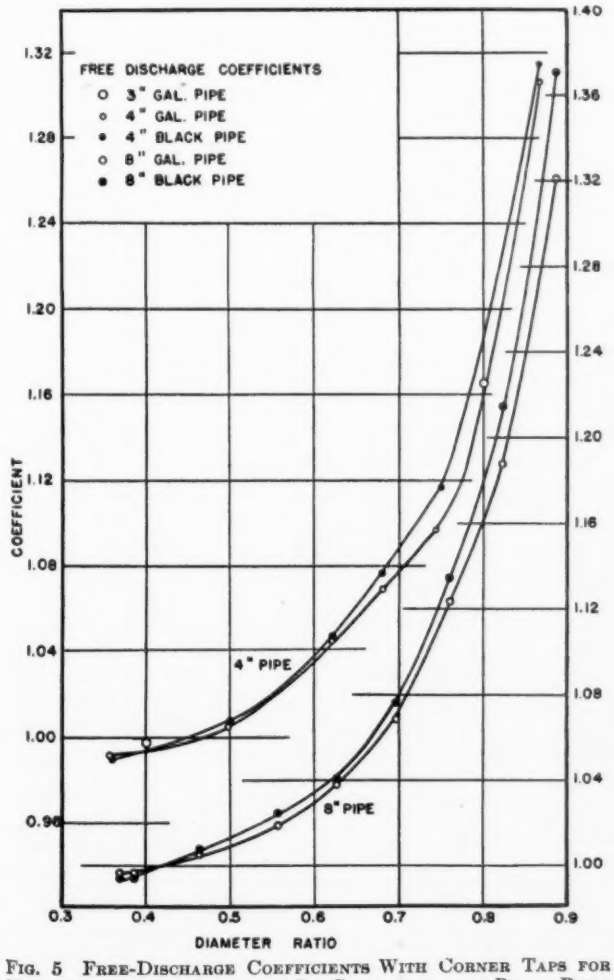

FIG. 5 FREE-DISCHARGE COEFFICIENTS WITH CORNER TAPS FOR NOZZLES IN 3-IN., 4-IN., AND 8-IN. GALVANIZED AND BLACK PIPES

Free Discharge With Corner Taps. Fig. 4 shows a typical nozzle-calibration curve, that is, the coefficient rises at low Reynolds number until a critical value is reached. At larger Reynolds numbers the coefficient is constant. The critical value is indicated as the minimum Reynolds number for a constant coefficient, in this case about 3×10^5. Coefficients used in this report refer to values in the constant-coefficient region. Insufficient data were obtained to determine a minimum Reynolds-number curve throughout the diameter ratios investigated.

The summary of tests with new galvanized and service-rough[3] or new black pipe is presented in graphical form in Fig. 5. Specific values are tabulated in Table 1. The values for the largest diameter ratios are approximate since repeat tests did not check original values. For these diameter ratios ($D_2/D_1 > 0.82$, where D_1 is pipe and D_2 is the nozzle diameter), the coefficient is extremely sensitive to conditions of nozzle surface, eccentricity with the pipe, and pipe roughness.

In Line With Corner Taps. The usual coefficients for quantity rate meters refer to installations in the middle of a pipe line. Table 1 contains a column of coefficients obtained for this type of application. Previous treatments of free-discharge conditions have expressed the coefficients in terms of the coefficients for the in-line installation. Table 1 shows this comparison as obtained from this series of tests. The 4-in. nozzles show an average ratio slightly less than unity, while the average for the 8-in. nozzles is slightly greater than unity, the average of all runs being close to unity. Thus, according to this investigation, the coefficients for the in-line and free-discharge operation differ by a negligible amount.

Pressure-Tap Location. The type and position of pressure taps depend on many factors. The experience of some laboratories has indicated that a well-made pipe tap is less sensitive to extraneous influences than corner taps. On the other hand, experience has demonstrated the difficulties involved in produc-

[3] Translation from reference (6): "A service-rough pipe may be understood to be a cast-iron pipe which has rusted internally through long use, but which has no thick encrustations on the surface."

ing a well-made pipe-tap connection under field conditions. In view of the uncertainty regarding the optimum position, investigations were made to determine the relationships of heads measured at various points.

The method selected to present the results of upstream pressure investigations assumes that if the coefficient based on the corner tap were constant, then the coefficients based on other taps investigated would be constant also. Analysis of the original data indicates this procedure to be valid. The results are expressed in terms of a ratio of heads based on the head measured at the corner tap.

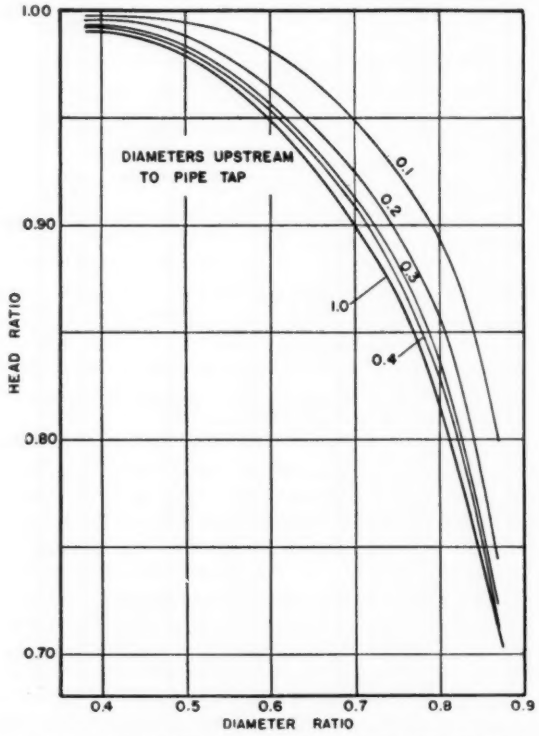

FIG. 6 RATIO OF HEADS AT UPSTREAM PIPE TAPS TO HEADS AT CORNER TAPS FOR FREE DISCHARGE

The results of head measurements in galvanized pipes at the corner tap, and taps about 0.1, 0.35, 0.5, 0.6, and 1.0 diameters upstream are shown in the faired curves of Fig. 6. The square root of the pressure ratio will give the change in coefficient at any upstream distance with respect to the coefficient based on the corner tap for corresponding diameter ratios. For example, at a diameter ratio of 0.62 and a distance of 1 diameter upstream the pressure ratio is 0.94. If the coefficient for the corner tap were 1.033, then the coefficient for one diameter upstream would be $1.033 \div (0.94)^{1/2}$ or 1.065.

The pressures measured at 1 diameter upstream from the upstream face of the nozzle and $1/2$ diameter downstream from the downstream side of the nozzle plate have been shown to be the most satisfactory (3). Several of the nozzles were tested in the line with these pipe taps. Also tests on free discharge with 1 diameter upstream pipe taps were made. The results for both series of investigations are given in Table 2 and Fig. 7.

Short Approach Lengths. In actual fluid measurements, it is frequently necessary to install a quantity rate meter with insufficient upstream straight approach pipe. Specifications for straightening vanes have been proposed (8), but the straight lengths of pipes specified are longer than desired. Data on some nozzles installed a short distance downstream from a single elbow

[b] Ratio of differential heads measured at corner taps to that measured with taps 1 diameter upstream and $1/2$ diameter downstream.

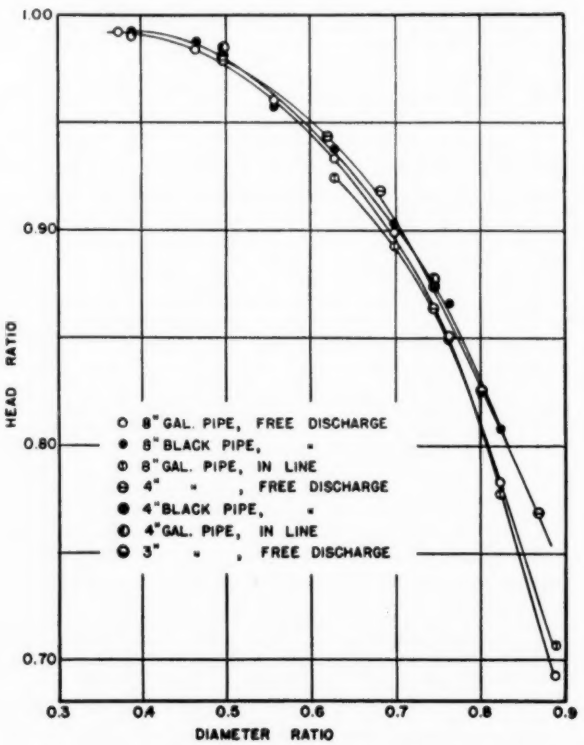

FIG. 7 RATIO OF HEADS AT A PRESSURE TAP 1 DIAMETER UPSTREAM TO THE HEAD AT THE CORNER TAP FOR FREE DISCHARGE; ALSO, THE RATIO OF HEADS AT 1 DIAMETER UPSTREAM AND $1/2$ DIAMETER DOWNSTREAM TO THE HEAD WITH CORNER TAPS FOR IN-LINE POSITION

were obtained to demonstrate the effects of distorted velocity distribution on the coefficients. All measurements were made with corner taps and black or service-rough standard steel pipe; the results are shown in Fig. 8. Throughout the diameter ratios studied, the coefficient reduces as the length of upstream pipe decreases, the reduction being greater the larger the diameter ratio.

A curve for nozzle coefficients with a highly corroded pipe is also shown in Fig. 8. As the pipe becomes rougher, the coefficient rises, the rise increasing with the diameter ratio.

I.S.A. Nozzles. Nozzles manufactured in the laboratory shops were calibrated in order to compare coefficients with standards specified in the "Regeln" (6). Bronze or brass castings were machined to required dimensions as indicated by a template and given a high polish. No measurements were made on the actual

contour of the finished nozzle. Table 3 presents the test results and the comparison with standard values. The *a* value for the 3-in. nozzle was measured about 3 months prior to the *b* value, the pipe and holder in each case being the same. During the interval, the nozzle had been used but no deposit developed and the surface was merely polished for the *b* series of tests.

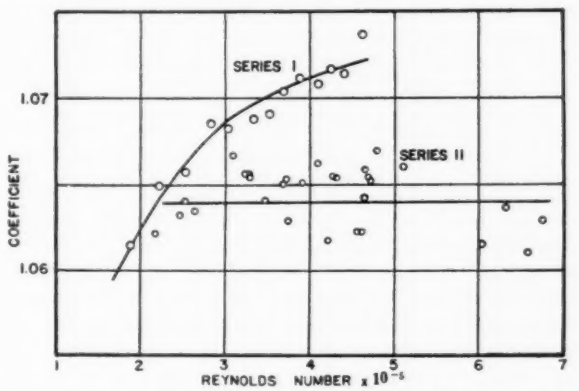

FIG. 9 CALIBRATION DATA ON NOZZLE NO. HN-7 FOR FREE DISCHARGE

(Series I tests are for a smooth nozzle surface, and series II tests apply when deposits were present on the nozzle surface.)

Fig. 9 shows the data for two tests on the HN-7 nozzle. Series I corresponds to new highly polished conditions. Series II is the calibration after the nozzle had been installed in a regular laboratory service line long enough to build up a sand-like surface. The new diameter is tabulated; the measured rough diameter was 2.4897 in. The coefficient is based on the diameter when new. Similar results on nozzle roughness have been reported elsewhere (3).

Tests on two of the nozzles for in-line and free-discharge operation indicate no appreciable difference in coefficient. This corresponds with the data obtained on the long-radius nozzles.

The comparison of the test coefficients with the values predicted on the basis of methods in the "Regeln" (6) shows satisfactory correlation except for nozzle HN-7. The difference is less than 1 per cent which is within the tolerances specified for service rough pipes. The coefficient for nozzle HN-7 is about 2½ per cent high. The reason for this difference has not been ascertained.

SUMMARY

The conclusions stated here apply to the results of this limited series of investigations with water as the fluid. Further work and comparison with data obtained by other laboratories may modify these statements.

1 For nozzles of the same area ratio with free-discharge operation with corner taps, there is no consistent difference in coefficients for the size range used in a given type of pipe. The service-rough or black pipe produces coefficients slightly higher than those corresponding to galvanized pipe.

2 Using corner taps, there is no appreciable difference in coefficients for free-discharge and in-line operation.

3 The head measured at an upstream pressure-tap location is lower than the corresponding head at the corner tap. Graphs and data present the relationships. The pipe size and roughness affect the head ratio; the ratio increases as the pipe relative

roughness increases, the amount of the increase being dependent on the diameter ratio.

4 Nozzle coefficients are appreciably reduced for installations having less than 10 diameters of straight pipe between a single elbow and the meter.

5 The nozzle coefficients become larger as the roughness of the pipe increases.

6 All other factors remaining constant, deposits or roughness on the nozzle surface change the coefficients as indicated in Fig. 9.

7 All except one of the I.S.A. nozzles constructed by the laboratory gave coefficients within the tolerance limits specified by the "Regeln" (6).

8 Diameter ratios greater than about 0.82 are not recommended as the meter is supersensitive to pipe roughness, nozzle surface conditions, and the particular installation.

Acknowledgments

The work reported in this paper was made possible through a grant from the A.S.M.E. Special Research Committee on Fluid Meters, assistance in experimental observations by the National Youth Administration workers, and computation assistance from Works Progress Administration personnel. Professor M. P. O'Brien acted in an advisory capacity representing the Fluid Meters Committee.

Discussion

Howard S. Bean.[4] As stated at the beginning of this paper, the series of tests reported forms a part of the research program on flow nozzles sponsored by the Special Research Committee on Flow Nozzles. It is appropriate to add that the tests made at the University of California were the only ones using water as the fluid, where the nozzle was placed at the end of the pipe, thus giving free discharge into the air. In connection with this program there were a few other tests made at the Ingersoll-Rand plant with nozzles on the end of the pipe to provide free discharge, but in these the fluid was air.

From the standpoint of this particular feature, the second conclusion reported by Dr. Folsom is of particular interest. Except that corner taps were used more often at the University of California than the pipe-line tap locations, there seems to be no reason why this conclusion should be limited to corner taps. The results of the tests with air at the Ingersoll-Rand plant, as well as some earlier tests made by the National Bureau of Standards[5] agree very well with those which were made on the same nozzles within a pipe.

Author's Closure

In discussing the second conclusion of the paper, Mr. Bean calls attention to other results which demonstrate the same correspondence of free and submerged discharge coefficients. This conclusion is generally accepted when a single fluid is present, but some uncertainty exists when a free jet of liquid discharges into a gas. The surface tension has some effect, the magnitude of which is imperfectly understood. The results reported in this paper indicate that this effect is negligible for water discharging into air for the nozzle sizes investigated. The author concurs in the opinion that the pressure tap location has no influence on this conclusion.

FIG. 1 SPECIMEN TESTED

Creep in Tubular Pressure Vessels

BY F. H. NORTON,[1] CAMBRIDGE, MASS.

The paper is a report of tests on the circumferential and longitudinal creep, under internal pressure and high temperature, in steel tubes such as are used in boilers and oil stills. A description of the testing apparatus is given and the results are shown in the form of tables and curves comparing the tubular creep with the creep of tensile specimens at the same stress.

The tentative conclusion is reached that the circumferential creep is about half that of tensile specimens. The longitudinal creep is negligible.

THIS RESEARCH was started to determine the creep properties of cylindrical pressure vessels as compared with the creep properties of tensile specimens of the same steel, at the same temperature, and under a stress equal to the circumferential stress in the cylinder. Previous work[2] has indicated on a theoretical basis that metal under combined stresses has a lower rate of flow than when under a pure tensile stress of the same magnitude, due to the reduction in shear. Some experimental work[3] has confirmed this and some has shown close agreement between the flow under tensile conditions and the flow under combined stresses. It was, therefore, desired to make careful creep tests on closed pressure vessels of the size and material comparable with tubes used in commercial installations, such as superheaters and oil stills. In the fall of 1936 this research was turned over to the Massachusetts Institute of Technology and work was at once started on the design of the apparatus to test such specimens.

SPECIMENS

The specimen shown in Fig. 1 consists of a carefully machined steel tube with welded-on hemispherical ends and a pressure tube welded to the lower end. The specimen contained a filler which allowed only $^1/_{16}$ in. of free space inside the walls for the gas used to provide the pressure. A cross section of a specimen is shown in Fig. 2 in place in the furnace. The dimensions of the specimen selected by the committee were: over-all length, $28^3/_4$ in., outside diameter, 4 in., and wall thickness, $^3/_8$ in. Whether or not the length is sufficient to eliminate entirely end effects in the center is not certain.

Two types of steel were used in these specimens, one a carbon-molybdenum steel and the other a 4 to 6 per cent chrome-molybdenum steel. The characteristics of these steels have been given in a report prepared by metallurgists of The Babcock and Wilcox Company.[4]

THE FURNACE

A drawing of the furnace is shown in Fig. 2. The base plate (1) supports an 18-8 tube (2) which carries the heating elements. This tube is closed at the ends by the disks (3) of K-30 insulating refractory, and the whole furnace is then covered with 1 in. of high-temperature pipe covering (4). Over this is placed a layer of aluminum foil (5) to reduce the radiation. The furnace tube is wound with five layers of mica tape (6) and then over this is wound No. 14 Kanthal A wire with separate end coils in order to permit a uniform temperature over the specimen. The specimen itself has lugs (8) welded to the outside to guide it centrally in the furnace tube, and the weight is taken by the supporting frame (9) which is carried on separate leveling screws so that the specimen can be accurately adjusted in the furnace.

Stainless-steel bolts (10) connect the crosspiece (11) with the upper end of the furnace tube. This crosspiece is connected in turn to the stationary platform (12) by the support (13) and the horizontal springs (14), thus holding the top of the furnace in alignment with the upper platform. A strut (20) resting in a hardened socket (19) screwed into the platform (11) transmits the expansion of the furnace tube to the lever (15) which is supported by a thin-strip knife-edge (17) between the supporting block (16) and the clamp (18). The lever (15) therefore magnifies the motion of the furnace tube approximately 50 times, thereby opening and closing the contacts (21) as the temperature changes. The lower contact can be adjusted by the knurled head (22) passing through the bushing (23) in the insulating block (24). The beam itself is insulated by fiber strips (14). The upper platform is kept at a constant distance from the base plate by two fused-quartz

tubes (26) which are held in slight compression by the long bolts (25) and the springs (27).

The principle of operation of this temperature controller has been previously described[5] and need not be discussed in detail. It might be said, however, that this method has proved particularly reliable, and the temperature generally stays within ± 1 F. The temperature of the specimen is measured by four thermocouples, one each on the ends of the gage length and two in the center at opposite diameters.

The measurement of increase in diameter is carried out by employing small fused-quartz tubes (35) which rest on a platinum fixture welded to the surface of the tube in the form of a small tack. The outer end of the fused-quartz tube is supported by a cantilever spring (39) attached to the supporting block (38) which keeps a slight pressure on the fused quartz all the time to hold it firmly on the specimen. A reference mark (40) exactly 5 in. from the center of the specimen is used as a sight for the same pair of telescopes used in the 10-in. tensile test. A small alloy tube (36) welded into the wall of the furnace serves to protect the quartz tubes from injury. The telescopes for measuring the diameter of the specimen are supported on a horizontal post (32) which has a ball-and-socket joint as well as an eccentric mounting to allow accurate alignment of the telescopes at the beginning of the test. A fine screw (48) adjusts the telescopes horizontally. Both telescope posts for horizontal measurements are mounted on the heavy angle (33) in order to give a solid support.

The vertical length measurements are made with the same telescopes supported on the post (31) which also has a ball-and-socket joint and an eccentric mounting for complete alignment. The sighting of the telescopes is carried out through the stainless-steel tubes (41) with the plate (43) welded on the face of them. On this plate is a glass window (44) held by a brass frame (45). An angle tube (42) is used to project a light beam on to the specimen at the point of sighting. The automobile headlight lamps used for this purpose are not shown on the drawing. The reference mark on the specimen is a platinum wire, spot-welded to the surface, which is our usual practice with the tensile specimens. Fine V marks on the wire serve as reference points.

As it would be impractical to employ a small pump in the laboratory capable of producing gas pressures of 10,000 psi for these tests, it was thought advisable to use bottled nitrogen gas up to a pressure of 2000 psi and then compress this gas to the desired amount with an accumulator (50) which has a connection to a small hand-operated hydraulic pump (51) capable of forcing oil into the bottom of the accumulator and thus compressing the gas ahead of it. The connection (49) goes to the tank of nitrogen through the tee (54) which connects with a short capillary tube to the specimen itself. Due to the small volume inside the specimen it is possible to compress the gas from 2000 to 10,000 psi quite readily by this method. Thanks to Dr. Keyes of the chemistry department fittings and valves were constructed which were absolutely tight at pressures up to 10,000 psi. Under no conditions did any leaks occur in the system except through the porous metal of the ends of some of the specimens themselves. This was because the cup-shaped ends were turned out of a billet with considerable longitudinal strain. The pressure itself is read by the gage (53) connected to the bottom of the accumulator. The pressure gages were calibrated before and after the test, and while some hysteresis of the spring was noted, the error was not sufficiently large to be taken into account. A second standard gage was also on hand for periodic checking of the pressure. The whole furnace is supported on a pipe-leg frame (52) to bring it up to a convenient height for reading the telescopes.

Two units of this type were constructed and set up in a separate research room especially devoted to this test, as shown in Fig. 3. As it was necessary to have constant room temperature in order to maintain a constant pressure and constant temperature of the furnace, a room-temperature controller was constructed in connection with a powerful ventilating fan which maintained the room at 85 F with variations of not more than ± 2 F. As this controller is of a simple thermostatic type, a description of it is not necessary here.

[5] "A New Device for Creep Testing," by F. H. Norton and J. A. Fellows, *Metal Progress*, vol. 24, 1933, p. 41.

Method of Making the Test

The tubular test specimen was first placed in a jig and the positions of the reference marks and strut attachments were carefully laid out with a fine scratch on the surface of the specimen. It was then taken over to a welder and the platinum attachments spot-welded in place in their correct location. The thermocouples were next put in place and bound to the sides of the specimen with Chromel wire. The thermocouple wires themselves were insulated with porcelain beads to the end of the furnace and then with asbestos tubing. The connecting nipple was then soldered on to the capillary tube with soft solder, which completed the work on the specimens.

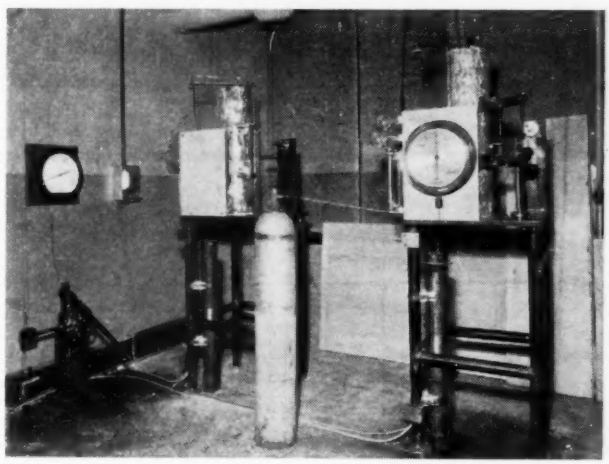

Fig. 3 Testing Laboratory With Two Furnaces

The placing of the specimen in the furnace was a rather delicate operation and it was found advisable to raise the furnace itself with a tackle supported from the ceiling and place the specimen on its supporting ring with another tackle, allowing the capillary tube and the thermocouple to pass down through the bottom of the furnace. The specimen was then adjusted in a vertical position and held there temporarily while the furnace itself was lowered carefully around the specimen, and clamped down with the three bottom bolts. Great care had to be taken during this operation to prevent dislodging the platinum reference marks, and it was found advisable to wrap the center of the specimen with soft twine which protected the platinum marks and which later burned off.

After the furnace itself had been carefully leveled, the specimen was adjusted for height and rotary position as well as possible, but the silica struts were not put in place at this time.

The furnace was heated up gradually, taking a period of several days to reach the equilibrium value. Then, during a period of several weeks, the current through the end coils was adjusted to get a satisfactory temperature distribution. Because of the heavy specimen it was necessary to wait at least 24 hr after each adjustment before the next one could be made. After the temperature had become satisfactorily balanced, the height of the

specimen was finally adjusted with the leveling screws and the silica struts were put in place. The telescope posts were then lined up to give simultaneous forms on the two marks.

Length measurements were taken with the telescopes with no pressure, then the pressure was brought up to the working value as quickly as possible. At the lower pressures this could be done in a few minutes, but at the higher pressures it took from 6 to 8 hours' pumping to reach the desired value. Another length measurement was taken with the telescopes immediately after the correct pressure was established, and readings were taken thereafter every 24 hr. All the readings were taken by two observers and the results averaged.

In case a specimen showed a drop in pressure due to leakage, the pressure was pumped up to the correct value every morning and every night. In some cases the leakage was small; in one case there was none at all, and in one case leakage was considerable. Except in the two cases where leakage was severe the pressure was held within ± 1.0 per cent at all times.

(4–6 Cr steel at 1200 F and 923 psi.)

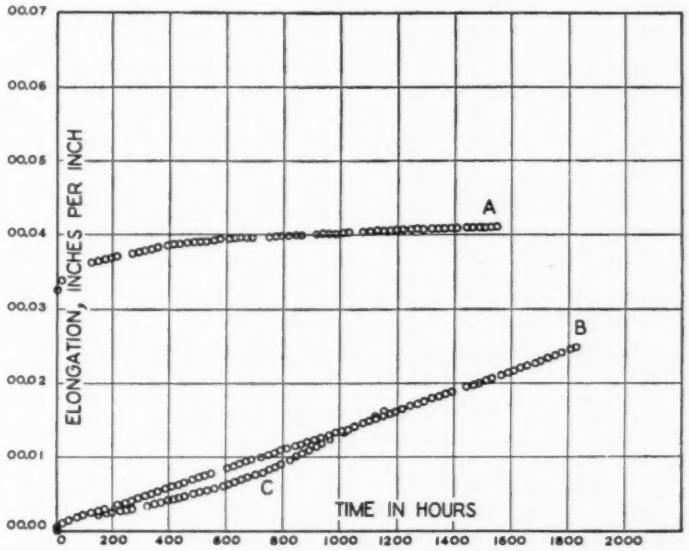

FIG. 9 TENSILE CREEP TEST

A	= C-Mo steel	800 F	39,170 psi
B	= 4–6 Cr steel	1200 F	3,982 psi
C	= C-Mo steel	1050 F	13,933 psi

CONDITIONS OF TESTING

The temperatures selected by the committee for these tests were 800 and 1050 F for the carbon-molybdenum steel, and 1200 F for the 4–6 chrome-molybdenum steel. The duration was to be 1000 hr. The pressures were selected, as nearly as could be determined from past experience on these materials, to give circumferential creep rates of 5 and 50 per cent per 100,000 hr. The loads were altered somewhat after the first test under a given condition in order to adjust the second load more nearly to the conditions wanted. The final pressures and stresses in the metal figured out by the Lamé formula by The Babcock and Wilcox Company are given in Table 1.

PRECISION OF THE MEASUREMENTS

The readings of the longitudinal creep are accurate to two parts in a million, which is equivalent to the regular 10-in. tensile creep tests. The creep in diameter, however, is good only to six parts in a million, because the gage length is only $^1/_3$ as great. In regard to the temperature, the distribution was good to ± 3 F over the gage length, and the variation in temperature from day to day was ±1 F.

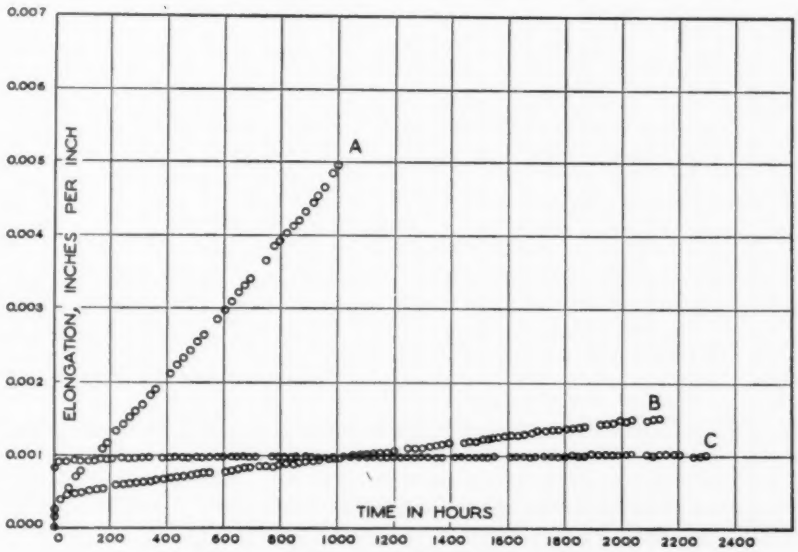

FIG. 10 TENSILE CREEP TESTS

A	= 4–6 Cr steel	1200 F	2,818 psi
B	= C-Mo steel	1050 F	6,973 psi
C	= C-Mo steel	800 F	17,226 psi

Micrometer readings of the diameter in the center of the specimen were made before and after each run. In every case the permanent increase in diameter determined in this way agreed with the telescope readings.

The first specimen was run at 1200 F and initially some difficulty was had in adjusting the silica struts to give an even bearing so that consistent readings could be obtained, but toward the middle of the run this difficulty was eliminated and satisfactory readings were obtained. However, due to the rather rapid leakage of gas through the ends of the specimen it was necessary to pump up the pressure frequently, which gave a condition of alternating stress causing the results to be out of line with the later tests. Therefore, the results are shown merely to indicate the improvement in technique during the first run. The specimen run at 800 F and 9240 psi also leaked so badly that creep rate is only an approximation. The flow curves in both a circumferential and longitudinal direction are shown in Figs. 4 to 8.

It will be noted first that the longitudinal creep is rather low in most cases and sometimes has even a negative value. The circumferential creep gives a curve quite similar to the usual tensile creep curves except there seems to be a tendency to take a longer period of time in coming to an equilibrium rate, which is due, perhaps, to adjustment of stresses in the tubular specimen. Therefore, there is some possibility that the rates given in the first runs may be a little higher than the equilibrium rate even though the tests were run as long as is generally considered necessary in the tensile test. The last specimen run was carried along

for a considerably greater period as requested by the committee at H. J. Kerr's suggestion and we find here a definite decrease in the rate after a period of around 2000 hr, a change which might have occurred in the other specimens had they been carried through this period.

Tensile Tests

Specimens were cut out of the walls of the same batch of tubing that the pressure vessels were made from and these were run in the regular 10-in. furnace as a standard tensile creep test. These were cut with their length parallel to the axis of the tube. The creep curves for these runs are shown in Figs. 9 and 10 and need no special comment.

Comparison of the Creep Rates in the Tubular and Tensile Specimens

Log-log plots of the circumferential creep rate, based on the average stress, and the creep rate in tension are shown in Fig. 11, while the specific data on the creep rates are tabulated in Tables 2 and 3.

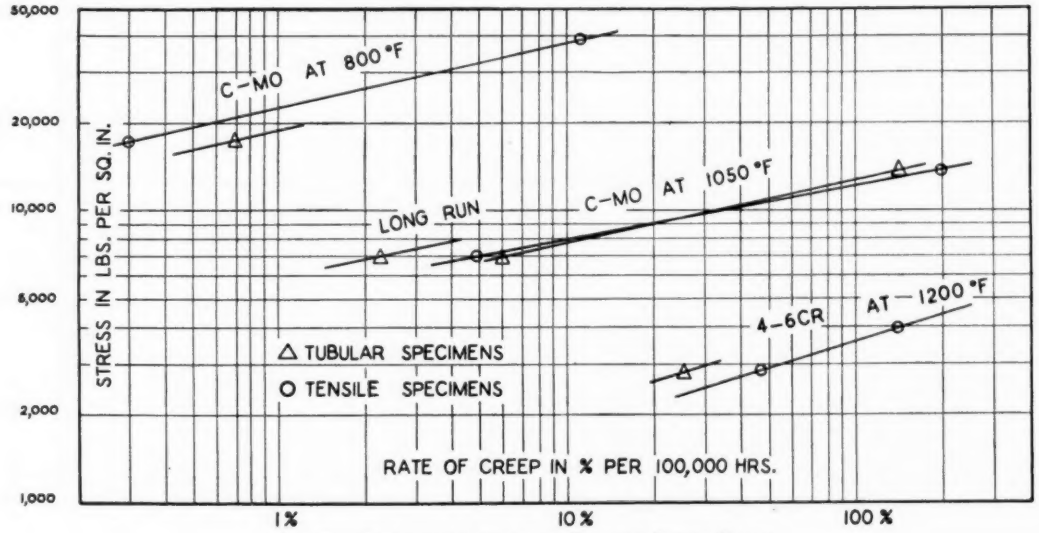

Fig. 11 Circumferential and Tensile Creep Rates

The comparison between the circumferential creep of the tubular specimens, and the tensile creep would indicate that at 800 F the tubular specimens creep faster under the same stress. At 1050 F there is little difference between the two conditions, while at 1200 F the tube creeps somewhat more slowly than the corresponding tensile specimen. The differences, however, are not greatly in excess of the experimental error and it would look in general as if the rates were substantially the same under the two conditions. However, if the tubular specimens are run for a longer period of time, which was done in the case of the carbon-molybdenum steel at 1050 F, a material decrease in the rate occurs from 5.8 per cent at the end of 1000 hr to 2.2 per cent from 2000 to 4000 hr. It would, therefore, seem, at least from this single test, that the tubular specimens take a much longer time to reach an equilibrium rate of flow than the tensile specimens. It is probable that if all of the tubular specimens had been run for from 4000 to 5000 hr the rates would have been materially lower. Some work carried out by Prof. H. F. Moore[3] on the flow of lead tubes confirmed this conclusion, as he states that the tubular specimens required a considerably greater length of time to reach an equilibrium flow than the tensile specimens. If this point of view is correct then it may be stated that the tubular specimens creep at about half the rate of the tensile specimens under the same stress.

It should be realized that it is improper to base any general conclusions on the few tubular tests carried out in this project. More data are needed to supplement the present information in order to formulate definite factors for converting creep rate in tension to creep rates of tubes under internal pressure. Especially, tests should be made with other diameters and wall thicknesses.

The longitudinal creep is in most cases small; sometimes it is slightly positive and sometimes slightly negative. It is probably safe to assume in any design problem a zero change in length of the tubular member during its life.

Acknowledgments

The author wishes to express his appreciation for the assistance received in this investigation by members of the Joint High Temperature Committee. The assistance of The Babcock and Wilcox Company, and especially H. J. Kerr, in the difficult problem of making up the test specimens and for advice and suggestions during the test are especially appreciated. Also, the help and suggestions of C. E. MacQuigg, chairman of the committee, have been most helpful. The work of John Fellows in setting up the apparatus and Donald Fellows in making the observations has been of the greatest assistance in carrying out these tests.

Discussion

C. O. Rhys[6] and M. S. Northup.[7] The purpose of the investigation is of extreme interest because of the high-temperature high-pressure equipment now in service and the certainty that temperatures and pressures of future equipment will increase rather than decrease.

The tests reported by the author carry on more completely and fully a line of investigation touched briefly by tests at room temperature made in our laboratory in 1933 on $3^1/_2$-in. OD × $^1/_4$-in. wall lead tubes to determine qualitatively any difference between creep in tension specimens and creep in tubes. It is of interest that these tests showed that in closed-end tubes the axial creep is negligible, a conclusion drawn by the author from his test results. In this connection R. W. Bailey,[8] Metropolitan-Vickers, Ltd., England, also found that axial creep need not be considered.

The range of creep rate generally used in design work is from 0.1 to 10 per cent per 100,000 hr. An examination of the tables for tubular and tensile specimens shows that most of the deformation rates on the specimens were outside this range and the writers are reluctant to discuss the results. These enormous creep rates may and probably do have a considerable effect on the creep-rate distribution through the wall.

According to experiments made by R. W. Bailey with a lead cylinder $3^1/_4$ in. OD and $^1/_8$ in. thick the diametral creep rate with no axial stress is from three to four times as much as with the axial stress set up by the internal pressure.

From experiments made in our own laboratories with a lead cylinder $3^1/_2$ in. OD and $^1/_4$ in. thick, the ratio is between 1.5 and 2.5 to 1. The theory for a very thin cylinder would give about 5 to 1. It is interesting to note that as the cylinders become relatively thinner the theoretical result is approached as shown in Table 4.

According to Bailey's experiments for these cylinders, the diametral creep rate is a minimum, when the axial stress is that due to internal pressure. It would appear from this that most pressure vessels are subjected to the least possible amount of diametral creep. By treating the $3^1/_2$ × 3-in. lead tube tested in our laboratory as a thick cylinder, the ratio of diametral creep rates at the outside surface, with and without axial pressure stress, is 1 to 2.57. This is a good check with the 2.5 found experimentally. For the steel cylinder of the paper the calculated ratio is 1.42 which is a close check with 195/139 = 1.4.

TABLE 4 RATIOS OF DIAMETRAL CREEP WITH AND WITHOUT THE AXIAL STRESS CAUSED BY INTERNAL PRESSURE

	OD/ID	Creep ratio
Standard Oil Development Co.	1.17	1.5 to 2.5
R. W. Bailey	1.08	3 to 4
Theoretical	1.00	5

Comparisons of creep rate at the inside wall of tubular specimens would be of great interest as it is this creep rate which governs design of cylindrical pressure vessels.

We agree with the author that the few tests covered by the report are insufficient to arrive at any definite conclusions. It is believed that further work along the same lines is desirable, but with deformation rates of from 0.1 to 10 per cent per 100,000 hr and different ratios of diameter to thickness, so that the results will apply to both pressure-vessel and tube design. Ultimately, for tube design, such a program should include the determination of the effects of heat transfer through the wall if any practical way can be found to do so.

Author's Closure

The comments of Messrs. Rhys and Northup give some interesting data on lead cylinders which seem to check well with the theoretical work of Bailey. We quite agree that some of the creep rates in our work were much higher than would be encountered in service, but due to the fact that reliable tensile values of the particular steels used were not available before the tests on the tubes were started, some of the pressures were set too high.

We agree also that it would be desirable to carry the test with a thermal gradient through the tube wall, but the experimental difficulties of carrying this out are so great that we can see no way of accomplishing it without extremely costly equipment.

Effect of High Temperatures and Pressures on Cast-Steel Venturi Tubes

By W. S. PARDOE,[1] PHILADELPHIA, PA.

The author presents results of tests showing the expansion in the main and throat diameters of cast-steel venturi tubes under dry heat and pressure, respectively. From these data values are obtained for the coefficient of expansion and the modulus of elasticity, and the comparative effects of high temperatures and pressures are shown.

THE RESULTS of temperature tests conducted on a 5.625 × 4.25-in. extra-heavy cast-steel Simplex venturi tube at H. Brinton Company's oven on April 24, 1929, are shown in Fig. 1.

The coefficient of expansion of the throat per deg F is 0.0000108 and that of the main is 0.00000946; a mean value of 0.000010 might be used. This is greater than the usually quoted values for cast steel and about equal to that of bronze.

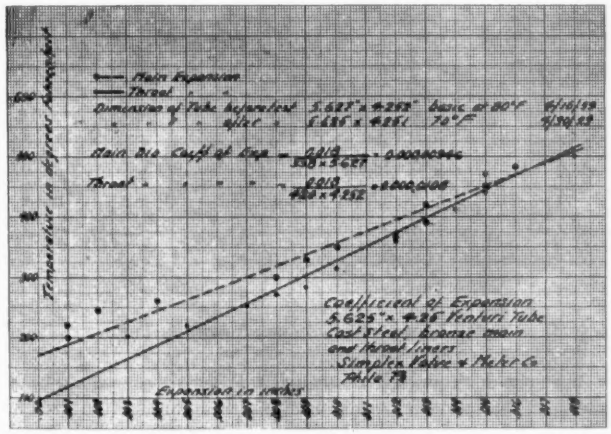

FIG. 1 EXPANSION OF VENTURI TUBE IN DRY HEAT

Since the discharge varies directly as the square of the throat diameter, the error resulting from neglecting the expansion is 0.2 per cent per 100 deg F, which is not a negligible quantity when the rise in temperature may be 800 deg or more.

The tests were conducted as follows:

The basic dimensions were taken at a temperature of 80 F. These were main diam 5.627 in., and throat diam 4.252 in. An outline sketch is shown in Fig. 2. The tube was then placed in the oven, the temperature of the oven was raised to 200 F, and held constant for 15 min. The tube was withdrawn, measured in less than 30 sec, and replaced, after which the oven temperature was again raised and held stationary for 15 min. This process was repeated for each temperature.

The high-pressure tests were conducted in the hydraulic laboratory of the civil-engineering department of the University of Pennsylvania on an 8 × 5-in. extra-heavy cast-steel Simplex venturi tube, dimensions of which are shown in Fig. 2.

The results are shown in Fig. 3 and give a modulus of elasticity (defined as unit pressure, in lb per sq in., divided by unit expansion of the throat diameter in in. per in.) of 17,000,000 lb per sq in.

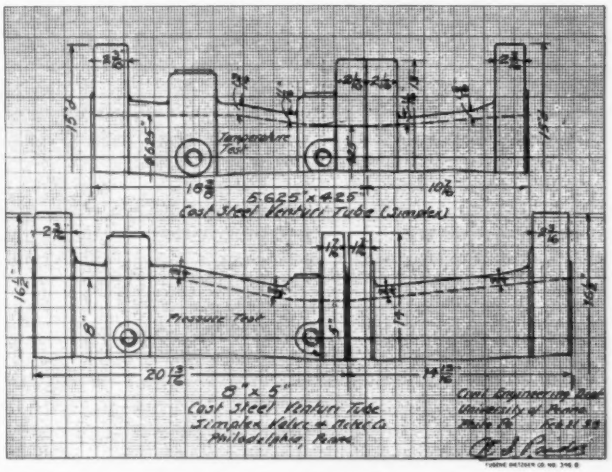

FIG. 2 DIMENSIONS OF VENTURI TUBES USED IN TEMPERATURE AND PRESSURE TESTS

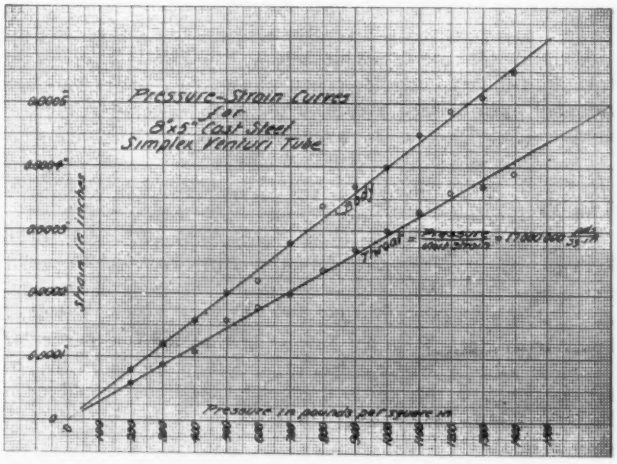

FIG. 3 PRESSURE-STRAIN CURVES FOR 8 × 5-IN. CAST-STEEL VENTURI TUBE

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

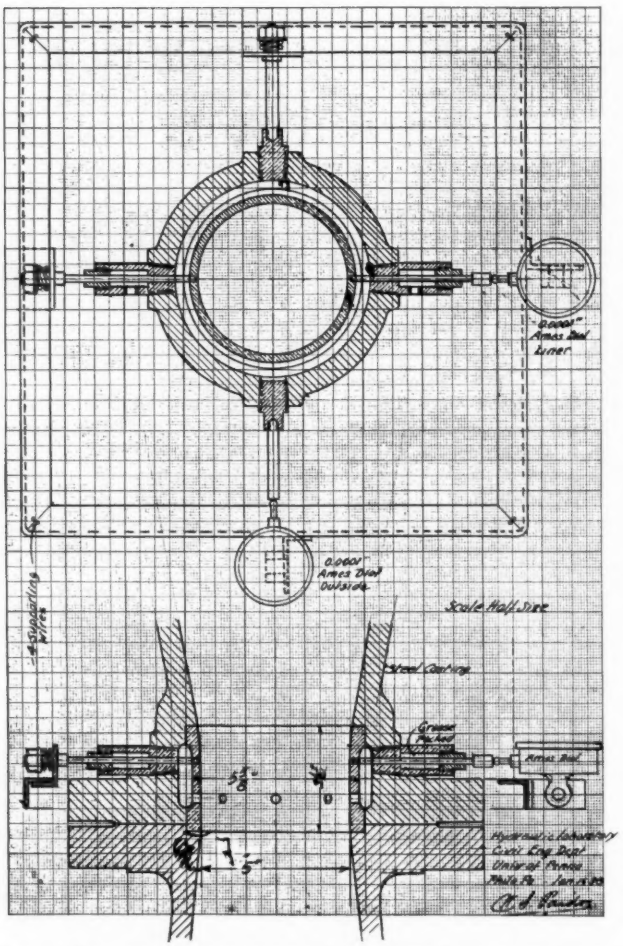

FIG. 4 DETAILS OF APPARATUS FOR MEASURING THROAT AND BODY EXPANSIONS UNDER PRESSURE

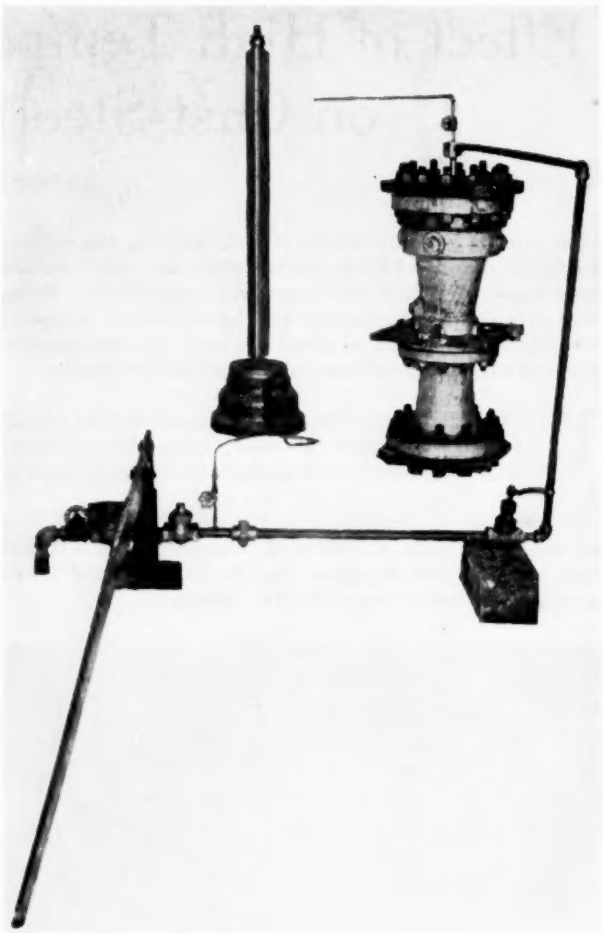

FIG. 5 APPARATUS USED FOR PRESSURE TESTS

Thus there is an expansion of 0.00025 in. for a pressure of 850 lb per sq in., which if neglected would make an error of 0.01 per cent, an entirely negligible quantity.

The apparatus for measuring the throat and body expansions is shown in Fig. 4. Steel rods of $\frac{1}{8}$ in. diam pass through grease stuffing boxes and are tapped into the bronze throat liner. A square frame of 1-in. angle iron, hung by wires from the meter flange, support two 0.0001-in. Ames dials which can be read to 0.00001 in. The meter was blank-flanged and water pumped into it with a 1-in. hand pump having a long lever. The pressure was recorded by a 5000-lb pneumercator gage (differential plunger mercury-loaded). The entire apparatus is shown in Fig. 5.

Discussion

S. R. BEITLER.[2] These tests, especially those having to do with the effect of temperature on venturi tubes, are of major importance for accurate measurements of high-temperature fluids, since such tubes are used generally for the measurement of boiler feedwater. It is not surprising that for this particular design of tube the coefficient of expansion approximates that of bronze; since the piezometer ring behind the throat would mean that the bronze throat section was not supported by the steel shell at this point.

Since the description does not tell whether there was a bronze insert at the inlet-pressure connection, it is difficult to predict whether this reasoning would follow for this section.

A paper[3] which was presented to the Society in 1931, reported on a set of similar tests for sharp-edged orifice plates and steel flow nozzles clamped in steel flanges. The tests showed that for these primary elements it was possible to calculate the increase in diameter for the coefficient of expansion of the metal (monel and 0.12 carbon metal) as accurately as it could be measured. It was also found that no change in shape or flatness was caused either in the nozzles or in the orifice plate.

L. K. SPINK.[4] The author does not draw any conclusions regarding the effect on the flow coefficient due to the measured change in dimensions caused by temperature and pressure. It is possible that warping caused by use of dissimilar metals, having different coefficients of expansion, may create effects exceeding those calculated from the changes in dimensions. It has been found that the use of 18 and 8 steel orifice plates in steel flanges at high temperatures in some cases produces undesirable warping. The present engineering trend is toward choosing orifice-plate materials to minimize warping or toward

[4] The Foxboro Company, Foxboro, Mass.

mounting the plates with means to permit expansion and contraction without warping.

Nevertheless, it is sound practice to correct for all known variables and to eliminate in so far as possible all unknown variables. The writer believes the author would have been justified in concluding that the venturi-coefficient calculations should be based upon the dimensions at operating conditions.

Author's Closure

Professor Beitler's suggestion that the high coefficient of expansion can be explained by a loose throat piece does not seem tenable. The pressure-strain curves indicate that the bronze throat expands, although subject to no difference of pressure, which would indicate that the bronze throat piece was prestressed by force fitting and expanded with the body. Also, there was no bronze liner in the inlet section and it had approximately the same coefficient of expansion, i.e., 0.00000946 main and 0.0000108 throat.

The author welcomes the reference to "A Study of Primary Metering Elements," by Professors Beitler, Bucher, and Barnes. He should have referred to this before rather than after his experimental work, but such is life: We go through it smashing in open doors. The results indicate an appreciable error in using the normal coefficient of expansion (0.0000065) in this particular tube.

Mr. Spink draws attention to the warping of large orifice plates. Professors Bucher and Barnes say there is none. This paper concerns itself with venturi tubes and the whole idea is to determine the corrections to the diameters as measured at normal temperatures and pressures when using the tubes at high temperatures and pressures.

The author desires to take this opportunity to thank those contributing written and oral discussions to his paper.

Twenty Years of Machine Activity in the Woolen-and-Worsted Industry

By A. W. BENOIT,[1] BOSTON, MASS.

The paper is a discussion of data, compiled from various sources and presented in the form of graphs and tables, tracing conditions in the woolen-and-worsted industry with a view to determining what may be expected in the future. Past performance is analyzed with respect to basic equipment, its active working time, the amount of raw materials used, and working hours.

The conclusions are reached that the liquidation of mills as a whole is nearly finished, that present spindle equipments are not excessive, but that there is still considerable excess loom capacity.

DURING the last twenty years the textile industry has been passing through a critical period, the end of which is not yet in sight. While the depression has been a contributing factor, it was not the principal cause, because the present difficulty made its first appearance about 1923. There has been a buyers' market with rare exceptions for many years, and the textile manufacturer has been at the mercy of the purchaser of his products. He has been unable to make consistent profits, burdensome legislation has dogged his steps, labor unrest has added to his difficulties, raw-stock markets have been unsteady, styles have changed frequently and radically, and, like the caged squirrel, he has gone round and round, getting nowhere.

Within the industry itself there is much hesitation and uncertainty among its members, due somewhat to the rapid political, social, and economic changes which affect its operation. The competition between mills for the business which is available is so sharp that it is destructive, and many liquidations have resulted. This is equally true of both the cotton and wool branches of the industry.

In the eleven years from 1925 to 1936, the number of cotton spindles in the United States dropped from about 38 million to 27 million, or at the rate of a million a year. At the same time, the consumption of cotton by the mills, while it had its usual annual fluctuations, averaged about the same as prior to 1925. An analysis of this situation, made in October, 1937, showed quite clearly that the increased number of hours at which spindles and looms were being operated was the greatest contributing factor and that, if the cotton mills continued to operate 80 hours or more per week, there still would be considerably more machinery in place than would be necessary to supply the country's needs.

A similar analysis of the machinery in the woolen-and-worsted industry was deemed desirable to determine, if possible, the facts as to trends and future possibilities. There are certain data prepared by various federal agencies, as well as those kept by private groups, which are available and from which tables and graphs can be made which show what has occurred. The analysis has been confined, in so far as possible, to that part of the industry which is engaged in making apparel, omitting the carpet and felt manufacturers. These latter are such a relatively small part of the whole that they affect the general picture but little.

Where it has been possible, the data on woolen and worsted machinery have been kept separate, and the reports are so made that this can be done up through the spindles. The looms, however, in many cases weave both woolen and worsted fabrics and it is impossible to make any intelligent division of this machinery.

In order to get a general picture of the industry as it is at present, with reference to its location and size, Table 1 was prepared. Worsted spindles include flyer, cap, and ring spindles, and woolen spindles include both frames and mules.

TABLE 1 UNITED STATES DISTRIBUTION OF WOOLEN AND WORSTED MACHINERY IN 1938

(Information furnished by textile-mill directories and other sources)

Section	Woolen and worsted spindles	Per cent of total	Woolen and worsted looms	Per cent of total
1	3887000	93	52500	92
2	201000	5	3600	6
3	69000	2	900	2
	4157000	100	57000	100

Section 1, north of Maryland and Kentucky, and east of Mississippi River.
Section 2, south of section 1, and east of the Mississippi River.
Section 3, west of the Mississippi River.

It will be noted that the total figures of Table 1 do not check exactly with the data from the U. S. Bureau of the Census, used later in this paper; however, they are sufficiently accurate to show distribution in percentages and, at any rate, they are the only data on this phase of the subject that the author has been able to find.

It is to be noted that the great bulk, over 90 per cent, of this industry is in the northeastern section of the country, including the New England States, New York, Pennsylvania, New Jersey, Delaware, Ohio, Indiana, Michigan, and Wisconsin. Of the total, about 60 per cent is in the New England States and 20 per cent in New York, Pennsylvania, New Jersey, and Delaware. This area is compact and homogeneous, and much alike as to climate, working conditions, labor rates, usual hours of labor, and general competitive conditions such as freight, power, and proximity to raw stock and market.

At the present time a small part of the machinery is in the South, and if this region operates under any different conditions as to hours and rates of labor from the northeastern section of the country, it will have comparatively little effect upon the general situation.

The United States Department of Commerce, Bureau of the Census, reports the monthly activity of woolen and worsted machinery, and its report as of July, 1938, shows the following machinery in possession of mills:

[1] Member of the firm and head of the textile department of Chas. T. Main, Inc. Mem. A.S.M.E. Mr. Benoit was graduated with the degree of B.S. in civil engineering from Tufts College in 1907. He has worked with Chas. T. Main and Chas. T. Main, Inc., since 1909 and in his present position since 1919.

Contributed by the Textile Division and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

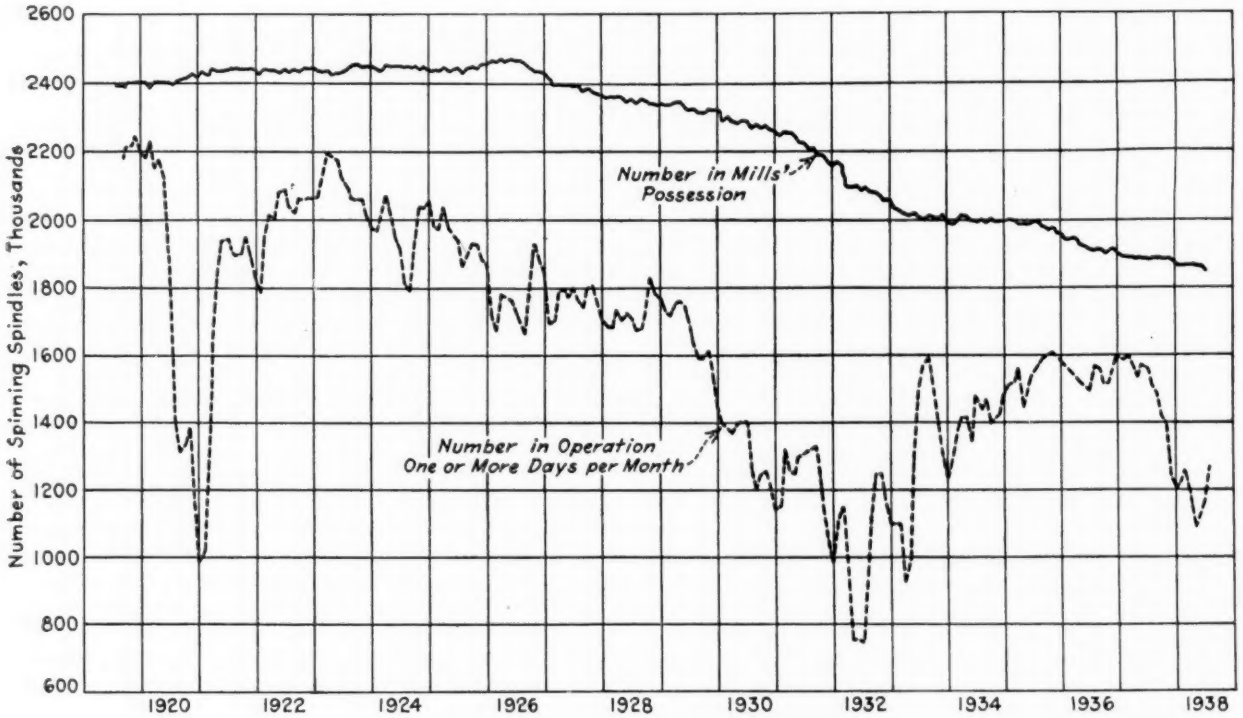

FIG. 1 NUMBER OF WOOLEN-SPINNING SPINDLES

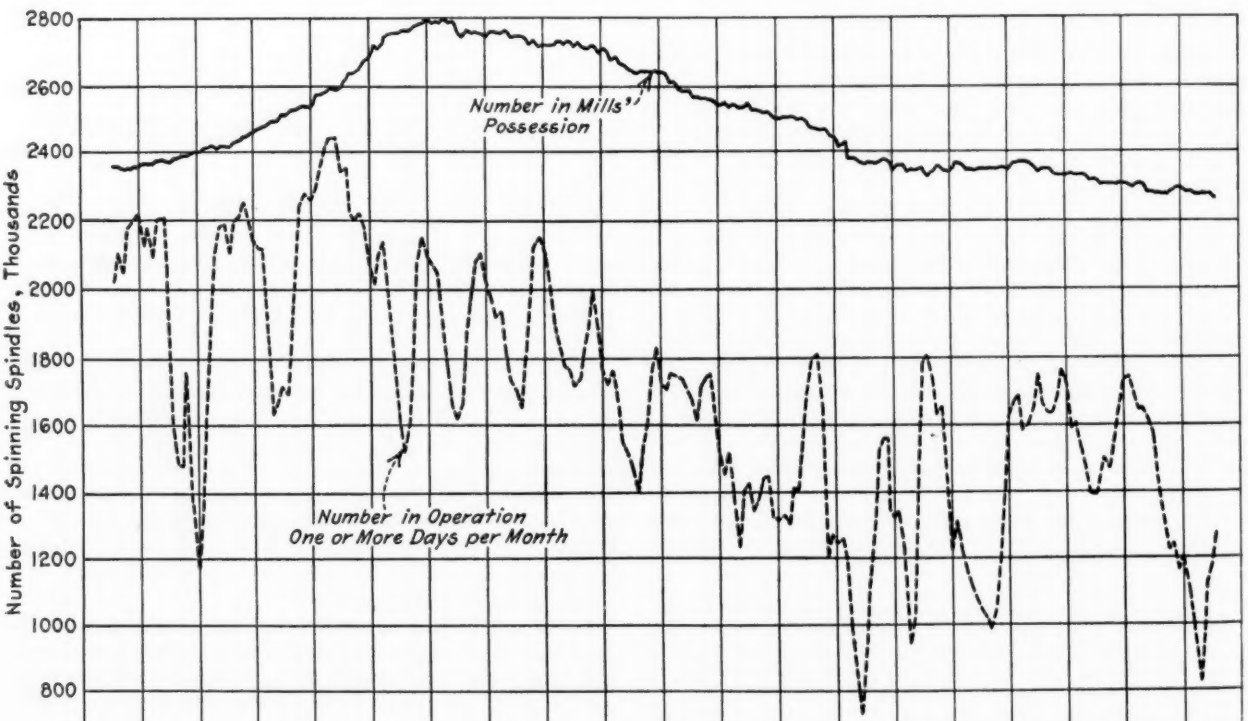

FIG. 2 NUMBER OF WORSTED-SPINNING SPINDLES

Woolen and worsted broad looms[2]	44,887
Woolen and worsted narrow looms	7,948
Woolen-spinning spindles	1,856,844
Worsted-spinning spindles	2,258,045

Of the 44,887 looms listed, 26,307 or 58 per cent are of the automatic type of one kind or another; the remainder, 18,580, are hand feed or nonautomatic. There are about 1,856,000 woolen spindles reported, of which it is estimated that about 78,000 are frame spindles and the remainder are on mules. As stated before, the worsted spindles include flyers, caps, and rings, but no information is available as to the division and all are included under one heading.

The twenty-year period being considered covers two important decades, the first of which was the rehabilitation period after the War, with its tremendous demands for textiles and other commodities. The end of this period saw the greatest boom in securities in our history, culminating in the crash of 1929. The second decade covers the worst depression this country has ever experienced, which has carried all industry, including the textile, to new lows in percentage of activity. Although the crash of 1929 marks the beginning of the decline in industry as a whole, the textile industry reached its peak back in 1923. From 1923 to 1929 there was a gradual decrease in activity and also in the amount of machinery in place, followed by a sharp decline during the depression and up to the present time.

A good picture of what has happened to the woolen-and-worsted industry can be obtained by plotting the data collected by the Department of Commerce and showing graphically the trend of machinery in place and that active. While this information is probably not 100 per cent complete or correct, and only recently has a distinction been made between automatic and nonautomatic looms, it is the best information available and has been used as the basis for these graphs.

Fig. 1 shows the woolen spindles in place from 1919 to and including July, 1938. The peak of spindles in place was reached in 1926, with a total of about 2,477,000 spindles, and since then there has been a continuous reduction year by year to a total of about 1,856,000 in July, 1938, which is a reduction of 621,000 spindles, or 25 per cent. This averaged about 52,000 spindles a year, or approximately 10 ten-set average mills per year. Viewed from this angle we get some real conception of the extent of this decline.

On the same graph is shown the number of active woolen spindles in any month. A spindle is counted as active if it has been operated at any time during the month. This gives a good graphic picture of the tremendous fluctuations in production in this industry. There is one significant thing to be noted, that, even in the boom years of 1919 and 1923, there were always 200,000 spindles idle, or about 8 per cent. Because of its many ramifications, the woolen industry never can be 100 per cent employed, but there are indications that at that time there was an excess of machinery. While the spindle activity started to drop off in 1923, the number of spindles installed increased until 1926. This graph shows that the beginning of the recession for the woolen industry was about 1923, with a gradual sliding off until 1929, and then the sharp drop with little let up, into the depths of the 1932 depression. The effect of the National Recovery Administration is shown by the burst of activity in 1933, followed by the gradual recovery up to 1935 and the see-saw activity of 1936 and early 1937. Then came another sharp decline which did not stop for practically a year, and out of which the industry is now laboriously fumbling its way.

Fig. 2 gives a similar picture of the worsted spindles in the country. It is of interest that in 1919 there were about 2,400,000 woolen spindles in the country and about 2,350,000 worsted spindles, or practically the same number.

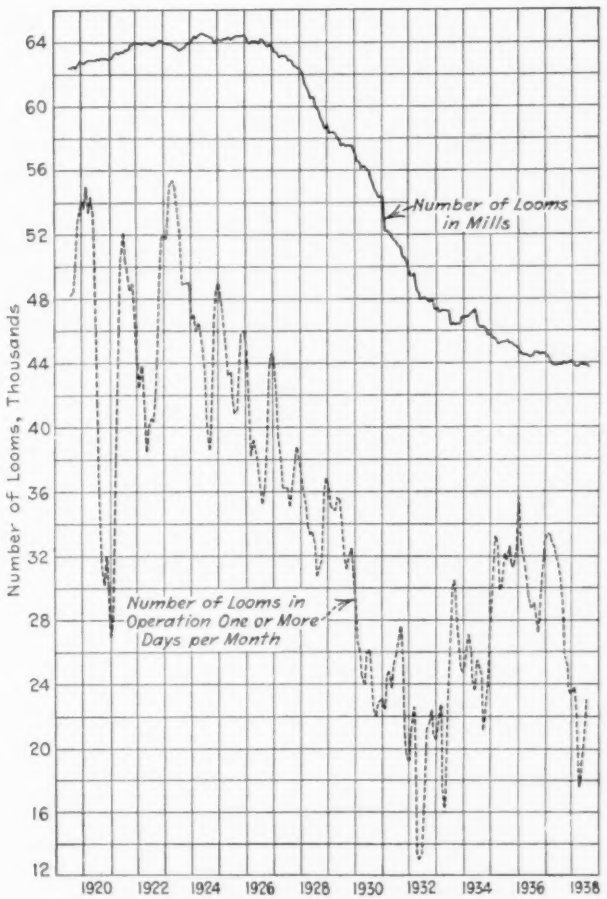

FIG. 3 WOOLEN AND WORSTED BROAD LOOMS[2]
(Includes idle mills.)

The graph shows that the number of worsted spindles increased to about 2,800,000 in 1924, after which there was a steady decline, and in 1938 the number had been reduced to a little less than 2,300,000, or a decrease of 500,000. This is about 18 per cent as compared with the 25 per cent reduction in woolen spindles. The activity curve is, in general, the same as that of the woolen spindles, except that it is considerably more erratic and the fluctuations are more violent. The year 1923 was the peak point of activity, followed by several years of erratic but always decreasing business, which finally reached a record-low-activity period in 1932. The hypodermic effect of the N.R.A. in 1933 is evident, with its sad aftermath. The partial recovery during 1935 and 1936, as in the woolen industry, was followed by the sharp recession beginning in the early part of 1937, which did not turn upward until the spring of 1938.

It is to be noted that the industry continued to install spindles after the peak of activity had been reached. The fluctuations in machinery activity are so great in the industry that it is difficult at any time to forecast future trends. In 1923 the industry came very close to running all of its spindles for a short time, but since then there has always been a half million or more idle.

This picture would not be complete without showing a graph of the looms in place and their activity. Since the same looms may use both woolen and worsted yarns, they cannot be sepa-

[2] Looms with more than 50 in. reed space are classified as broad looms.

rated as can the spindles, and so they have been grouped into broad looms[2] and narrow looms. The broad looms represent 85 per cent of the total number in place and the narrow looms are of only minor importance.

Fig. 3 shows the number of broad looms in place from 1919 to July, 1938, inclusive. The maximum number of looms was about 64,600, reached in 1924, following the great activity of 1923. There was no appreciable reduction in the number of looms in place until 1926, from which time, as the graph shows, the liquidation has been continuous and rapid until at the present time there are less than 45,000 in place. This is a decrease of 32 per cent or a reduction of about 1700 looms a year. The year of maximum liquidation was 1931, when there was a reduction of about 4600 looms.

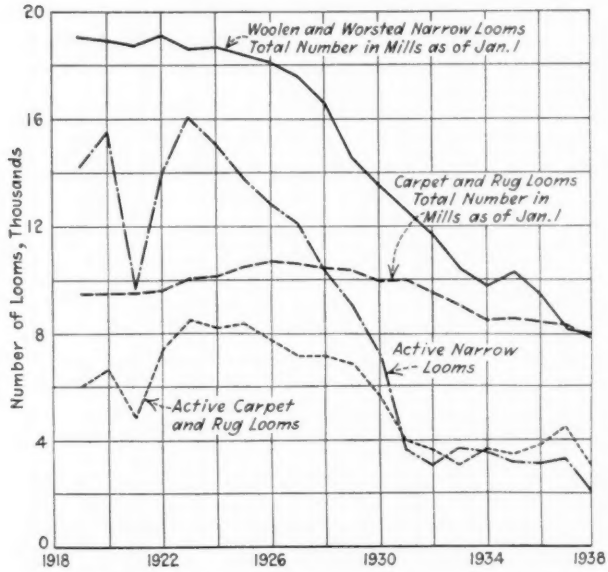

FIG. 4 WOOLEN AND WORSTED NARROW LOOMS

On the same graph is shown the number of active looms, which represents all looms which have run any part of the month in which they were reported. It is to be noted that during these 20 years, for only one period of 3 consecutive months were there more than 55,000 looms active, which is about 85 per cent of those installed. The nature of the woolen-and-worsted industry is such that except in boom periods it does not expect to operate on an average of over 75 per cent of the full capacity, which, at the maximum number of looms in place, would have been about 48,500 looms. Until 1926 the average of activity was in this neighborhood, but in 1930, with 56,000 looms in place, the activity was 25,000; in 1932, the low point, with 48,000 in place, the activity was from 13,000 to 22,000; in 1934, with 46,000 looms in place, the activity was 26,000; and in 1935, with 45,000 in place, the activity was 32,000, or 71 per cent (nearly normal); and in 1938, with 44,000 looms in place, the activity is 22,000, or 50 per cent.

This graph definitely shows a sharp division between the first and second decade of the period considered. During the ten years previous to 1928, the activity was seldom less than 36,000, while in the years since then it has never reached 36,000.

In order to complete the presentation of the loom situation, Fig. 4 has been prepared to show narrow looms in place and active. This shows that there were 19,000 narrow looms in place in 1919 and that in 1938 only 8000 of them remained. It also shows that the peak of activity was in 1923 with 16,000 looms running, and that at the present time there are only 2000 active. It is to be observed that the narrow-loom activity was between 3000 and 4000 looms from 1930 to 1937. The demand for narrow goods has been decreasing steadily and this is reflected in the loom activity. It is not possible to say just how far this will go, but it would seem from the indications that it may reach the point of almost complete extinction. It would naturally be assumed that the broad-loom activity would have been benefited by the decrease in narrow fabrics, and undoubtedly it was, but in spite of this the number of broad looms decreased steadily during this period.

On this graph also is shown the carpet looms, in place and active, in the United States. These are shown only as a matter of passing interest.

The graphs which have been presented show the extent of the liquidation of the spindles and looms in the industry during the 20-year period, and the decrease in activity which has been even more marked. The question naturally rises as to the causes for this apparent wiping out of from 25 to 50 per cent of an industry in 20 years.

A number of things may have contributed to this result, such as, (1) more efficient machinery, (2) lower consumption of woolen and worsted fabrics, and (3) a greater number of hours of operation of the active machinery.

There have been some rather radical changes in a few operations which would have had some effect on the amount of machinery required.

The spinning of woolen yarns on frames instead of mules has reduced the number of spindles required. The best information available indicates that there are about 78,000 frame spindles which, under average conditions, it is estimated would have replaced about 120,000 mule spindles, so that there might have been expected a reduction of 42,000 spindles due to this factor alone, but there was a reduction of 600,000.

The introduction of ring spinning in place of cap spinning in the making of worsted yarns might account for some reduction in this machinery, but not for the 500,000 spindles which have disappeared.

The wide adoption of automatic looms was a real factor, however, in the number of looms required. Twenty years ago probably not more than 3000 looms, or about 5 per cent were automatic. Today, there are reported to be 26,307 automatic looms, many of them of the latest models operating at much higher speeds and efficiency than the old nonautomatic looms. Some measure of this can be obtained by a study of the ratio of spindles to looms for the 20-year period. Table 2, giving the numbers of spindles and looms every 5 years, shows the trend.

TABLE 2 RATIO OF SPINDLES TO WOOLEN AND WORSTED BROAD LOOMS

(Machinery in place)

Year	Number of spindles in thousands			No. of looms	Spindles per loom
	Woolen	Worsted	Total		
1919	2393	2354	4747	62289	76.0
1924	2445	2718	5163	64111	80.5
1929	2345	2638	4983	58363	85.6
1934	1994	2368	4362	46834	93.0
1938	1866	2281	4147	44887	92.2

The average number of spindles per loom has increased from 76 to 93, or about 22 per cent, in spite of the fact that the spindle production per hour has also increased. Although there are no data available, it is quite certain that where the fabrics will permit, the automatic looms are run in preference to hand-feed looms. It is probably a conservative statement to say that the average active loom-hour today produces 20 per cent more than the loom-hour of 1923. This would account for a reduction of about 13,000 looms, whereas the actual reduction has been about 21,000.

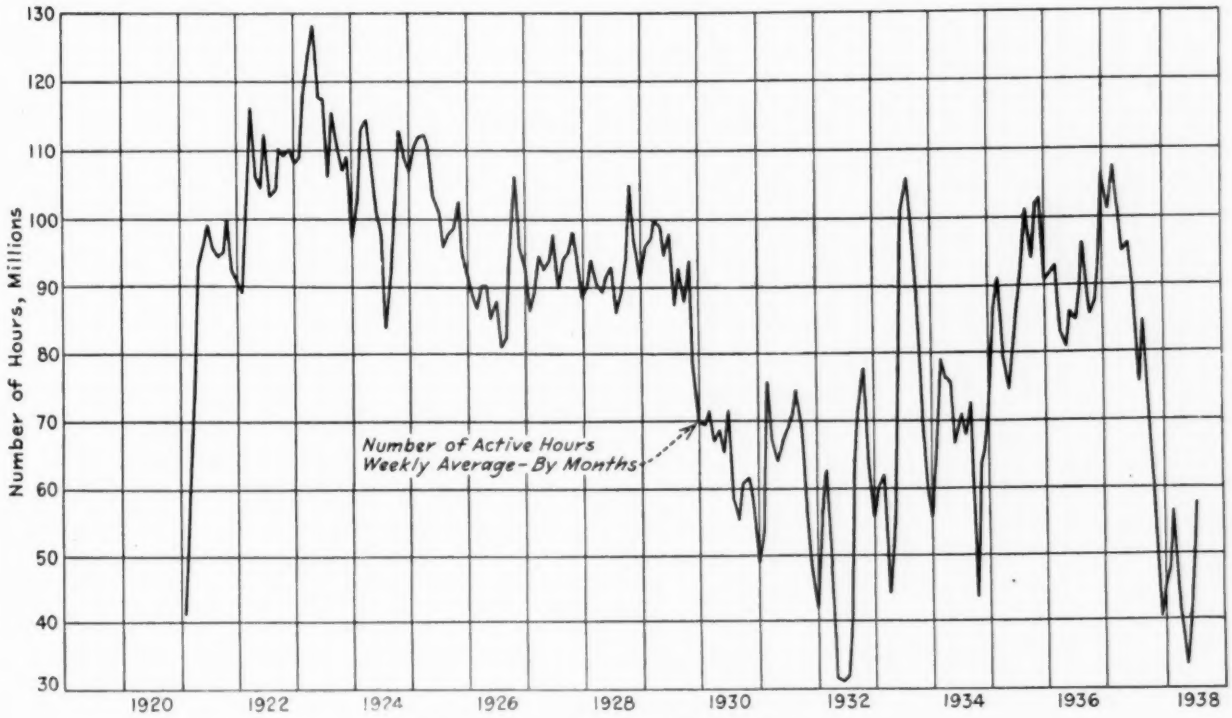

FIG. 6 ACTIVITY OF WOOLEN-SPINNING SPINDLES
(Active hours, weekly average by months.)

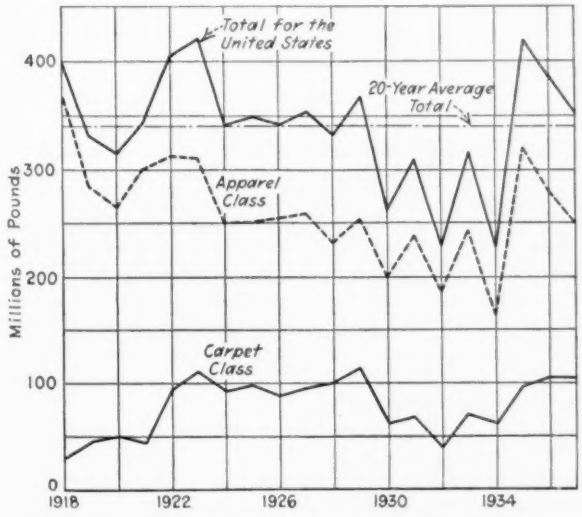

FIG. 5 RAW-WOOL CONSUMPTION BY CLASS, SCOURED BASIS

It would seem, therefore, that machinery changes alone account for only a part of the liquidation.

The question of consumption changes presents some difficulties. The worsted-and-woolen industry consumes a great variety of raw materials besides wool, such as animal hair, cotton, rayon, and silk, and in addition uses large quantities of reworked wools.

The information available from the government reports does not cover all years, and is in itself a little confusing. However, Table 3 shows the various materials used per year for the years when it was reported. The figures are probably not entirely correct for the minor items, but are reasonably so for the main ones and any inaccuracy would not affect the results materially.

The totals would indicate that there has been no general downward trend in production. The years from 1925 to 1929 were normal years and consumption was practically constant. The low production of 1931 is accounted for by the depression, and the 1935 peak by the increasing production from the 1932 low point. The average for the years reported is 523.45 millions of pounds of materials used, which is close to the more normal years from 1925 to 1929.

In this same table is given the total time which the looms were run for each year. From this was determined, at least arithmetically, the average production in pounds per loom per hour, which is given in the table. It probably is not entirely correct but it indicates that the production per loom-hour does not vary too much even with wide fluctuations in total production, and that the trend is toward higher levels, as one would expect.

Since the principal raw material of the woolen-and-worsted industry is wool, Fig. 5 was prepared, which shows the total consumption of scoured wool in the United States per year and that used by the apparel industry.

While the total consumption during the last 10 years is less than in the 10 preceding years, the 1935 peak would indicate that, under more normal conditions, consumption of wool might

TABLE 3 PRINCIPAL MATERIALS USED IN WOOLEN-AND-WORSTED-GOODS INDUSTRY

Material	Millions of pounds used in—					
	1935	1931	1929	1927	1925	1919
Wool, scoured basis	417.6	311.0	368.1	354.1	349.9	329.1
Animal hair	27.3	15.4	27.5	26.1	27.2	28.3
Cotton	12.5	14.5	20.2	22.8	26.6	17.3
Rags, clips, and recovered wool	111.4	51.8	93.0	81.6	106.5	79.6
Rayon	12.7	2.6	3.5	1.5	2.5	....
Silk and spun silk	0.65	0.45	1.2	1.9	0.6	0.4
Cotton yarns	37.3	27.0	43.0	31.5	26.8	28.7
Total materials	619.45	421.75	556.50	519.50	540.10	483.40
Yearly run, millions of loom-hours	95.6	74.4	95.6	98.6	112.8	....
Pounds per loom-hour, average	6.50	5.66	5.82	5.23	4.78	....

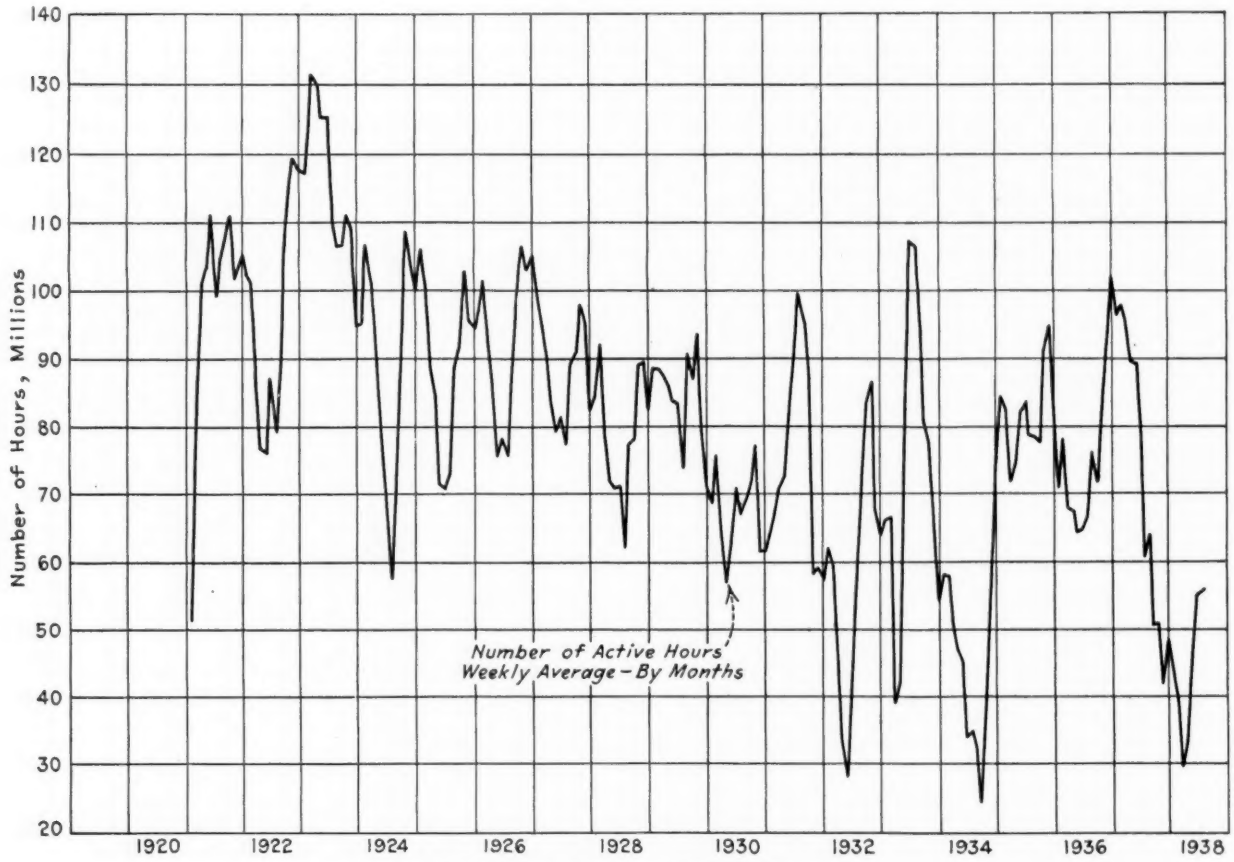

FIG. 7 ACTIVITY OF WORSTED-SPINNING SPINDLES
(Active hours, weekly average by months.)

be expected to be as much, if not more, than was consumed from 1919 to 1929. The table previously given, of all materials consumed, would lead to the same conclusion.

It is a logical conclusion that the use of higher production and more efficient machinery does not account for the decrease in machinery installed, and also that there is no permanent reduction in the quantity of raw materials consumed. In 1935, 319,000,000 lb of wool were consumed for apparel purposes as compared with 312,800,000 lb in 1922, with 534,000 fewer spindles, and 15,700 fewer looms.

And so the next point is the consideration of the hours of operation of the machinery in the industry. The actual number of spindle- or loom-hours operated per week or per year is, after all, the best measure of the condition of the industry, and a good indicator of consumption. It will be recalled that the amount produced per loom-hour varies little between periods of high and low consumption. There have been prepared some graphs of spindle- and loom-hours operated, which are interesting. These graphs show by months the weekly average for the month of the hours of operation. They do not show the maximum and minimum weeks but these would not be very different.

Fig. 6 shows the woolen-spindle activity on this basis. The graph accentuates what has been indicated on some of the previous graphs, and that is the higher general average of production of the first decade over the second. For the first time a real picture is given of the activity of recent years as compared with the period prior to 1930. In 1933, 1935, and 1937, the hours of operation reached a plane which compares favorably with the heights reached prior to 1930.

Fig. 7 shows the same information for the worsted spindles. It is to be noted that the annual fluctuations for these spindles are much greater than for woolen spindles. Peaks of activity and the depths of slack periods are more extreme than in the woolen industry but the general shape and trend are the same in both cases. It is the general impression that operations are much more erratic now than previous to 1929 and this graph would seem to bear out that impression, but it is also evident that the earlier period was not without its troubles. The greatest slump was the one that started in the middle of 1933 and continued downward for 15 months, almost without a stop.

Fig. 8 shows the average weekly number of hours of broad-loom operation, plotted by months. In general form, it follows the two previous graphs with its peaks and depressions coinciding as to time and varying as much in their swings.

The loom-hour is probably the best index of production in the woolen-and-worsted industry and because many looms use both woolen and worsted yarns, its activity is a reflection of the conditions in both branches. There is a noticeably general downward trend from 1921 to 1932 and what appears to be an upward trend since that time. The 1937 recession cast some doubt as to "where we go from here." It must be remembered that, in the period from 1926 to 1938, the number of looms in place dropped from about 64,600 to about 43,900 in spite of the fact that the 1937 consumption of raw stock was the maximum since 1919 when the keeping of such records was started.

Another interesting observation is that it required 12,750,000 loom-hours to consume 540,100,000 lb of raw stock in 1925, and in 1935 only 10,400,000 loom-hours for 619,450,000 lb of raw stock.

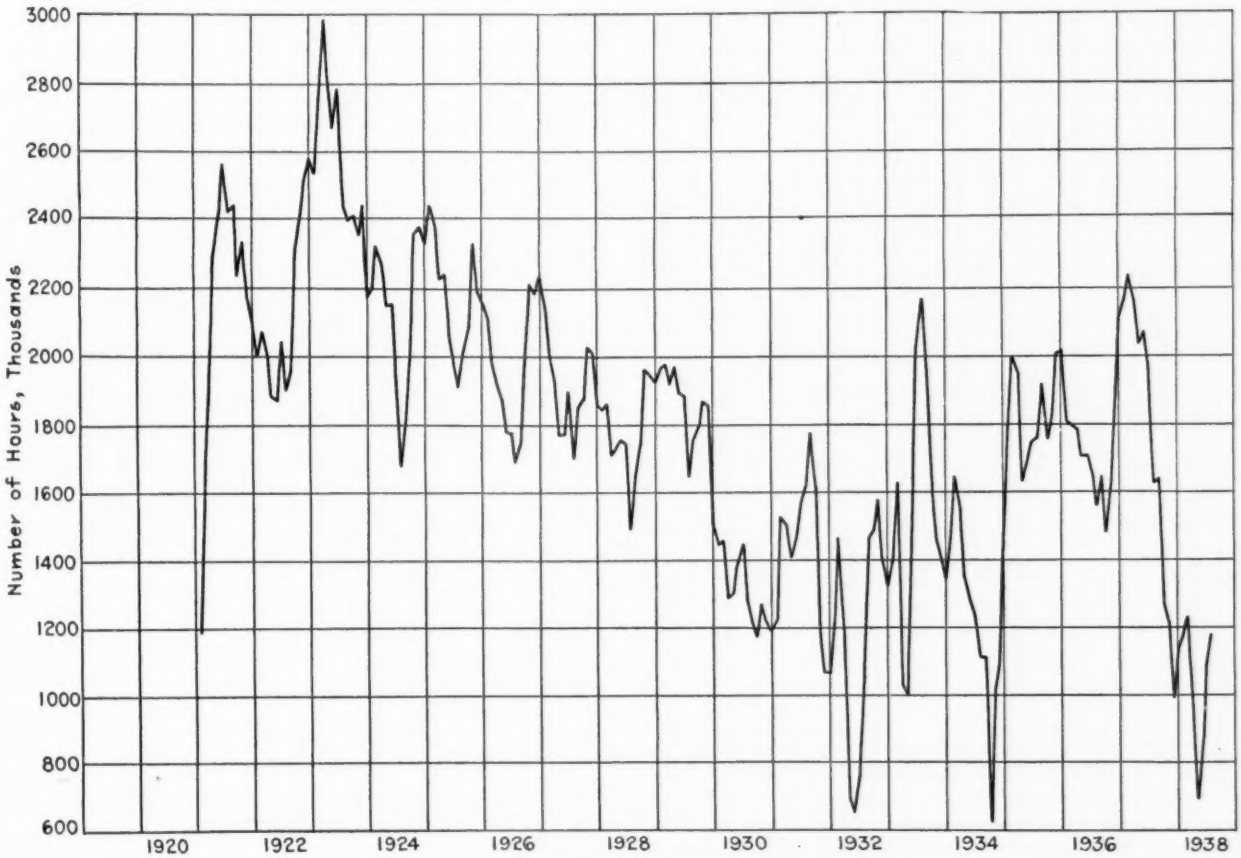

FIG. 8 ACTIVITY OF WOOLEN AND WORSTED BROAD LOOMS
(Active hours, weekly average by months.)

In order to properly evaluate such comparisons, there are tabulated in Table 4 several computations which were made of woolen and worsted spindles and looms at the beginning and end of the 20-year period. The raw-consumption figures are only available for certain years and the hours of operation only since 1921, so the years 1925 and 1935 were chosen because complete information was available for those years. However, since it covers only ten years, Table 4 does not reflect the full change in the 20 years.

TABLE 4 COMPARISON OF HOURS OF OPERATION IN 1925 AND 1935

Year	Thousands of spindles: In place	Thousands of spindles: Active	Approximate average, spindle-hours per week	Hours run per week: Spindles in place	Hours run per week: Active spindles
WOOLEN					
1925	2420	1950	92,700,000	38.4	48
1935	1950	1550	90,500,000	46.5	58.5
WORSTED					
1925	2760	1900	89,000,000	32.5	47
1935	2340	1650	82,500,000	35.3	50

Year	Looms: In place	Looms: Active	Approx. average loom-hours per week	Hours run per week—Looms in place	Hours run per week—Active looms	Raw materials, millions lb
LOOMS						
1925	64200	44200	2,168,000	34	49	540.1
1935	45200	32070	1,847,000	41	57.5	619.4

There are certain observations which can be drawn from Table 4, as follows:

1 While the number of woolen spindles in place was reduced 23.5 per cent, and the number of active spindles 20 per cent, the average weekly number of spindle-hours increased 21 per cent for those in place and 22 per cent for those active.

2 The number of worsted spindles decreased by 15 per cent of those in place and 13 per cent of the active spindles, but the number of hours operated per week for both in-place and active spindles increased only 6 per cent.

3 From the total yearly number of spindle-hours run by woolen and worsted spindles in 1925 and the raw-stock consumption of 540 million pounds per year, it is found that each spindle accounted for 2.70 lb of stock per week, whereas the corresponding figures for 1935 show that each spindle accounted for 3.76 lb per week, or an increase of 39 per cent.

4 The raw-stock consumption of 1925 divided by the loom-hours operated per year, gives 234.7 lb of raw-stock required to supply an active loom for an average week, while in 1935 an active loom, operating for its average weekly number of hours required 372.9 lb of raw stock, or an increase of 59 per cent.

The year, 1925, was quite normal for that period as to raw-stock consumption and hours of operation. The year, 1935, was a year of high consumption and a quite different setup as to hours of operation. In 1925 the mills in general operated one shift with some overtime, but in 1935 they were endeavoring to run two 40-hr shifts per week.

The figures would indicate that the production per loom had increased materially between 1925 and 1935. Eventually the 1937 figures will be available and this trend can be traced further.

The industry, because of its many ramifications in stocks and fabrics, the wide fluctuation in seasonal activity, and the relatively narrow range of yarns over which spindles can operate, is

bound to have a considerable number of spindles idle at any one time even though they all operate on an average 75 per cent of the year. It is not clear, therefore, that there will be much more liquidation of spindles except that due to the introduction of more efficient machinery.

The situation with reference to looms is somewhat different. Table 5 shows the average weekly number of hours operated per loom from 1921 to 1937. The first column is the weekly average for the year; the second column is the weekly average for the maximum month and the third column is the annual consumption of raw stock for the years in which it is available.

TABLE 5 ACTIVITY OF WOOLEN AND WORSTED BROAD LOOMS

Year	Active loom-hours, in thousands: Average week of year	Active loom-hours, in thousands: Average week of maximum month	Raw stock consumed, millions lb
1921	2140	2563	...
1922	2130	2577	...
1923	2560	2986	...
1924	2140	2389	...
1925	2170	2433	540
1926	1960	2235	...
1927	1900	2136	520
1928	1780	1963	...
1929	1840	1984	557
1930	1310	1463	...
1931	1430	1783	422
1932	1190	1584	...
1933	1550	2167	...
1934	1250	1649	...
1935	1840	2021	619
1936	1760	2119	...
1937	1710	2244	...
17 years' average.....	1810	2140	...

The noticeable feature is the steady decrease in loom-hours over the period without a corresponding decrease in raw-stock consumption. Assuming that the consumption of woolen and worsted fabrics is to continue at about the same rate as the present average year, which is reasonable, the figures would indicate that the average number of loom-hours required per week will be around 1,800,000 and the maximum not over 2,250,000. This gives a measure which can be applied to determine the number of looms which the industry can support for different numbers of weekly operating hours. Table 6 shows the results of applying this yardstick.

TABLE 6

Hours operated per week	No. of looms[a]: For 100% operation	No. of looms[a]: For 75% operation	No. of looms[b]: For 100% operation	No. of looms[b]: For 85% operation
40	45250	60400	56100	66000
54	33500	45000	41600	49000
80	22600	30000	28100	33000
108	16800	22400	20900	24600
120	15100	20100	18700	22000

[a] Based on an average number of 1,800,000 loom-hours per week.
[b] Based on an average number of 2,250,000 loom-hours per week.

On the basis of 1,800,000 loom-hours average per week, column 2 would indicate the number of active looms and column 3 the looms in place assuming 75 per cent activity for the conditions indicated in column 1. Column 4 gives the number of active looms on the basis of using 2,250,000 loom-hours per week average but it is assumed that if the activity reached this high level there would be only 15 per cent idle and column 5 gives the number of looms in place using this assumption.

It is probably useless to try to predict the actual hours of operation which legislation or other agencies will determine, but it is highly improbable that the work week will be a single 40-hour shift, because of insufficient capacity, or a single 54-hour shift because of opposition from many sources. Neither is the third shift likely to be acceptable in the long run, and operation for 120 hours per week is therefore doubtful. The most probable hours will be 80 per week, or possibly a few more. From the table it is seen that this would not require more than 33,000 looms, or about 10,000 fewer than are now in place. No prediction to this effect can be made, but a study of the graph of looms in place gives no clear indication that the liquidation has ceased. It is possible that there is no great excess of spindles but the further introduction of automatic looms must necessarily reduce the number required and the new automatic looms which can be converted to 4 × 4 box looms for pick-and-pick fabrics eliminates the necessity of keeping the older looms for that purpose, and again reduces the necessary number of looms in place.

The author is inclined to believe that the liquidation of woolen and worsted mills as a whole is nearing its close although there will be some further reduction in numbers of spindles and looms in operating plants.

The loom situation, however, is not quite as bright and there are many indications that the number of looms can be further reduced without any lessening of the amount of goods produced. This, again, does not mean the liquidation of existing weaving and finishing plants, but rather a reduction in the number of looms which they will operate.

The making of woolens and worsteds is a basic industry and its continuance at its present average rate of production is an absolute necessity. This does not insure, however, that because a plant is in existence today it must continue; only those who keep abreast of the times in their mechanical equipment, who foresee style trends, and who exercise good judgment in the management of their plants can expect to go on.

The Elastic Theory of Wood Failure

By CHARLES B. NORRIS,[1] GRAND RAPIDS, MICH.

This paper deals with various theories advanced for the failure of wood. The formulas developed by Jacoby, Howe, and Hankinson for expressing the crushing strength of wood are examined and their relative practical value indicated. Of the three the Hankinson formula, while being strictly empirical, agrees with experimental results better than the others. The author then proceeds to outline the steps of derivation of Hankinson's formula, applying the theory of failure advanced by Hencky. A second theory is analyzed which also leads to Hankinson's formula. The author points out that the methods used in deriving Hankinson's formula are very approximate but that such a formula is better than none.

THE FAILURE of wood has long been studied by the Forest Products Laboratory. Publication has been made of the strength values of woods grown in the United States when the stress is applied either parallel or perpendicular to the grain (1).[2] This study was greatly accelerated during the World War due to the extensive use of wood in the construction of aircraft. Numerous studies have also been made of the compressive strength of wood when the stress is applied at an angle to the grain of the wood. As a result various formulas have been developed, notably those of H. S. Jacoby, N. A. Howe, and R. L. Hankinson (2).

These formulas all express the crushing strength of wood N, in terms of the crushing strength of the wood parallel to the grain P, the crushing strength of the wood perpendicular to the grain Q, and the angle to the grain θ at which the stress is applied. The formulas are

$$\text{Jacoby} \ldots\ldots N = P\cos^2\theta + Q\sin^2\theta$$

$$\text{Howe} \ldots\ldots N = Q + (P - Q)\left(1 - \frac{\theta}{90}\right)^{1/2}$$

$$\text{Hankinson} \ldots\ldots N = \frac{PQ}{P\sin^2\theta + Q\cos^2\theta}$$

The Jacoby formula gives values which are too high compared with experimental results. The Howe and Hankinson formulas give very similar curves, especially for values of θ over 25 deg. The Hankinson formula is strictly empirical and agrees with the experimental results better than the other two. It seems to be the best formula but it cannot be applied to more general conditions of stress because of its empirical nature.

Considerable light is thrown upon the problem by applying the theory of failure developed by H. Hencky (3). This theory is very clearly described by A. Nádai (4). In this theory the total energy per unit volume, stored in a body due to elastic distortion, is divided into two parts, that due to the change in volume and that due to the change in shape. It is assumed that, when the elastic energy due to the change in shape reaches a certain value, the material changes from an elastic condition to a plastic one, i.e., it starts to fail. This has been found to be true of a great number of materials. The energy constant is different for each material but is independent of the manner in which the material is stressed.

The total energy stored in the material per unit volume is

$$^1/_2(s_1e_1 + s_2e_2 + s_3e_3) \ldots\ldots [1]$$

The energy stored due to a change in volume is

$$^1/_6(s_1 + s_2 + s_3)(e_1 + e_2 + e_3) \ldots\ldots [2]$$

where s_1, s_2, s_3 are the principal stresses and e_1, e_2, e_3 are the principal strains.

Subtracting Equation [2] from [1], the energy stored per unit volume, due to the change of shape, is obtained as follows

$$^1/_6(2s_1e_1 + 2s_2e_2 + 2s_3e_3 - s_1e_2 - s_1e_3 - s_2e_1 - s_2e_3 - s_3e_1 - s_3e_2) \ldots\ldots [3]$$

For simple compression $s_2 = s_3 = 0$, and Equation [3] becomes

$$^1/_6(2s_1e_1 - s_1e_2 - s_1e_3) \ldots\ldots [4]$$

or

$$\frac{s_1}{6}(2e_1 - e_2 - e_3) \ldots\ldots [5]$$

The three relations are

$$e_1 = \frac{s_1}{E_1}, \qquad e_2 = -\frac{s_1}{E_1}r_1, \qquad e_3 = -\frac{s_1}{E_1}r_2$$

where, r_1 and r_2 are the Poisson ratios in the two directions and E_1 is the modulus of elasticity in the direction of the stress s_1. Substituting these values in Equation [5], the energy per unit volume due to the change in shape becomes

$$h = \frac{s_1^2}{6E_1}(2 + r_1 + r_2) \ldots\ldots [6]$$

If this equation is applied to wood, first applying the stress in a direction parallel to the grain and then in a direction radial to the annular rings, the two following equations are obtained

$$h_L = \frac{s_L^2}{6E_L}(2 + r_{LR} + r_{LT}) \ldots\ldots [7]$$

$$h_R = \frac{s_R^2}{6E_R}(2 + r_{RL} + r_{RT}) \ldots\ldots [8]$$

At the point of failure

$$H = \frac{P^2}{6E_L}(2 + r_{LA} + r_{LR}) \ldots\ldots [9]$$

and

$$H = \frac{Q^2}{6E_R}(2 + r_{RL} + r_{RT}) \ldots\ldots [10]$$

Substituting values obtained from Equations [9] and [10] in

[1] Consulting Engineer, Mem. A.S.M.E.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Presented at Joint Meeting of the Wood Industries Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS and the Cost and Production Division of the Southern Furniture Manufacturers' Association at High Point, N. C., September 21–23, 1938.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until May 10, 1939, for publication at a later date.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Equations [7] and [8], the following values of the energy stored per unit volume due to the change of shape are obtained

$$h_L = s_L^2 \frac{H}{P^2} \quad [11]$$

$$h_R = s_R^2 \frac{H}{Q^2} \quad [12]$$

The first equation applies when the stress is applied in a direction parallel to the grain and the second when the stress is applied in a direction radial to the annular rings. The value of H is the same in both equations because the theory assumes that failure will take place at the same energy in either case.

Now, if a stress s is applied to a block of wood at an angle g to the grain, the state of stress of the wood can be described in terms of a stress parallel to the grain, a stress perpendicular to the grain, and a shear stress. These relations may be expressed as

$$s_L = s \cos^2 g \quad [13]$$

$$s_R = s \sin^2 g \quad [14]$$

$$q = s \sin g \cos g \quad [15]$$

The values given by the first two of these equations may be substituted in Equations [11] and [12] to obtain that part of the elastic energy due to each of the stresses s_L and s_R.
Thus

$$h_L = s^2 \frac{H}{P^2} \cos^4 g \quad [16]$$

$$h_R = s^2 \frac{H}{Q^2} \sin^4 g \quad [17]$$

The energy caused by the shear stress is all due to a change of shape. This energy is given by

$$h_S = \frac{s^2}{N} \sin^2 g \cos^2 g \quad [18]$$

where N is the rotational modulus of elasticity.

The sum of these three last equations gives the energy per unit volume due to the change of shape of the block of wood. This sum is equal to H at the point of failure.

$$H = s^2 \left[\frac{H}{Q^2} \sin^4 g + \frac{1}{N} \sin^2 g \cos^2 g + \frac{H}{P^2} \cos^4 g \right] \quad [19]$$

It is desired to find the value of H which will reduce this equation to Hankinson's formula. If

$$H = \frac{2PQ}{N} \quad [20]$$

this condition is satisfied. Both sides of [19] can be divided by H and the expression in the bracket becomes a perfect square. Taking the square root of both sides of Equation [19]

$$1 = s \left[\frac{1}{Q} \sin^2 g + \frac{1}{P} \cos^2 g \right]$$

Multiplying both sides by PQ and solving for s

$$s = \frac{PQ}{P \sin^2 g + Q \cos^2 g}$$

The foregoing derivation of Hankinson's formula is of course an approximate one. Yet by it Hencky's theory is made to apply to wood. The relation expressed by Equation [20] is a fundamental one. This relation can be used and the theory applied to more complicated conditions of stress. The theory should be checked by tests in which two separate stresses are applied to a block of wood at the same time.

The value of H can also be obtained by the use of both Equations [9] and [10] if the values of Poisson's ratios are known. The two values obtained in this way do not agree very well. This fact might be expected since the measured values of Poisson's ratios are only virtual because of the cellular structure of wood. The energy value given by Equation [20] should be the true elastic energy due to the change of shape of the cell walls.

Another theory of failure of wood can be devised which does check very well with the virtual values of Poisson ratios determined by test. This second theory also leads to Hankinson's formula and may be equivalent to the theory just given, the difference being due to the use of the true Poisson's ratios in one case and the virtual values in the other.

The criterion of failure in this theory is that the expression $(2e_1 - e_2 - e_3)$ reaches a certain value. In examining the meaning of this term, consider a block of material subjected to stress. The material is given the unit deformations e_1, e_2, and e_3 by the application of the stress. Of these e_1 is the greatest. Assume now that stresses are added so that these three deformations become equal. The expression above becomes zero. If the extra stresses are relieved, a unit volume of the material will change. The expression $(2e_1 - e_2 - e_3)$ is exactly equal to that change in volume. The units in which it is measured are cubic inches per cubic inch. According to this, as well as to Hencky's theory, hydrostatic pressure is incapable of causing failure. Of course this is not true of a cellular structure like wood, unless the liquid enters the spaces within the cells.

The development of this theory is similar to the development of the first theory but much simpler. The change in volume, when the extra stresses are removed, is of course given by

$$k = 2e_1 - e_2 - e_3 \quad [5a]$$

If the three stress-strain relations given in the first part of this paper are applied to this equation it becomes

$$k = \frac{s_1}{E_1} (2 + r_1 + r_2) \quad [6a]$$

The method is parallel to that just given.
Then

$$K = \frac{P}{E_L} (2 + r_{LR} + r_{LT}) \quad [9a]$$

$$K = \frac{Q}{E_R} (2 + r_{RL} + r_{RT}) \quad [10a]$$

$$k_L = s_L \frac{K}{P} \quad [11a]$$

$$k_R = s_R \frac{K}{Q} \quad [12a]$$

If the two relations given by Equations [13] and [14] are applied to the last two of these equations then

$$k_L = s \frac{K}{P} \cos^2 g \quad [16a]$$

$$k_P = s \frac{K}{Q} \sin^2 g \quad [17a]$$

The shear strain does not change the volume of the block of wood, so it does not affect the value of K and is therefore omitted.

The total change in volume caused by removing the extra stresses referred to is given by the sum of the foregoing expressions. At the point of failure

$$K = s\left[\frac{K}{Q}\sin^2 g + \frac{K}{P}\cos^2 g\right] \quad [19a]$$

The volume-change constant K cancels out and it can be seen at once that the equation reduces to Hankinson's formula.

The volume-change constant K can be obtained from either Equation [9*a*], Equation [10*a*], or a third one designated as Equation [10*b*]

$$K = \frac{R}{E_T}(2 + r_{TL} + r_{TR}) \quad [10b]$$

The agreement between the values obtained by the use of these three equations is very good. The Poisson ratios for various woods are not very well known. However, C. F. Jenkin (5) has given values for spruce, mahogany, ash, and walnut with the other elastic constants and the strength values for the same pieces of wood. The values for spruce under compression will suffice to show the agreement obtained. These values are

$$K = 0.00905,\quad 0.00635,\quad 0.00962$$

Considering the difficulty in obtaining accurate test data the agreement seems very good indeed.

The author realizes that the methods used in deriving Hankinson's formula are very approximate. There are twenty-one elastic constants for a material such as wood (6). Only ten have been used in this work. However an approximate formula is better than none. If this paper stimulates interest in the theory of wood failure it will have served its purpose.

Discussion

Energy Distribution in the Pulverized-Coal Furnace[1]

ADDENDA AND CORRECTIONS

W. J. WOHLENBERG.[2] While the use of radiant-mean positions of burning and ash particles for the purpose of approximating the equilibrium solution in Parts I to IV of the paper is valid, extension of their use for approximating the distribution of energy absorption as heat over the cold walls is not valid. The latter yields the artificial distribution shown in Fig. 9 of the paper. This could exist only if the particles were actually concentrated in their radiant-mean planes. Hence the secondary peak shown in curve No. 1 is the result of an assumed condition and has no place in reality.

It follows that Part V of the paper from its beginning to the heading "General Deductions and Conclusions" and Appendix 5 each involve such errors of assumption and should be replaced by the information submitted herewith for that purpose. Certain other omissions also are noted later in this discussion.

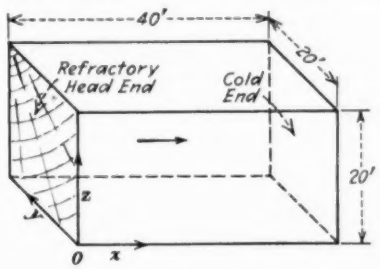

FIG. 1 CONDITIONS IN FURNACE CAVITY

(The cavity is single flow with charge entering through nozzles uniformly distributed over head-end wall. Since the cross section is a square and the longitudinal walls are alike (cold), the origin O may be taken at any one of four corners at the head end and the resulting pattern of contours of energy absorption as heat over cold walls will be the same. The fuel is carbon with 10 per cent ash, pulverized to 70 per cent through 200 mesh, and fired with 120 per cent air at 15,000 Btu per cu ft per hr. Radiant-mean temperatures from equilibrium solution are, in deg F abs: $T_a = 3460$, $T_r = 2540$, $T_g = 2465$, $T_f = 2453$, and $T_c = 1000$.)

Two of the latter affect the equilibrium solution in Parts I to IV. When these corrections are introduced the radiant-mean-temperature values change from those shown in Figs. 8 and 12b of the paper to those given here with Fig. 1. The total energy absorbed by the furnace walls as corrected is now 51.4 per cent of that supplied instead of 48.8 per cent as shown in Fig. 8 of the paper. Other details of this figure are of course also affected slightly but not sufficiently to alter either the qualitative nature of the results or the discussion with respect to them.

For the purpose of evaluating the distribution of energy absorption as heat over the cold walls of the cavity from the data obtained in the equilibrium solution it is necessary to consider the burning and ash particles in their real instead of in their radiant-mean position. The net radiating power of burning particles and ash particles is then determined with respect to each point of cold surface which it is proposed to investigate. This of course must also be done for radiation absorption at such points from the radiating gas molecules and the refractory wall. The relations and methods by means of which this is accomplished are stated later.

Referring to Fig. 1 herewith the points investigated in the longitudinal walls of the cavity $z = 0$ were chosen in lines $y =$ const with x variable. In the cold end the points were taken at $z = y$, that is, in lines connecting diagonally opposite corners. The results when plotted, Figs. 2 to 6, then form contours of energy absorption as heat for the longitudinal walls. For the cold end the points falling in the two similar diagonal contours are indicated.

The curves of Fig. 6 represent the final result sought. They are composed of information contained in Figs. 2 to 5 and so a brief discussion of each will aid in an understanding of this final result.

It is noted that in each figure the contour of lowest absorption rate is that for $y = 0$ where two walls intersect. Minimum points fall in corners at $y = 0, x = 0$ and $y = 0, x = 40$ ft. The rate of energy absorption rises more or less rapidly across the cavity from $y = 0$ to $y = 10$ for any given value of x and the contour of maximum absorption rate is in all cases that for $y = 10$. Corresponding contours are of course equally spaced, as to y, on either side of the central line $y = 10$.

Peaking of the contours in Fig. 2 is the net result of two effects which oppose each other. One of these is a geometrical influence which tends to increase the absorption rate at the point, from particles in suspension, as this point moves away from the end wall of the cavity. The other is due to the rapidly decreasing extent of radiating surfaces of burning particles as these move away from the head end of the cavity. The peaks occur in a zone close to the radiant-mean position of burning particles because in fact by far the larger fraction of burning-particle surface is concentrated in a region close to this radiant-mean position. This accounts for the close proximity to each other of contours $y = 1.0$ and $y = 10$ for $x > 5$. Contours for $y > 1$ and < 10 of course fall between those for $y = 1.0$ and $y = 10$. It is seen that the error introduced by computing the distribution of radiant-energy absorption over the cold walls from the radiant-mean position is not a large one in so far as burning particles are concerned. This however is quite the reverse for the ash particles represented in Fig. 3.

It is noted in this case that there is no similarity whatever between the shapes of the contours in Fig. 3 and curve No. 2 in Fig. 9 of the paper, which is supposed to represent the same thing. This clearly illustrates the magnitude of the error in distribution which was introduced on the former basis.

The rather abrupt rise from the left, of the curves shown in Fig. 3, is caused by the fact that as the surface point moves from the head end of the cavity it is rapidly passing into regions of greater and greater concentrations of ash particles.

Comparing Figs. 3 and 4 it is noted that the proportional spacing of contours $y = 1$ to $y = 10$ is considerably greater in Fig. 3. This is due to the difference in effect of radiant-mean thickness of the cloud in the two cases. As shown, this effect is much larger for ash particles in suspension than it is for the radiating gas

molecules in the range of thickness variations which occur in the present cavity.

In Fig. 5 all contours shown for absorption rate from refractory end, except that for $y = 0$, begin at substantially the same point for $x = 0$. That for $y = 0$ falls in a head-end corner of the cavity. For this corner the angle factor F'_{cr} subtended by refractory walls is 0.25. With $x = 0$ it requires only a small finite displacement from $y = 0$ toward $y > 0$ to increase F'_{cr} from 0.25 to 0.50 at which value it remains for all points $x = 0$, $20 > y > 0$. This accounts for the grouping of points shown on the ordinate of Fig. 5, at $x = 0$.

In Fig. 6 any ordinate of the contours of total energy absorption as heat is the sum of ordinates from Figs. 2 to 5 for the given surface point. The absorption rate over the total cold walls as computed on the basis of Fig. 6 differs by 5 per cent from the same thing as computed directly on the basis of the results, found in the equilibrium solution. This difference represents 2.5 per cent of the energy supplied by the fuel. In view of the numerous approximations, some of which are unavoidable, the check is probably as close as should be expected.

With respect to the cold end of the cavity it should be kept in mind that the absorption rates shown are due to radiation only. Hence if the gases leave through this end, the total absorption rate here will be increased considerably because of the large transfer by convection between gases and tubes. This has no influence on the temperature of the contents of the cavity because it does not occur until such contents are leaving the cavity. Thus it is seen how information furnished by the contour lines of Fig. 6 might be employed for estimating the convectional heat transfer at exit more closely.

All of the contours shown in Fig. 6, except that for $y = 1.0$, peak near the left end. Reasons for the peaking are now quite

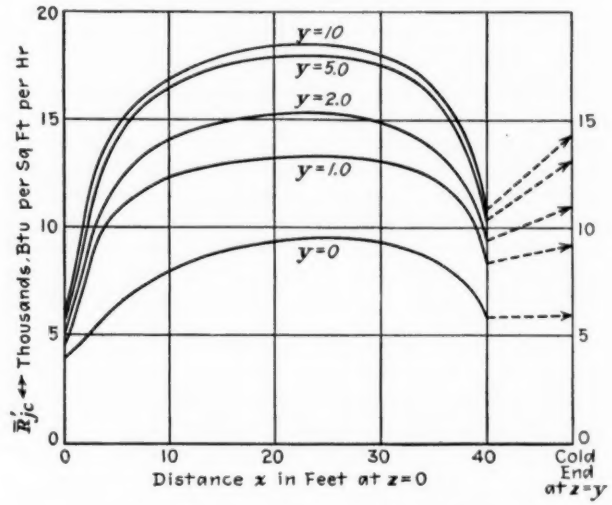

FIG. 3 $\bar{R}'_{jc}$, ASH PARTICLES ⇆ COLD WALLS

plain. Curve $y = 1.0$ does not peak because the combination of the rapid drop in the refractory curve for $y = 1.0$, Fig. 5, plus the effect of decreasing surface of burning particles more than offsets the sum total of other influences which tend to increase the absorption rate as the surface point moves away from the head wall. For $y = 0$, however, the curve again peaks because, as shown in Fig. 5, the contour for $y = 0$ starts low and so its gradient is much smaller than is that for $y = 1.0$. It follows that, for the conditions of this problem, the total contours between $y = 0$ and $y = 1.0$ except possibly those for which y is a very small quantity Δy, fall from a high point at $x = 0$ to a low point at $x = 40$ without peaking.

Relations for Determination of Radiant-Energy Absorption at Points on Cold Walls of Cavity. At any point of cold surface the radiant-energy absorption, Btu per sq ft per hr is

$$\bar{R}'_c = \bar{R}'_{uc} + \bar{R}'_{jc} + \bar{R}'_{gc} + \bar{R}'_{rc} \quad \ldots\ldots [1]$$

where index prime denotes this basis of reference. Then, with the same notation[1] except where otherwise noted

$$\left.\begin{aligned} \bar{R}'_{uc} &= \sigma\, \bar{\mu}'_{uc} F'(T_u^4 - T_c^4) \\ \bar{R}'_{jc} &= \sigma\, \bar{\mu}'_{jc} F'(T_j^4 - T_c^4) \\ \bar{R}'_{gc} &= \sigma\, \bar{\mu}'_{gc} F'\,(T_g^4 - T_c^4) \\ \bar{R}'_{rc} &= \sigma\, \bar{\eta}'_{cr} F_{cr}(T_r^4 - T_c^4) \end{aligned}\right\} \quad \ldots\ldots [2]$$

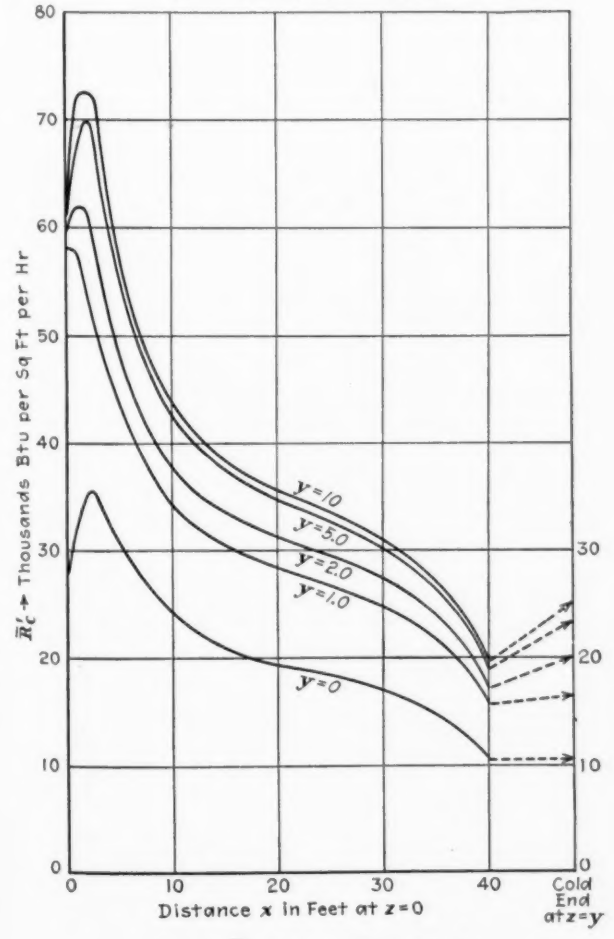

FIG. 6 $\bar{R}'_c$, TOTAL OF FIGS. 2 TO 5

FIGS. 2 TO 6 CONTOURS OF ENERGY ABSORPTION AS HEAT OVER COLD WALLS OF CAVITY
(Coordinates x, y, and z and furnace conditions as in Fig. 1.)

Angle factor F' is unity at all wall points except at an edge where two wall surfaces meet, or in a corner where three wall surfaces meet. For rectangular parallelepipeds $F' = 0.50$ along edges and 0.25 in corners. The special form on the right for $\bar{R}'_{rc}$ follows from the relation

$$A'_c F'_{cr} = A_r F'_{rc} \quad \ldots\ldots [3]$$

where cold surface A'_c is now unity. It is noted also that $\bar{\eta}'_{cr} = \bar{\eta}'_{rc}$.

Emissivity coefficients $\bar{\mu}'$ and transmissivity coefficient $\bar{\eta}'$ are each radiant means with respect to the point of cold surface under consideration. As an example, let μ' represent the value of the emissivity coefficient for differential region subtending angle factor dF from the considered point of cold surface. Then

$$\bar{\mu}' = \frac{1}{F}\int_0^F \mu' dF \quad \ldots\ldots [4]$$

where F is the angle factor of the total region from which the radiation under consideration may be thought of as converging toward the point under consideration. For an element dF of this region

$$\left.\begin{aligned} \mu'_{uc} &= (1 - \psi'_j f'_{jc})\,(1 - G''_{uc}) f'_{uc} \\ \mu'_{jc} &= (1 - \psi'_u f'_{uc})\,(1 - G''_{jc})\, f'_{jc} \\ \mu'_{gc} &= G'_{gc} - f'_{gc}\,(G'_{gc} - G''_{pgc}) \\ \eta'_{cr} &= (1 - f'_{cr})\,(1 - G'_{cr}) \end{aligned}\right\} \quad \ldots\ldots [5]$$

Here ψ'_j represents the probability that ash particles j will fall between burning particles and cold-surface point c. Factor ψ'_u is the same thing for burning particles u, relative to ash particles and cold surface. For uniform distribution relative to each other for the particles u and j, $\psi'_u = \psi'_j = 0.50$. If particles u and j are completely confined to separate zones with respect to each other along the radiant beam through both sets of particles, and radiation is from, say, particles u through particles j to wall point c, then $\psi_j = 1.00$. If under the same conditions radiation is from particles j through particles u to the wall, then $\psi_u = 1.00$. In view of these statements it is obvious that the following values of ψ apply to the conditions in the present furnace cavity:

All transverse beams, $\psi_u \approx \psi_j \approx 0.5$.

Radiation u to refractory end, $\psi_j \approx 0$.

Radiation j to refractory end, $\psi_u \approx 1.00$.

Radiation u to cold surfaces, ψ_j is between 0.5 and 1.00 and the mean value for radiation to all cold points is closer to 1.00 than to 0.5.

Radiation j to cold surfaces, ψ_u is between 0 and 0.5 and the mean value for radiation to all points is closer to 0 than to 0.5.

Factors G'' in Equations [5] are similar to factors G' but the beam length l'' varies in value between 0.5 l' and l' depending on the relative distribution between the intervening class of particles u, j, or p and the radiating gas molecules. The following range of values is seen to apply for the furnace conditions in the present cavity:

For G''_{uc} and point c near head end of cavity, $l'' \approx 0.5\, l'$. For point c at cold end $l'' \approx l'$.

For G''_{jc} and any location of point c, $l'' \approx 0.5\, l'$.

For G'_{pgc} all particles are considered as in one class p, and $l'' \approx 0.5\, l'$.

In other respects the notation of Equations [5] is similar to that employed in the paper.

In order to see how information, on which values of ψ', f', G', and G'' depend, may be furnished in such form that the results for $\bar{\mu}'$ and $\bar{\eta}'$ approximate those for radiant means of the type illustrated by Equation [4], consider the geometry shown in

Fig. 7, which applies to rectangular parallelepipeds. Here p is the surface point under consideration. For a given set of furnace conditions the radiant-mean values of ψ', f', G', and G'' throughout plane section $pqrs$, with respect to point p, may be approximated by reference to: (1) The radiant-mean beam length from p throughout the plane section; and (2) the line-mean values along x from x at p to x at q, of the concerned particle areas a_w, a_j, or a_g and of the concentration v of radiating gas molecules.

Of these line-mean particle areas between x at p and x at q, Fig. 7, that for a_w applies to f'_{wc}, that for a_j applies to f'_{jc}, and

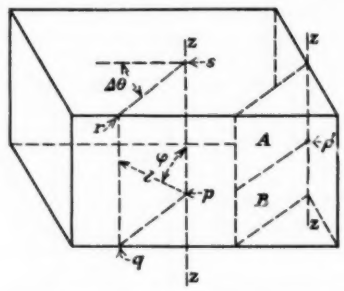

Fig. 7 Geometrical Aids in Approximating Radiant-Mean Values With Respect to a Point on a Wall

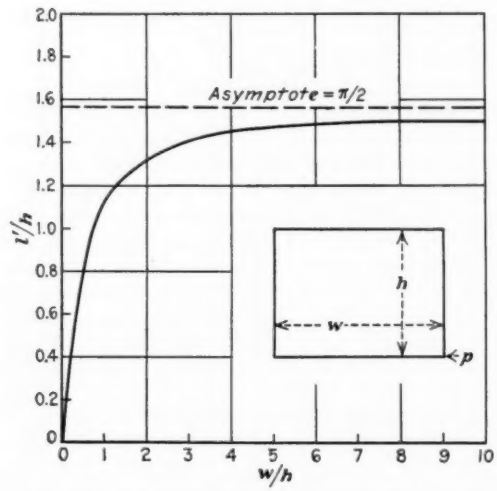

Fig. 8 Mean Beam Length l' With Respect to a Corner p for a Rectangular Plane Section

that for a_g to both f'_{gc} and f'_{cr}. The mean beam length l' from a corner p of plane section $pqrs$ is, of course

$$l' = \frac{2}{\pi}\int_0^{\pi/2} l\cos\varphi\, d\varphi \quad \text{..... [6]}$$

which on integration may, for convenience in use, be represented as shown in Fig. 8.

If p is located in the cold end of the cavity as at p', Fig. 7, the plane section is divided into parts A and B. The mean beam length l' for the whole section is a simple average of those for the two parts. Thus it is seen how values of ψ', f', G', and G'', and hence those of μ' and η' may be approximated for plane section $pqrs$ in any given position of rotation θ.

Suppose for a moment now, that instead of approximating μ' as just outlined, it had been evaluated on the basis of the relation

$$\mu' = \frac{2}{\pi}\int_0^{\pi/2} \mu\, d\varphi \quad \text{..... [7]}$$

where the emissivity coefficient has value μ along any direction l in section $pqrs$. This is its exact radiant-mean value for this plane section. On this basis the value of $\bar{\mu}'$ as found by means of

$$\bar{\mu}' = \frac{1}{\theta}\int_0^{\theta} \mu'\, d\theta \quad \text{..... [8]}$$

where edge qr of the plane section slides along the walls of the cavity, is exactly equal to that found on the basis of Equation [4]. Hence, if μ' in Equation [8] is determined on the approximate basis before outlined instead of by means of Equation [7] then Equation [8] yields a value of $\bar{\mu}'$ which closely approximates that found on the basis of Equation [4].

The integration indicated in Equation [8] is of course seldom possible or feasible for actual furnace conditions. In lieu of this, let plane section $pqrs$ occupy successive positions θ spaced by equal intervals $\Delta\theta$ from each other and covering the region θ from which radiation converges to the point p. On this basis the value of $\bar{\mu}'$ is a simple average of values found for each of the successive positions of $pqrs$.

It is noted that this procedure may be employed to find the radiant-mean values $\overline{\psi' f'}$, $\overline{G'}$, and $\overline{G''}$ of the coefficients $\psi' f'$, G', and G'' which appear in Equations [5]. When this is done the values $\bar{\mu}'$ and $\bar{\eta}'$ are computed from Equations [5] with $\overline{\psi' f'}$, $\overline{G'}$, and $\overline{G''}$ substituted for $\psi' f'$, G', and G''. They are thus products of the radiant means of the involved factors instead of the radiant mean of the product of such factors. This of course superimposes an additional approximation. The error involved is, however, a small one in most cases and the procedure is less cumbersome when this is done. For these reasons it was employed.

Additional Omissions and Corrections. In Equation [34], angle-factor term F_{wr} was omitted from both numerator and denominator. The corrected equation is thus

$$v_{wr} = \frac{\frac{1}{\varphi_s}\int_0^{\varphi_s} v_\varphi a_w F_{wr}\, d\varphi}{\frac{1}{\varphi_s}\int_0^{\varphi_s} a_w F_{wr}\, d\varphi} \equiv \frac{\overline{v_\varphi a_w F_{wr}}}{\overline{a_w F_{wr}}} \quad \text{.....for [34]}$$

In Equation [43] the radiation coefficient σ should appear in the denominator. Thus

$$G_{12} = \frac{\pi - \pi_2}{\sigma(T_1^4 - T_2^4)} \quad \text{..... for [43]}$$

Beam-length values for $\bar{l}_{wr}$, $\bar{l}_{wc}$, $\bar{l}_{wg}$, $\bar{l}_{jr}$, $\bar{l}_{jc}$, and $\bar{l}_{jg}$ in Equation [40] should have been computed on the basis that the source of the radiation is composed of *spherical* particles scattered uniformly throughout the radiant-mean plane for the class of particles indicated by the subscript. The beam length is then between this source just defined and the boundary indicated by the second subscript.

On this basis the following beam-length values should replace corresponding values in Equations [40] and [42].

$\bar{l}_{wr} = 3.7$ ft $\quad \bar{l}_{wc} = 13$ ft $\quad \bar{l}_{wg} = 9.0$ ft

$\bar{l}_{jr} = 14.5$ ft $\quad \bar{l}_{jc} = 13.5$ ft $\quad \bar{l}_{jg} = 13.7$ ft

$\bar{l}_{wpg} = 4.5$ ft $\quad \bar{l}_{jpg} = 6.8$ ft

On the basis of Equation [34] as revised and the corrected beam lengths, the corrected data for the equilibrium solution are as before indicated in this discussion.

Equation [57b] should be

$$\bar{R}_{rj} + \bar{R}_{wj} + \bar{R}_{gj} + \bar{L}_{gj} = 17 \text{ per cent} \quad \text{..... [57b]}$$

Term $\bar{R}_{rj}$ was omitted.

Combination Oil-and-Gas Burners[1]

H. H. WELLANDER.[2] The writer would like to have the author explain the method he uses to correct for sulphur dioxide in gas samples. In the burning of refinery gases rich in hydrogen sulphide, a considerable amount of sulphur dioxide is found in the flue gases. In an ordinary gas analysis, the carbon dioxide and sulphur dioxide are both measured as carbon dioxide. Therefore, the author should explain whether or not his curves are based on a sulphur-free determination of the flue gases.

D. S. FRANK.[3] The author's paper presents a timely comprehensive picture to the engineer interested in fuel. With the advent of low-priced natural gas, which is available in various territories, and the extra incentive of having burner equipment capable of taking natural gas at periods of low demands on the gas-company's distribution system, the combustion engineer is faced with the problem of selecting proper fuel stand-by equipment. This stand-by equipment must be for either pulverized coal or fuel oil, depending on the cost per 1,000,000 Btu.

The paper points out very clearly the main factors which should be taken into consideration when selecting the combination oil-and-gas burners.

The prime function of any oil burner is to properly atomize the fuel oil. Whether the atomization is obtained by pressure, as in the mechanical burner, or by steam or air, the important point is to break the oil up into particles as minute as possible. The next function is to surround properly each minute globule of oil with sufficient air to burn the oil completely, quickly, and with a minimum amount of excess air.

The problem of controlled flame length and efficient combustion is primarily one of turbulence. The importance of this one factor assuming sufficient time and temperature are present, cannot be overestimated.

Generally speaking, the greater the turbulence the shorter the flame, but also a noticeable increase in flame width on expansion through the burner throat. In view of this, the design of the combustion chamber tends to limit the choice of burner. In a long narrow firebox, the burners shown in Figs. 8, 9, and 10 of the paper would be more conducive to lower wall maintenance than the burners shown in succeeding figures. However, it appears that the burner illustrated in Fig. 16, due to the adjustable feature of the gas jets and individual air control, lends itself to practically any combustion-chamber design. This adjustable feature with ability to obtain various flame contours should tend to minimize burner troubles which have heretofore existed.

The proper selection of burner tips is also important. The writer has found that the multiple-round-hole tip is more conducive to low excess air when used with an air register than the flat flame tip. In a burner employing multiple gas jets, either the multiple-round-hole tip or the flat tip can be used with equal success. Here again, the design of the combustion chamber and spacing of the required number of burners tend to fix the correct type of tip to be used.

Ordinarily, the greater the turbulence, the higher the draft drop across the burner. In a forced-draft installation, this point can be taken care of in the fan and duct design, but in designing natural-draft installations it must not be overlooked.

Draft loss through the vanes and throat of an air-register type burner is a function of Btu release—the higher the Btu release, the higher the draft loss. For example, firing natural gas with 20 per cent excess air, the draft loss at a release of 10,000,000 Btu per hr is 0.19 in. of water, whereas at a release of 14,000,000 Btu per hr, the draft loss increases to 0.41 in. of water. Draft loss is also a function of throat diameter and the values just given by the writer are for a definite throat size. At the same Btu release on a larger throat diameter, the draft loss would be less than the values given. However, with increase in throat diameter, there is a decrease in turbulence for the same Btu release.

In burning fuel oil, the draft drop changes with the atomizing medium, as the draft loss is less for a mechanical-atomizing burner than for steam-atomizing burner, comparison being made at the same Btu release.

When designing the wind box for a forced-draft installation, considerable thought should be given to the capacity on natural-draft operation. If quickly detachable plates are incorporated in the wind-box design, and friction drop is low, the forced-draft burner can be operated on natural draft within reasonable limits. Longer flame lengths will, of course, be obtained.

The writer is familiar with the author's combustion charts and has found them very useful in making rapid furnace-efficiency calculations.

It is interesting to note that the stack-loss chart for a 10 A.P.I. residual petroleum oil can be used with very little error on any gravity fuel oil from 0 A.P.I. to 40 A.P.I. Assuming an arbitrary condition of 600 F stack temperature and 10 per cent excess air, a 0 A.P.I fuel oil shows a stack loss of 17.5 per cent; a 10 A.P.I. oil shows a stack loss of 17.7 per cent; and a 40 A.P.I. oil shows a stack loss of 18.5 per cent. Therefore, under the foregoing conditions, a maximum error would exist of 1.0 per cent. At 100 per cent excess air, the stack loss varies from 26.5 per cent for a 0 A.P.I. oil to 27.3 per cent for a 40 A.P.I. oil, or a maximum error of 0.8 per cent is involved.

Since industrial fuel oil is within the previously mentioned gravity range, and normally the excess air is also within this range, the chart can be used for rapid furnace calculations with a negligible error.

The stack-loss charts for a combination of fuels have proved to be helpful in determining furnace efficiency, and they are recommended for plants firing more than one fuel simultaneously.

R. C. VROOM.[4] In connection with the charts the author has prepared, perhaps it might be well to emphasize that those giving heat losses are in all cases based on complete fuel combustion.

Small furnaces and high rates of heat release, as the author points out, require efficient burners. The writer has fired with oil at a rate of 1300 lb of bunker fuel per burner per hr with excellent efficiency into a boiler furnace where the heat release approached 1,000,000 Btu per cu ft hr. In the U. S. Navy, heat releases exceeding 300,000 Btu per cu ft per hr with oil fuel are standard practice and the boiler efficiency is excellent. Our European neighbors are ahead of us in putting into practice in stationary plants what is possible in the way of furnace-heat releases. There is no valid reason why similar heat releases are not feasible with gas fuel using combined burners.

The author has in a sense defined the combined gas-and-oil burner as one having the ability to burn oil or gas equally well, separately or in combination. The words "equally well" are vital in this definition because there are few burners which fulfill that part of it. There are many which burn gas with a reasonable degree of economy; however, the oil feature is suitable only for stand-by purposes. In certain of these, when shifting from gas to oil, the output must be reduced and the excess air greatly increased. With some designs the use of oil alone for extended periods results in irreparable damage to the gas-burning elements.

[4] Chief Engineer, Peabody Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

The mere ability to burn oil temporarily by no means qualifies such burners as combined burners.

The ability of a burner to operate without cleaning is of major importance where oil-refinery heaters are fired with wet gas, especially if no distillate trap is installed. Several of the special designs for refineries shown in the paper, including the open-ring burner shown in Fig. 14 (in which the operating mechanism now has been modified to avoid the mechanical difficulty mentioned), are in general applicable to one particular kind of refinery heater.

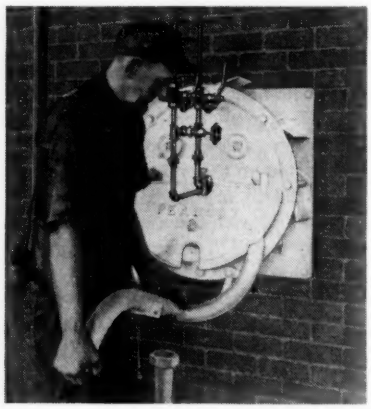

FIG. 1

However, the open gas ring which has no restrictions to cause plugging can be used with a standard air register and this assembly has been employed for firing boilers and many types of oil heaters. The removable closed-ring burner design, shown in Fig. 1 of this discussion, has found wide application in many refineries because it permits replacement of a plugged gas ring and at the same time permits oil to be burned during replacement.

In regard to liquid fuels, it is stated in the paper that any grade of fuel oil which can be delivered to a burner can be burned satisfactorily if the burner design is correct. This is true, but it is important in selecting a burner that full consideration be given to all the fuels which will have to be burned and to the results which will be considered as constituting satisfactory operation. A distillate burner, for example, could not be considered of incorrect design because it will not handle bunker *C* fuel. Neither should a burner be termed unsatisfactory if a fuel contains salts which attack the furnace brickwork. Sometimes such difficulties as unforeseen steam temperature, tube failure, high excess air in the exit gases, high stack temperature, low efficiency, and pulsation are due to faulty burner design or operation. Not infrequently the amount of superheater surface, scale in the tubes, leaky settings, fouled heating surface, and insufficient draft are largely responsible for such troubles.

In boiler firing, a combined burner is gaged by its ability to operate indefinitely with either fuel without damaging the elements provided for burning the other, and to do this over the full capacity range with complete combustion and a minimum of excess air. At the same time, the burner must be of a type which permits changing from one fuel to another almost instantaneously. Fig. 2 of this discussion shows a type of combined burner which is giving an excellent account of itself in most of the modern gas-and-oil-fired utility plants, as well as in many industrial plants and refineries, on the Pacific Coast. There are 225 burners in one station in Los Angeles. These plants are firing natural and refinery gases, bunker oil and refinery sludges, including acid sludge. For liquid fuel, some plants employ steam atomization while others use mechanical atomization. All types of boilers are being fired including integral-furnace and other recent designs.

In referring to the burner shown in Fig. 12 of the paper, the author mentions its lack of flexibility when burning oil due to mechanical fuel-oil atomization. Many engineers are of the opinion that all mechanical atomizers are greatly limited in capacity range, because such is the case with most of them. However, Estcourt[5] and others, who have had operating experience with the type of burner he describes, which is that shown in Fig. 5 of Philo's paper,[6] realize that a mechanical atomizer can have an extraordinary degree of flexibility.

In Estcourt's paper,[5] which describes what has been adopted as the regular low-load operating procedure at Station *A* of the Pacific Gas and Electric Company, San Francisco, Calif., it is shown that the automatic-control equipment is required to operate satisfactorily over a load range between maximum and less than 5 per cent of maximum capacity. With the 1400-lb boilers, each having a steam-generating capacity of 500,000 lb per hr, the

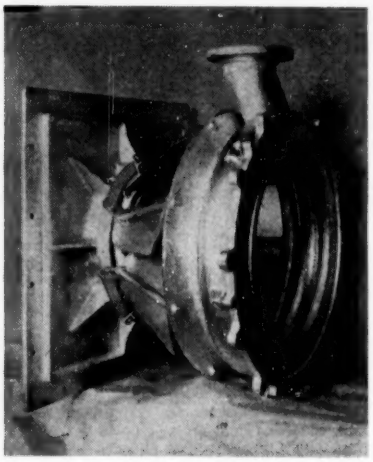

FIG. 2

minimum steam flow for satisfactory continuous operation with all burners in service is approximately 30,000 lb per hr (17-to-1 range) for gas fuel, and 65,000 lb per hr (8-to-1 range) for oil fuel. This paper[5] also states that it is entirely possible to operate (on swings) down to the same minimum load (oil fuel) with all burners in service (17-to-1 range) as is obtainable with gas fuel. In other words, the mechanical atomizers in this plant are anything but inflexible.

The paper[5] also states that "it is entirely possible that still lower loads may be obtainable. . . .(but) the figures just given are based upon a conservative opinion as to what is a satisfactory operating condition in the furnace." The burner gas pressure was 8 lb per sq in. at maximum capacity, and anyone who is interested can readily calculate what pressure would have been required for the minimum capacity. The arrangement for firing oil employed is essentially the constant-differential method of control mentioned by Philo in his paper.[6]

AUTHOR'S CLOSURE

In reply to Mr. Wellander's question regarding the flue-gas analysis to correct for sulphur dioxide in flue-gas samples, it will be necessary to know the refinery gas analysis and calculate the SO_2 produced as CO_2 and the stack-loss chart calculated on this basis. The CO_2 curve will be the CO_2 plus SO_2.

The Behavior of Sodium Sulphite in High-Pressure Steam Boilers[1]

H. F. JOHNSTONE.[2] It is important to note that there is no essential disagreement between the results reported by the authors and those of Taff, Johnstone, and Straub.[3] The tests made by the latter were run at concentrations of about 4000 ppm of sodium sulphite. Under these conditions decomposition was found in every case at temperatures of 545 F and higher. These results have been verified by later tests made by Professor Straub using bombs under steaming conditions. There were two reasons for choosing the high initial concentration for the tests: (1) To explain the disappearance of sodium sulphite from a high-pressure boiler in which localized concentration was believed to exist; and (2) to permit following the reaction without using complicated semimicro analytical methods.

At the high concentrations the rate of decomposition is proportional to the concentration of residual sulphite, a relationship which is generally said to indicate a first-order reaction. In all of the tests made over a 36-hr period, however, the percentage of sulphite remaining was between 2.4 and 4.1 per cent of the original amount, corresponding to 96 to 160 ppm. Since this concentration would have been reached in a much shorter time (6 to 23 hr at 600 to 550 F), if the initial rate of decomposition had prevailed, it is evident that the reaction either reached equilibrium, or slowed down appreciably at low concentrations. The small concentrations of sulphide found in high-pressure boilers by Hitchens and Purssell,[1] using sensitive methods of analysis, show that the latter alternative is probably true. The results of the two investigations,[1,3] therefore, are not at variance and, since they were carried out under different conditions, may be considered as actually confirmatory.

The fact that the decomposition is "pseudounimolecular" rather than of true first order is only of academic interest. The practical engineer is primarily interested in knowing the answer to the question: "Does sodium sulphite decompose in actual operation?" On the evidence obtained so far, the answer is: "Yes, at appreciable rates at temperatures above 545 F and concentrations above 200 ppm. At lower concentrations, not exceeding 30 ppm and in a boiler in which no abnormal concentrations are likely to occur, the salt does not decompose at a rate to be of practical importance."

Even when decomposition does occur, little is known about the nature of the products and whether their presence would be considered detrimental to boiler operation. It would be expected that the hydrolysis of sulphides to give hydrogen sulphide in the steam would take place as readily as that of carbonates to give carbon dioxide. There is indeed some evidence that this hydrolysis does take place. First, in the laboratory tests under steaming conditions the total sulphur content decreases when the vapors come in contact with copper or clean iron surfaces. Second, in four of the tests reported by the authors[1] on high-pressure boilers, no sulphide was found in the boiler water but corresponding analyses by their sensitive methods showed sulphide in the saturated steam entering the superheater, before concentration of carry-over could have taken place.

It is obvious that the chemical investigation of this subject is not complete. In view of the complexity of the reactions of sulphur compounds as shown by the extensive work of Foerster on decomposition of sulphurous acid and its salts, further investigation would seem to be justified as a precautionary measure.

L. DREW BETZ.[4] The use of sodium sulphite for oxygen removal has assumed a prominent place of importance in the field of water-conditioning chemistry. The behavior of this salt at elevated temperatures and under pressure is therefore of considerable importance. Prior to the papers presented by Taff, Johnstone, and Straub[3] and the authors,[1] little was known of the action of sodium sulphite under boiler-operating conditions.

The authors in the paper under discussion present some very interesting data and are to be congratulated upon the thoroughness of their investigation. Particularly impressive are the methods of analysis they have worked out for the determination of sulphides and sulphites in minute quantities in condensed steam. Without having actually used the methods proposed by the authors, it is very difficult to present a constructive discussion. With such information available, however, it should lend impetus to additional research in this field.

Regarding test method *A* which the authors describe in this paper, no mention is made of the possible interference of iron. Snell,[5] in describing a method he proposes for sulphides based on the same reactions given by the authors, states that while small amounts of iron do not interfere, larger quantities may possibly cause some trouble. Also, in using this method for the determination of sulphides in boiler water, some difficulties might ensue if organic matter be present in sufficient quantities to cause a discoloration of the water. Such difficulties would be in the nature of matching the color produced with the color standards.

It would also be of material value to ascertain whether any reactions occur between sodium sulphite and organic matter at elevated pressures. An analysis, made some few months ago in the writer's laboratories, of a deposit from a boiler tube, showed the presence of sulphates in quantities greater than the amounts necessary to combine with the inorganic cations present. The deposit was high in organic matter, leading to the assumption that the sulphate was originally present in the form of sulphite and quite possibly combined with the high organic content. A reduction in the amount of sodium sulphite used, in this instance, eliminated further deposits of this character.

AUTHORS' CLOSURE

The authors agree with Professor Johnstone that there need be no essential disagreement between the results reported by himself and coworkers and those by Hitchens and Purssell since the tests were made under entirely different conditions.

It is still felt that the traces of sulphite and sulphide found in the steam of the two higher-pressure boilers mentioned in the paper did not originate from hydrolysis of sulphites and sulphides in the boiler water but rather from decomposition of sodium sulphite carried over mechanically into the steam. The evidence for this is that the sulphite and sulphide both disappeared completely in the steam with decreased load on the boilers, a situation which is untenable with hydrolysis which proceeds at a rate quite independent of the steaming rate.

The authors still feel that the extent of contamination of the steam is too minute to be of any practical significance.

It is true as Mr. Betz says that appreciable amounts of ferric iron interfere with the colorimetric determination of sulphide with lead plumbite in method *A*. In fact the two react as follows

$$2\,Fe^{+++} + S^{=} \rightarrow 2\,Fe^{++} + S$$

[5] "Colorimetric Analysis," by F. Dee Snell, D. Van Nostrand Company, Inc., New York, N. Y., 1921.

There was too little iron in the samples of condensed steam to be of importance.

In the boiler water the presence of ferric iron is improbable since the excess sodium sulphite present would reduce it to the ferrous condition. It is felt that iron did not interfere with the tests for sulphide in the boiler water since addition of definite amounts of sulphide gave colors comparable to those with distilled water, iron-free.

It is true of course that the method is applicable only to a clear boiler water. Those the authors encountered were clear. It should be feasible to filter the water before applying the test with no loss of sulphide since the excess sulphite would keep it in the reduced form. Discoloration caused by organic matter might be circumvented by removal of the sulphide with nitrogen in a faintly acid solution and collecting on a lead-acetate strip. Each such water would be a research problem in itself.

The authors have no information on the reaction of sulphite with organic matter in boiler water at high temperatures and pressures. It will react quantitatively with aldehydes and ketones at lower temperatures. The authors are much interested in Mr. Betz's findings and would appreciate hearing of any later developments in the problem.

An Oil-Bath-Lubricated Railway Bearing[1]

H. M. Warden.[2] The writer has studied prints and has seen the "Disc-Flo" journal units in operation. There are several features that are improvements over the conventional box and parts, some of which would greatly improve the performance of present bearings if they were incorporated in A.A.R. designs.

One such item is dust guards. The old wood dust guard universally used insures no certainty of oil supply as it will not prevent the loss of oil. It is frequently detrimental to good bearing and journal performance as it fails to keep water and dirt out of the box. They make a poor fit between the box and the axle, and are not moisture-proof.

The paper in my opinion is correct in its statement that "serious trouble experienced today with A.A.R. type of bearing and box is not friction." Journal friction when reduced to a minimum by use of suitable oil and waste, properly turned journals, and broached bearings is but a small part of the total rolling friction. If oil, waste, journals, or bearings are not correct, hotboxes are apt to occur; however, failures of these parts are frequently due to presence of foreign matter in the box. A poor grade of oil or unstable feeding of oil, as well as presence of dirt in the box, are causes of most failures.

A good dust guard should provide an oil seal around the axle and in the dust-guard cavity, and the design should readily fit present A.A.R. boxes. It should also be manufactured at a reasonable cost.

Another item is the necessity of providing for lateral thrust of the axle to be applied against the fillet of the journal bearing by the journal fillet. A majority of bearings show excessive wear on the collar, which, besides loosening the lining, increases lateral play on a truck which already has too much. With present A.A.R. trucks operating under bad conditions, such as poor track, it is possible for the back of the boxes to strike the hub of the wheel. Changes necessary to locate lateral thrust at the journal fillet can be made by reducing tolerances and changing dimensions of bearings and wedges.

The self-aligning fit between the wedge and the roof of the box will overcome any irregularities in the box or contained parts, but the writer believes if it were exaggerated as shown in this paper it would further cut down lateral play since it would take the place of the wedge stop. Lack of oscillating movement for which the wedge is intended will cause the brass to bind, producing uneven loading, excessive friction, and eventually a hot bearing. When the top bearing is untrue it gives uneven pressure on the journal on account of improper seating.

The writer does not believe that a flat-back bearing or that extending the sides of the bearing will materially eliminate bearing tilt caused by impacts, but would probably take care of side movement resulting from reasonable brake applications if the boss in the box were extended close to the center line. Heavy impacts and emergency air-brake applications, even at slow speed, cause the bearing, wedge, and box to raise momentarily off the journal. If impact be heavy enough to displace the packing, which may be caught under the bearing, the result will be waste grabs.

The use of hardened pedestal liners is desirable to minimize wear. When pedestals are worn, a jerky movement occurs between the box and the pedestal and rocking of the box produces a distorted bearing face in the lining. Excessive wear may cause partial locking of the box. A pedestal out-of-alignment may prevent proper seating of the bearing and produce collar friction.

If recognized methods of maintenance and application of parts be closely followed and suitable oil and waste used, the A.A.R. journal box and parts will give satisfactory service; however, if the A.A.R. would adopt some changes in design incorporated in the Disc-Flo unit there is no question but that we would obtain longer life at less maintenance and have less trouble with journal box and contained parts.

In the foregoing comments the writer has in mind freight equipment, whereas the use of the Disc-Flo journal unit as covered by this paper seems to be intended for passenger-car service and would necessitate carrying a different stock of parts at all points for protection to such equipment. It is true that our passenger-car boxes and parts, wheels, and axles are better maintained and inspected more frequently, yet at times they operate under severe conditions. The writer understands that very few units have been applied for service tests and is not familiar with such tests, but he believes additional long-time service tests should be made under all conditions so that reasonably accurate comparative figures with A.A.R. standards would be available.

G. W. Ditmore.[3] The writer is not in a position to discuss the Disc-Flo unit from a practical standpoint having had no experience with its operation other than laboratory demonstrations. Laboratory tests have shown this device to possess great possibilities toward improved car-journal lubrication, providing actual service conditions do not develop unlooked-for difficulties.

The problem of developing a satisfactory sealing arrangement at the back of the box, that will function properly for the service life of the wheels without constant policing, when solved should be of great economic value to the railroads.

The authors deserve commendation for the exacting and thorough manner with which they have approached and are working to overcome one of the difficult problems of railroad operation.

The operation of Disc-Flo lubrication units in actual service will be followed with keen interest.

Frank E. Cheshire.[4] The writer has observed much of the laboratory research and many of the service tests of the Disc-Flo journal-bearing assembly. These observations have been made

[1] Published as paper RR-60-3, by Albert Vigne and I. E. Cox, in the August, 1938, issue of the A.S.M.E. Transactions, pp. 499–506.

[4] General Car Inspector, Missouri Pacific Lines, St. Louis, Mo.

as a railroad mechanical man. It is apparent, from approximately two years of operation under varying but representative service conditions, that a constant supply of lubricant is delivered to the contact surfaces by the device described by the authors. The problems encountered throughout these tests have not involved the lubrication as such. Alignment, control of the axle lateral play sealing the oil in and extraneous contamination out, and the difficulties arising therefrom have required correction. As long as oil has been available—and with one exception that condition has obtained—the requisite lubrication has been provided. That one exception developed the prime necessity for closer tolerances on axles new and reworked, on bearings, boxes, wedges, and truck dimensions. In this one failure the oil supply was lost due to a combination of wide tolerances permitting excessive uncontrolled axle lateral play. This condition is common in the conventional assembly and accounts for much of the loss of oil and entrance of extraneous contamination, in addition to excessive wear of the various parts of the assembly and resultant limited service life.

Since incorporation of corrective tolerances, several thousands of miles of satisfactory service indicates that this assembly will provide dependable service. This indication will be proved or qualified as the service mileage increases.

The writer believes that the inclusion of the research data in presenting this device offers a valuable contribution to advance in the science and art of journal lubrication. Speaking as a railroad mechanical man, it is encouraging to see presented a logical analysis of the fundamentals of one of our major problems. In something more than 20 years of almost daily contact with failures of journal lubrication, many of the phenomena, here broken up into causal components, have been observed. The writer has observed in service an incorporation of many of the corrections offered. The encouraging results therefrom induce a rather critical conviction that consistent improvement of considerable economic worth may justifiably be expected from an incorporation of the recommended corrections in the fundamentals of design and standards of practice. It is the writer's observation that our most difficult problems arise from the necessity for correcting faults in existing materials. The inexorable characteristics of established standards and practices have the weight of years of use. No one factor of railroad mechanical operation is more formidably surrounded by tradition than that of journal lubrication. Each railroad has followed a practice dictated by its individually traditional standard. It appears that efficiency in journal lubrication is measured by comparative reductions in transportation delays; or, in the words of an able contributor to critical investigation, "miles per hotbox is the operating bible." Such a yardstick does not include the greater economic factor, that is, the cost to attain that particular record.

It is the writer's further opinion that critical study and analysis of the data presented by the authors, and correlation thereof with service indications evident to anyone interested, will do much to remove prejudice, eliminate weak imitation, and discard outworn tradition in relation to journal lubrication. It occurs to the writer that the formulas presented by the authors for the determination of actual axle lateral movement, under any given set of dimensions, is a constructive contribution. The necessity for a definite imposition of the thrust load at the fillet end of the bearing should be obvious but has not been generally recognized. The means suggested for control of the axle lateral movement, within reduced limits, is simple and effective. Its effectiveness has been proved in service.

In the formulas, the truck dimension indicated as the inside flanges of the pedestal jaws, is assumed as a constant and constant it must be.

The increased, and increasing, demands of railroad transportation, in dependable service and economical operation, demand general recognition of the necessity for closer tolerances in both design and practice. The slight increase in initial cost to provide such tolerances is but a small portion of the higher operating expense resulting from a denial of this necessity.

Authors' Closure

The appreciated, well-qualified, and pertinent discussion raises two questions: What are the results of service tests on the Disc-Flo unit, and to what degree can the fundamental Disc-Flo improvements in journal-box and bearing design be applied to existing A.A.R. equipment.

At the presentation of this paper, 40 journal units in test service had accumulated 5,329,206 journal-bearing miles, or an average of 661,151 car-miles per car set, during which changes were made as described, incorporating lateral control, and improvement in disk drive and seal construction.

Since June, 1938, 48 journal units have accumulated 3,220,664 journal-bearing miles, or an average of 402,583 car-miles per car set. All of these journal units are in high-speed passenger service, and have given satisfactory operation with no maintenance other than routine terminal inspection.

A tender set of 6 × 11-in. journal units is being installed under a heavy high-speed passenger-locomotive tank and a car set of $3^3/_4$ × 7-in. units has just been installed in a modern high-speed streetcar, from which additional service data will soon be available.

Intensive study has been given to the application of the Disc-Flo improvements to the Standard A.A.R. journal box and bearing assembly.

A dust guard incorporating the design fundamentals of the Disc-Flo seal has been developed for the A.A.R. box. It consists of a resilient flexible sealing member sandwiched between two aluminum-alloy plates, one a seal plate, the other a follower plate. These plates are provided with bores of different diameters; the seal plate adjacent to the wheel fits snugly on the dust-guard seat of the axle, and the follower plate, having a larger bore, permits the flexible member to form an annular wiping flange which effectively seals the fit around the axle. The seal plate, due to its close fit on the axle, guides the seal assembly in following the movement of the axle in reference to the box, as the dimensions of the seal unit are such as to afford its unrestricted movement in a standard dust-guard well. The spring action of the resilient member holds the aluminum plates against the inside and outside walls of the journal-box cavity with sufficient pressure to seal against entrance of dirt and yet not interfere with the movement of the seal assembly.

Over 700 of this type of dust guard in its various stages of development are in service, and the oldest installation is still giving good service, having made a mileage of 260,000 in high-speed passenger service as of December 1, 1938.

The system of lateral control, standard in Disc-Flo design, can be applied without modification to A.A.R. axle, box, and bearing assemblies. By establishment of close tolerances on new and reworked axles, on bearings, boxes, wedges, and truck parts, and modification of dimensions of lateral-component lugs and collar of journal bearing, the evils of excessive lateral play can be overcome.

The degree to which it is desired to carry the bearing improvement as dictated by cost and departure from existing standards, requires a decision as to whether the standard steeple-backed A.A.R. journal bearing should have its collar and thrust-lug dimensions modified, or the standard wedge and bearing should be abandoned in favor of the flat-back lateral-control bearing with its modified wedge.

By modification of the collar and thrust-lug dimensions of the standard A.A.R. bearing, the desired reduction in axle free

lateral play can be secured, but to stabilize the respective running positions of the axle and the bearing and to increase the thrust capacity of the bearing the flat-back type has to be resorted to.

In answer to Mr. Warden's doubt as to the ability of the flat-back bearing with extended sides to overcome tilting, it should be pointed out that with this combination, using a flat wedge, there is no inclined plane formed by the wedge for the bearing to climb, when horizontal impact is imposed on the axle. Further the force of the horizontal axle impact against the more nearly vertical extended side of the bearing exerts relatively small lifting force on the bearing and this has to be in excess of the static vertical load before there is any raising of the bearing.

Over 4600 A.A.R. type bearings modified for lateral control have been put in service with results that justify the foregoing statements.

One hundred thirty-two flat-back lateral-control bearings have been applied in heavy locomotive-tender service, and on high-speed passenger cars, with a single brake shoe per wheel. Under this severe service, the life of the journal bearings has increased beyond all expectation.

Problems in Modern Deep-Well Pumping[1]

CARLTON W. DAWSON.[2] The author has presented a clean-cut mathematical analysis of deep-well pumping problems, and engineers who deal directly with these problems may learn much from his careful study.

Prior to this time the importance of the step-tapered rod string (the closest approach to the rod string of uniform stress) has been recognized and used almost exclusively in sucker-rod pumping at depths greater than 7000 ft. Reasonable rod service has been achieved, but production rates have been well below the maximum rates given by Equation [18] of the paper.

The author has analyzed plunger overtravel as a function only of the accelerations at the ends of the stroke. Assuming harmonic motion, the polish-rod-stroke correction factor becomes $F = 1 + [1.93\ (LN)^2/10^5]$. However, to give results in closer agreement with those obtained by field tests with the Gilbert-Sargent bottom-hole dynagraph, it is suggested that the pitman-crank-length acceleration factor be applied. With a ratio of four, the foregoing formula becomes $F = 1 + [2.4\ (LN)^2/10^5]$. This correction assumes the magnitude of acceleration at both ends of the stroke to be equal and opposite in sign. Actually, in the conventional pumping unit, the acceleration at the bottom of the stroke is due to the individual crank and pitman accelerations being additive when at 180 deg. Conversely, when at the top of the stroke the pitman overlies the crank and the acceleration of the pitman is subtracted from that of the crank. The sum of top and bottom acceleration is approximately equal to the sum if the motion be actually harmonic. The significance of this is that the first correction is the only one theoretically justified.

But, because calculations based on this formula do not agree with actual performance, it is obvious that a more involved treatment is justified. Various applications of Timoshenko's work on vibrations have been attempted; notably those of R. W. Rieniets[3] and Kendrick and Cornelius.[4] This approach gives promise of being much more satisfactory, although a great deal more correlation of field data is required to provide the essential support.

In the summary of the paper, the author states that pneumatic counterbalances are adapted to heavy loads and will give lower peak loads than beam or crank balances. This is true, but is due not to the type of balance but to the effect of the accelerations. The point of attachment of the pitman and crank on air-balanced units is between the samson post and polish rod, whereas the samson post of the conventional units is between the pitman and polish rod. As pointed out previously when the pitman overlies the crank the accelerations of each are of opposite sign, and when they are extended at 180 deg they are of the same sign. This means that the air-balanced units have greater rod acceleration at the top of the stroke where the effect is to reduce the rod load. The conventional unit has the greater acceleration at the bottom of the stroke where the effect is to increase the rod load.

AUTHOR'S CLOSURE

Mr. Dawson's criticism of the relation $F = 1 + [2.4(LN)^2/10^5]$ is well founded. This seems to fit field results more closely than the previously used relation, but its use must be based on its value as an empirical relation rather than a fundamental of crank motion.

The air balance whether directly applied as in the Sullivan head or in combination with a crank motion tends to smooth out the load measured at the polished rod. It is true that the point of attachment of the pitman is a factor, but the absence of the large mass of the counterbalance is thought by the writer to be of greater importance.

Industrial Power

By CHARLES W. E. CLARKE,[1] PHILADELPHIA, PA.

This paper covers briefly the progress that has been made in the generation of power in industrial plants. The author points out that industries and utilities are cooperating in the generation and interchange of electric energy in order to reduce waste in many manufacturing processes.

Higher steam pressures and temperatures are widely used, along with superposition of new turbines on old equipment. Only a few installations have pressures and temperatures which exceed 900 lb per sq in. and 850 F, respectively. A number of prominent industrial plants are described to indicate the application of all types of steam turbines to the three steam cycles most commonly employed. Steam-pressure-reducing and desuperheating equipment, as developed for topping units in central stations, is finding new applications in industry. Where large quantities of process steam are needed, many interesting arrangements of modern equipment can be used to reduce the cost of power generation.

The trend in design of boilers is toward larger units, higher steaming rates, and more complicated automatic controls to permit utilization of several different kinds of fuel in the same furnace. This presupposes the proper treatment of boiler feedwater, the importance of which is emphasized. Operating data from two outstanding installations are included. Among smaller plants there is a tendency toward the use of a self-contained boiler; also, there has been a revival of semi-outdoor constructions.

Progress is being made toward better utilization of unusual fuels, such as pulverized anthracite culm, lignite, acid sludges, and black liquor, the latter of which is obtained in the process of manufacturing kraft paper.

Improvements in electrical equipment for industrial plants include metal-clad switchgear, which may be located in any available space; also, air circuit breakers for voltages up to 5000 may soon be available in order to eliminate the fire hazard from using oil. Modern insulation on wire and cable offers greater resistance to high temperatures and the effects of moisture and other harmful substances.

THE art of providing suitable electric-generating facilities for industrial use requires analysis of many factors such as type of load, source of water and fuel supply, condition of existing equipment, future growth, possible steam pressures and temperatures, interconnections, and numerous other items incident to any particular project.

As a general premise it is safe to say that in industrial plants where there is a reasonable demand for process steam of moderately low pressure, it will generally be found economical to furnish generating capacity up to the requirements for this steam, and in cases where no process-steam requirements exist it will usually not be found economical to install condensing units. This premise assumes of course that there is available in the district satisfactory service from a local utility.

First let us consider cooperation between manufacturing plants and public-utility companies in generating steam and electricity. In most localities the manufacturing industry and the utility have many interests in common. There are, for example, by-products such as waste heat, coke, wood waste, coke-oven gas, blast-furnace gas, and oil-refinery refuse. In the interests of the community, as well as for conservation of resources, these products should be used. Production of steam and power is one important means of doing so. Yet in many plants using steam for process the demand for steam does not synchronize with the demand for electric energy. Seasonal demands also complicate the picture. When a tie line to the utility is available, the latter's resources of power can take care of fluctuations in demand. No condensing machines need be installed as the high-pressure turbines run exclusively for low-pressure-steam requirements. Spare equipment with its costly fixed charges can be omitted and when the turbine is out the utility supplies the electric load and the boiler the steam requirements, through reducing valves.

Power companies are now meeting this important economic problem, which frequently involves both the sale of electric energy to and its purchase from the same industrial customer. Progress along this line has been slow but is certain to accelerate in the future as the demand for cheaper industrial power becomes more determined. The two parties concerned have everything to gain and nothing to lose in disclosing all facts and marking out the correct solution. There are at the present time under construction on the west coast projects involving such cooperation between oil companies and the local utility.

Turbogenerators

Due to the great variety of conditions to be met in industrial practice, turbines for such applications are usually built to order, and the following types of turbines are available for both condensing and noncondensing service: Nonextraction, single automatic extraction, double automatic extraction, and mixed pressure. These turbines can be built for any reasonable capacity and steam condition and a wide choice of extraction and exhaust pressure is available. Except for special cases, the machines usually operate at 3600 rpm.

Although maximum steam conditions up to about 1300 lb and 950 F can often be justified, from the practical viewpoint 900-lb pressure and 850-F total temperature appear to be the sensible limits for most industrial plants. In a few cases, such as at the River Rouge Plant of Ford Motor Company, installations have been made at 1215 lb and 925 F. Incidentally, there is in the process of construction an installation which is to use 2500-lb pressure. Usually such plants approach the utility stations in size of units and skilled personnel to supervise operation. The ordinary industrial plant is not so fortunate. Here, generation of power is not a major function but only one item necessary in the manufacturing process. Until the power companies have

Contributed by the Fuels Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

had more practical experience with the higher steam conditions and accompanying precision in superheat control, the majority of industrial plants should operate under the lower pressure and temperature conditions just mentioned.

The superposed turbine has gained wide prominence during recent years. The rapid rise in pressures and temperatures has allowed old equipment to be so modernized that it can be used for operation on the low-pressure end of a cross-compound cycle. The overall-heat rate is greatly reduced as the same amount of heat is rejected to the condenser before and after superposition.

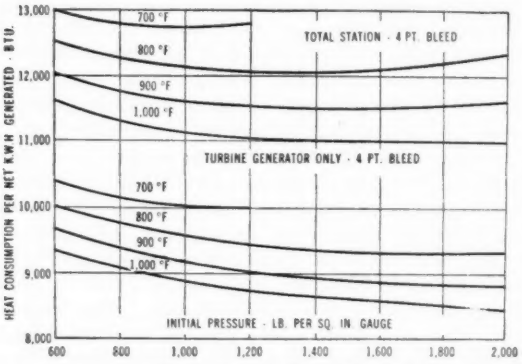

FIG. 1 ATTAINABLE HEAT RATES WITH HIGHER PRESSURES AND TEMPERATURES

Thus, obsolete and stand-by equipment become an integral part of an up-to-date installation and, in addition, the plant capacity is increased at a cost per kilowatt generally under that required for equal capacity in a condensing unit. One important item in favor of superposition is the fact that while the generating capacity of the plant is increased there is no additional demand for condensing-water facilities due to the increase in load. This is highly important in cases where the condensing-water supply is limited.

Most of the central-station topping units operate at about 1250-lb pressure and 900-F to 950-F total temperature. The effect of increased pressures and temperatures on the heat cycle are clearly indicated by Fig. 1.

As many industrial plants now operate at about 200-lb pressure, the 650-lb superposed turbine offers substantial returns on the investment and, moreover, utilizes medium pressures and temperatures. Generally speaking, industrial-plant conditions do not lend themselves to the straight superposed unit as readily as do those existing in central stations. Variations of the superposed turbine, permitting steam extraction for process use, are becoming widely used in industry as discussed later under "Steam Cycles." The common impression that superposition is the last step in modernization is quite erroneous, as 10 or 15 years hence it will be necessary in many cases to replace the low-pressure turbines now being topped. In fact, it is entirely possible that due to further experiments in the use of still higher steam pressures the units now being superposed may again be topped.

Ordinarily, the requisite pressures of process steam and the use made of it determine the most desirable conditions for the throttle steam. Usually a small amount of superheat in the process lines is desirable to ensure dry saturated steam at the point of use. To satisfy these conditions it is seldom necessary to exceed 600-lb pressure and 800 F at the turbine inlet.

A survey by *Power* of industrial plants in which 117 steam turbogenerators were installed during 1936 and 1937 discloses the classification as to types listed in Table 1. Grouping these turbines according to generating capacities, we obtain the tabulation given in Table 2.

TABLE 1 INDUSTRIAL-PLANT TURBINES INSTALLED IN 1936 AND 1937 LISTED ACCORDING TO TYPES

Throttle pressure, lb per sq in.	Total number of turbines	Types of turbines: Condensing	Condensing extraction	Back pressure	Back pressure extraction	Mixed pressure
1200	4	0	1	3	0	0
700–900	15	0	5	7	3	0
500–700	13	0	4	7	2	0
400–500	58	3	26	16	11	2
200–300	27	2	9	11	5	0
Total.....	117	5	45	44	21	2

TABLE 2 TURBINES LISTED IN TABLE 1 GROUPED ACCORDING TO GENERATING CAPACITIES

Throttle pressure, lb per sq in.	Capacity, kw: Under 500	500 to 1000	1000 to 2000	2000 to 3000	3000 to 4000	4000 to 5000	5000 to 10000	10000 to 20000	20000 and up
1200	0	0	0	0	0	0	2	1	1
700–900	0	1	1	1	4	6	1	1	0
500–700	0	0	3	2	1	2	4	0	1
400–500	5	5	13	11	4	5	13	1	1
200–300	6	8	5	3	1	3	1	0	0
Total.....	11	14	22	17	10	16	21	3	3

NOTE: Some pertinent facts gleaned from this survey (see also the data in Table 1) are as follows:

Only four machines operate at a pressure of 1200 lb per sq in. Two at the Ford Motor Company, one at the Firestone Tire & Rubber Company, and one at the Dow Chemical Company.

Pressures of 400 to 500 lb per sq in. are most popular.

Mixed-pressure turbines are still rarely used.

There are only five straight-condensing turbines.

Only two machines use steam of 950-F total temperature; four machines use steam of from 800 to 825 F; and the remainder use steam under 750 F.

All but six machines are under 10,000-kw capacity.

The speed for all but 22 of the units is 3600 rpm.

TABLE 3 EFFECT OF SIZE OF STEAM GENERATING EQUIPMENT ON PRICE

Size of steam-generating equipment, lb per hr	Cost per 1000 lb of steam, per cent
100000	Base
200000	0.700
300000	0.600
400000	0.550
500000	0.525
750000	0.500
1000000	0.485

TABLE 4 EFFECT OF SIZE OF TURBOGENERATORS ON PRICE

Rating, kw	Cost per kilowatt, per cent
1000	Base
1500	0.850
2000	0.775
2500	0.730
5000	0.635
7500	0.625
10000	0.687
15000	0.652
25000	0.623
50000	0.462

Before leaving the subject it is quite pertinent to remark that in too many new installations the block of additional power required is underestimated; consequently, the capacity of the new unit soon becomes inadequate. Future growth of electric load is a problem that deserves thorough study and analysis. Moreover, the greater the machine capacity, the less the unit initial cost and maintenance. In Table 3 are some recently published figures showing the influence of size on the cost per 1000 lb of steam for steam-generating equipment. Similarly, Table 4 indicates the effect of size on the price per kilowatt of turbogenerators. The figures in Tables 3 and 4 are for 450-lb 750-F units, but the ratios will be approximately the same for other pressures.

Encouraging this trend toward larger units has been the increase in availability of boilers. It is practically equal to that of turbogenerators. Hence, the common practice today of installing one boiler unit per turbine unit on interconnected systems or in plants having two or more units.

STEAM CYCLES

Conditions existing in each industrial plant dictate the steam cycle and type of turbine to be selected.

Steam Cycle No. 1. The simple cycle shown in Fig. 2 offers

large savings when applied to an existing power plant. The back-pressure turbine, with throttle pressure higher than the existing plant equipment, exhausts the steam into the old generating equipment or to the station steam header. A few of the industrial plants which recently have adopted this cycle are described below.

Weirton Steel Company at Weirton, W. Va., was faced with a rapidly increasing power load. There was no spare generating equipment and the 215-lb boiler plant was 26 years old. They installed a 10,000-kw superposed machine operating at 800-lb throttle pressure and 800-F total temperature. This unit exhausts at 215-lb back pressure and delivers sufficient steam to permit retirement of all the old low-pressure boilers. The result has been continuous and satisfactory operation with a saving of 500 tons of coal per day for the same load carried previous to the expansion. The two boilers, each with a capacity of 400,000 lb per hr, are fired primarily with pulverized coal, with coke-oven gas automatically spilled over into the boilers when not needed in the steel mill. The boilers operate on 100 per cent make-up water, chemically treated. As week-end shutdowns are not permitted by a steel-mill power load, these boilers have low steaming rates per foot of furnace width and ample drum space for liberation of steam.

The recent installation at Dow Chemical Company is another example of possible savings from power generation. The old plant consisted of several 400-lb 600-F boilers and turbines. Part of the 400-lb steam is used directly in the chemical processes and the remainder passes through reducing turbines, some exhausting at 150-lb pressure, some at 10-lb pressure, and the others expanding to 26 in. of vacuum, where the steam is exhausted to evaporators. Instead of enlarging their 400-lb plant they decided to purchase a 1250-lb 825-F boiler and back-pressure turbine.

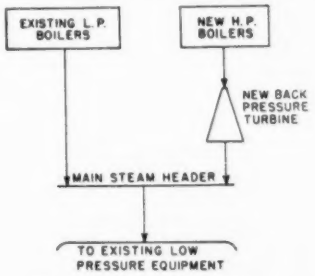

FIG. 2 STEAM CYCLE NO. 1

Some of the pertinent facts on which this decision was based were (1) favorable space requirements; (2) a 1250-lb plant, while providing additional 400-lb steam needed for process work, would allow the generation of approximately 30 per cent more power; (3) the thermal efficiency of plant, the fuel cost being relatively high; and (4) the additional cost of the development would be replaced out of earnings in a reasonable time.

Modernization of the Gulf Refining Company's power plant at Port Arthur, Texas, is another typical example. In 1917 the power facilities were designed for 200 lb and 530 F with 15-lb pressure exhaust to process. Six years later another plant was built designed for 240 lb and 580 F, and two 5000-kw condensing machines. In 1928 another 5000-kw condensing turbogenerator was purchased for a throttle pressure of 15 lb to use excess steam not required in process work. A year later they installed a 10,000-kw 500-lb 630-F turbine, exhausting to process at 130-lb pressure. Although these combined plants were generating a kilowatthour at a very low heat consumption, plans were made in 1937 to reduce this still further through increasing by-product generation. Six 225-lb boilers in use since 1917 were replaced with two modern oil-fired or gas-fired self-contained steam generators with capacities of 200,000 lb per hr at 725 lb and 650 F. Two new 650-lb 650-F steam turbines were installed to drive the existing 4000-kw generators. These turbines exhaust to process at 130 lb and 400 F. In case the turbines fail to maintain steam pressure in the process lines, three sets of pressure-reducing and desuperheating apparatus automatically make up any deficiency.

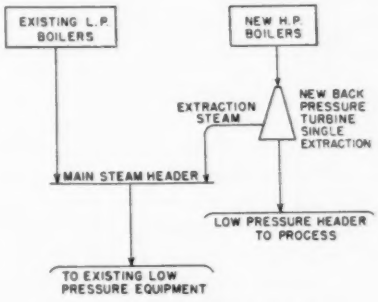

FIG. 3 STEAM CYCLE NO. 2

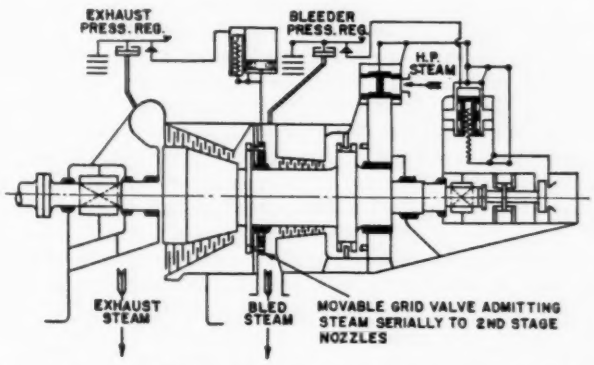

FIG. 4 CONTROL-MECHANISM DIAGRAM FOR AUTOMATIC BACK-PRESSURE BLEEDER TURBINE

A novel use of the back-pressure turbine occurs in one of America's leading plants devoted to the manufacture of rubber products. Due to a high percentage of impurities in the raw feedwater it was decided to use a closed circuit in the feed cycle. The 10,000-kw machine operates on a throttle pressure of 1250 lb and at a steam temperature of 750 F, and exhausts at 235 lb to evaporators which in turn supply steam to process at 180-lb pressure. Thus, the boiler-water problem is simplified and make-up practically eliminated. The evaporator feedwater is treated chemically in order to prevent hard scale deposits in the evaporator. In this case the cost of power is being materially reduced as compared with the cost of power from a complete condensing system, and the cost of the vapor leaving the evaporators compares favorably with that of process steam from the old low-pressure boilers. On the basis of normal-load operation the investment in the entire installation will be returned in $3^1/_2$ to 4 years.

In case of turbine outage, a pressure-reducing desuperheating station delivers steam to the evaporators from a single high-pressure boiler with a capacity of 300,000 lb per hr.

Designed to handle base load, the boiler and turbogenerator have been available 95 per cent of the time during the last year. The unit is shut down each week-end for a period of 24 to 36 hours. During this time the high-pressure boiler is bottled up and retains a pressure between 200 and 500 lb. After operating $2^1/_2$ years, the turbine was opened for inspection. It was found to be in good condition and free from deposits on the blading.

Steam Cycle No. 2 This cycle is illustrated in Fig. 3 and con-

sists of a turbine with throttle pressure higher than that of the existing plant, bled at one point only and exhausting into the old generating equipment or station header. It is ideal where the power-generating facilities already include condensing turbines. There are several industries which employ two pressures for steam process use, such as the kraft paper trade for example where this cycle is quite generally employed. The turbine-governing system is designed to maintain constant pressures at the extraction point and at the exhaust, with demands for steam varying independently. Fig. 4 shows this particular type of control.

The power facilities at Gaylord Container Corporation in Louisiana were modernized by the installation of equipment operating on this cycle—a 450-lb 710-F boiler unit and a 7500-kw back-pressure automatic-extraction turbine used in conjunction with the old 9000-kw plant of three condensing machines. The investment of approximately $400,000 produced savings in operating costs of $650 per day.

Similarly, in the food industry, General Foods Corporation at Battle Creek, Mich., recently invested about $500,000 in power-plant improvements and are obtaining annual operating savings of $100,000. Prior to 1937 all power was purchased and the five boilers operating at 150-lb pressure supplied the steam for cooking. This boiler plant is now stand-by equipment to one 100,000-lb-per-hr 625-lb 720-F steam generator supplying a 2500-kw 30-lb-back-pressure 125-lb extraction-type turbine. All electric energy needed beyond that generated by process steam is purchased from the local utility. One unusual feature which is used to provide additional flexibility is a surface condenser operated only during the summer time when there is no heating load. This plant has no spare boiler or generating capacity and an outage of the new turbine would mean throwing the entire electric load on the utility system, establishing a new demand which would cost about $15,000 for the ensuing twelve months. Outage of the high-pressure boiler would not be so serious, since about 1000 kw can be carried on the new turbine by using 125-lb steam through the extraction opening. An example in the chemical industry is the recent installation at the Columbia Chemical Division of the Pittsburgh Plate Glass Co., Barberton, Ohio. The process steam was originally supplied by exhaust from engine drives on pumps and CO_2 compressors. The balance between power and steam was obtained by generating electric energy with condensing turbogenerators, one of which was of the extraction type. For the new equipment a pressure of 900 lb was selected. At that time, 1935, this was thought to be the pressure limit at which boilers using a large percentage of treated make-up water would operate satisfactorily. In this case only a small amount of condensate returns from process. The temperature was limited to 750 F so that the turbine-exhaust temperature would about equal the temperature in the 140-lb header. A single boiler with capacity of 180,000 lb per hr serves a 6250-kw turbine bled at 400 lb for caustic drying, one of the highest bleed pressures used to date, final exhaust being at a pressure of 140 lb. This turbine, in Fig. 5, is a tandem unit with the 400-lb bleed connection between its two sections, but has only one cylinder and rotor. Automatic control of the bleed is provided for by a duplicate of the high-pressure steam chest and valves on the 400-lb to 140-lb section. This type of bleeder valve was necessary because of the very high extraction pressure, which was considered too high for the usual grid valve which at that time was limited to about 200-lb pressure. Operation indicates that approximately 25 per cent less steam is required with the high-pressure unit than with the old equipment for comparable loads. An additional unit is being installed in this plant using a newly developed water-cooled stoker which should prove beneficial as the plant operates on a relatively low grade of fuel. At the Akron plant, The Goodyear Tire & Rubber Co., a large percentage of the total steam generated is used in process work. About three years ago a study was made to determine the best plan of modernizing their old plant where boilers delivered 200-lb 530-F steam to a header supplying all powerhouse

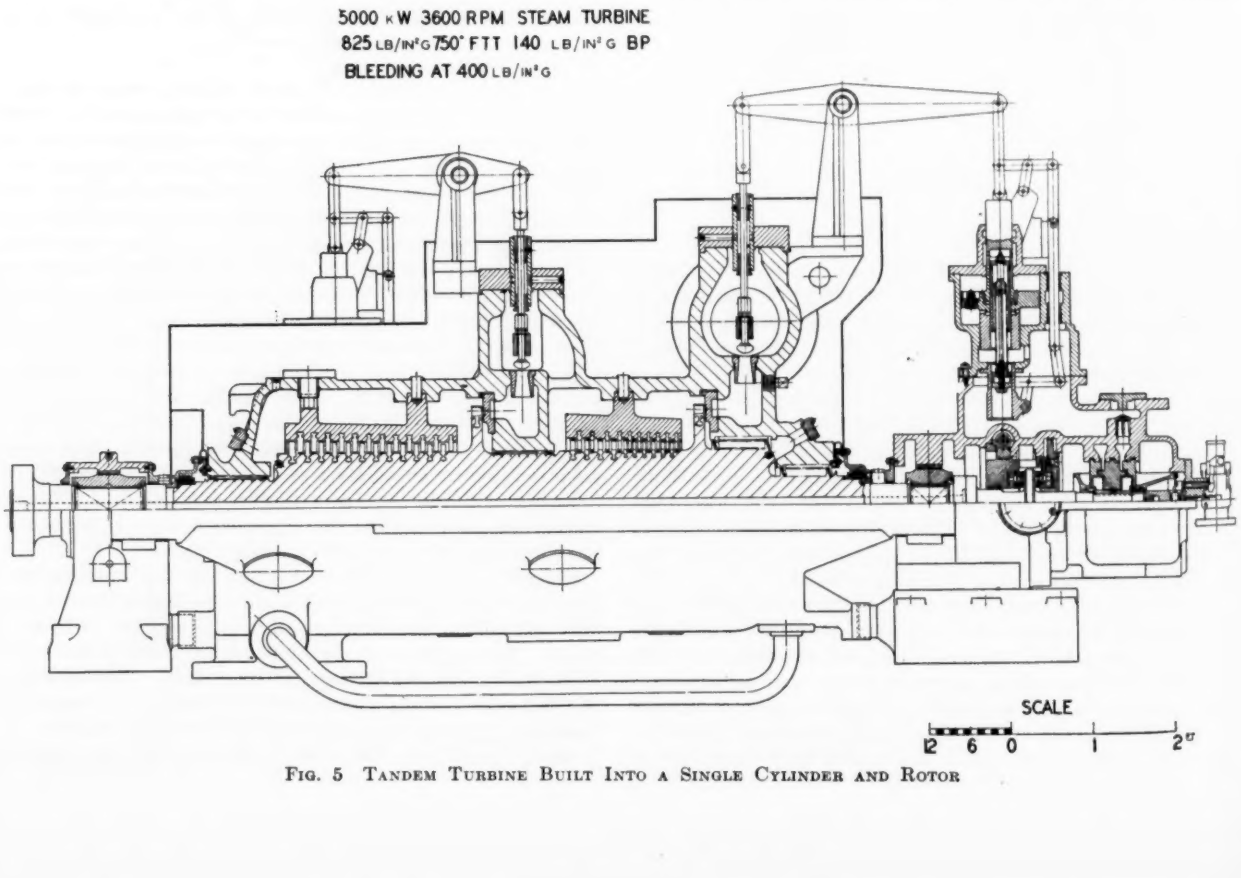

FIG. 5 TANDEM TURBINE BUILT INTO A SINGLE CYLINDER AND ROTOR

equipment. Process steam, 50 per cent of the total, was delivered through a reducing valve at a rate of 150,000 to 285,000 lb per hr. The study included pressures from 500 to 1200 lb. From these it was decided that 800-lb 750-F steam would best suit the local conditions. The new 7500-kw turbogenerator was of the noncondensing, extraction type arranged for extraction of 150,000 lb of steam per hr at 200-lb pressure to operate the old turbogenerators at full load if necessary. When no steam is extracted, all steam passes to the exhaust at 100-lb pressure for process use and the turbine operates as a straight back-pressure machine. When necessary a pressure-reducing desuperheating station supplies steam to process direct from the high-pressure system. The old boilers remain available for stand-by service.

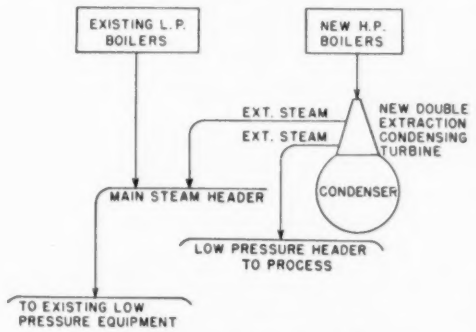

FIG. 6 STEAM CYCLE NO. 3

Steam Cycle No. 3. The double-extraction condensing turbine used in steam cycle No. 3, shown in Fig. 6, involves a more complicated control for maintaining constant-extraction pressures but it has the advantage of greater flexibility through using a condenser to balance the power demand. It is popular for new plants and has the same effect as applying Cycle No. 2 to old condensing plants. The necessity for controlling the extraction pressures and passing excess steam to the condenser requires throttling or by-passing of steam for all electric and steam loads except the one combination for which the machine has been designed. The farther the actual operating conditions depart from the design conditions the lower will be the turbine efficiency. However, a number of turbines of this type are in successful operation and have been very satisfactory, especially where the load has been fairly steady and predictable within reasonable limits. In any case it should be used where there is danger of serious lack of balance between steam or electric loads which would cause loss of economy.

Recently the R.C.A. Manufacturing Company, Inc., modernized their power plant by installing two new double-extraction condensing turbines to drive old 2500-kw generators. The two new boilers and the turbines are designed for steam at 900-lb pressure and 750-F temperature. The 175-lb extracted steam enters the station headers to operate old low-pressure turbogenerators. The 20-lb extraction opening supplies steam to process. The total cost of this reconstruction work was about $750,000 and the annual savings in the fuel bill and maintenance charges amounted to approximately $125,000.

During the last five years there has been rapid development in the kraft-paper industry throughout the southeastern section of the country. Electric power is a major item in the manufacture of paper and accordingly much engineering thought has been given to the reduction of power charges. The kraft process utilizes large quantities of steam at pressures of approximately 150 and 30 lb per sq in. gage. The double-extraction condensing turbine fits into this scheme perfectly and has been selected for such new mills as those of Union Bag & Paper Corporation at Savannah, Ga., St. Joe Paper Company at Port St. Joe, Fla., and Brunswick Pulp & Paper Company of Brunswick, Ga. In conjunction with this type of machine, and in order to get proper steam-electric balance, a back-pressure extraction turbine has been used in several of the new plants.

MIXED-PRESSURE TURBINES

The mixed-pressure type of turbine is provided with an opening which receives excess steam from process passing it through the lower pressure stages of the turbine, or should the requirements be reversed, steam is extracted to process. There are a number of special cases where such a turbine can be used to advantage, one of which is the forging plants of the automobile industry. Most automobile plants are located in regions where purchased power is available at attractive rates. Moreover, their steam requirements are generally met by low-pressure boilers without electric generation or with only sufficient power generation to balance the need for steam. The drop-hammers, using 125-lb to 175-lb steam, exhaust near atmospheric pressure to process, such as heating in winter, hot-water heating, drying ovens, and pickling tanks. Sometimes the use of motor-driven and steam-driven compressors gives control over this low-pressure steam to avoid waste to atmosphere. With these conditions in mind it becomes apparent that a combination extraction and mixed-pressure condensing turbine is an ideal method of controlling the process-steam supply and simultaneously generating some cheap power.

A case in point is one of the automobile plants in the Middle West. As first laid out, all excess low-pressure steam was absorbed in a mixed-pressure turbine. Recently the plant use of low-pressure steam has been increasing faster than the demand for high-pressure steam. This lack of balance in the steam loads has been corrected by removing a 5000-kw straight-condensing turbine and installing in its place a new 3000-kw turbine designed for either extraction or mixed-pressure operation. The old jet condenser continues to serve the new machine. This change also includes four new boilers, each with a capacity of 150,000 lb per hr, operating at 450-lb pressure.

Another ingenious arrangement of back-pressure, back-pressure-extraction, and mixed-pressure-condensing types of turbines is shown in Fig. 7, which is a line diagram of the power-generating facilities at Scott Paper Company, Chester, Pa. This plant operates 24 hours a day and prior to the installation of the new boiler and 3500-kw turbogenerator in 1936, about two thirds of

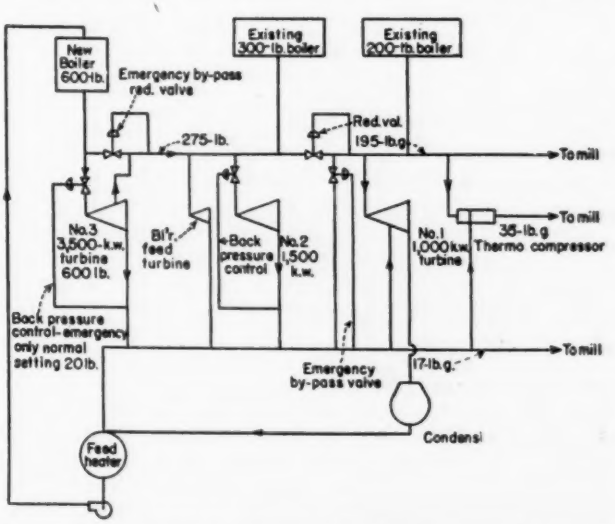

FIG. 7 FLOW DIAGRAM FOR THE POWER-GENERATING FACILITIES AT THE SCOTT PAPER COMPANY, CHESTER, PA.

the power requirements were purchased. As the system is now operated, No. 2 turbine governs the 17-lb back pressure; therefore, the power output depends on this 17-lb-steam demand. If this load falls below the control of No. 2 turbine, the emergency governor on No. 3 turbine, set at 20 lb, goes into action, automatically reduces load and, in turn, also the steam output of No. 3 turbine. All 17-lb steam in excess of normal process demands is absorbed by No. 1 turbine, running as a mixed-pressure machine either on 200-lb or 17-lb steam or both.

Steam-Pressure Reducers and Desuperheaters

The use of superposed turbines has been largely responsible for the recent rapid development in steam-pressure reducing and desuperheating equipment. In case of high-pressure outage, continuity of operation of low-pressure equipment is usually essential; therefore, availability and speed of response are of equal importance to high capacity and accurate regulation.

The two steps, reduction in pressure as well as control of temperature, are closely related and have a variety of uses. Although the heat loss is limited to radiation, the loss of potential power is considerable and for this reason such equipment should be used only for emergency operating conditions.

In a large eastern central station where the topping unit was out of service for months, the pressure-reducing-desuperheating station was in almost continuous service for about 5000 hr. Under these conditions the heat rate was 6000 Btu per net kwhr higher than normal operation. However, the use of this emergency equipment resulted in a heat rate about 10 per cent lower than that which would have been obtained by using the old standby low-pressure boilers.

As the foregoing illustration emphasizes the service reliability of this equipment, so is speed of response typified by the installation at the West End Power Station of The Cincinnati Gas & Electric Company. The requirements were that the pressure-reducing-desuperheating station must automatically react within the time consumed for closing the main-turbine governing valves, namely about $^1/_2$ sec, in order that the steam supply to the low-pressure generating equipment may not be interrupted by the failure of the high-pressure turbine. To accomplish this, two valves were used: A shut-off valve which moves quickly to its wide-open position and a regulating valve floating always in the proper position to pass a quantity of steam corresponding to the low-pressure demand. The desuperheating element is a venturi nozzle fitted with sprays and a water-storage tank located so that the water level is at the same elevation as the venturi. Thus, when steam flows through the venturi, a pressure drop is created which forces water into the hot steam and no automatic valve mechanism is required in the water line. However, in all cases, the required speed of action depends entirely on the steam-storage capacity of the low-pressure system.

Another unusual feature of this development is the ability to control extremely high quantities of steam. The flow through a 1200-lb 50,000-kw topping unit exceeds 1,000,000 lb of steam per hr, yet the pressure-reducing-desuperheating station picks up this load almost instantaneously and continues to "pinch hit" for the turbine with no interruption of steam supply to the low-pressure system.

Although the central-station industry has contributed largely to this development, the acceptance of high pressures in manufacturing plants has made such equipment indispensable there. In addition to the by-pass for a topping unit, the maintenance of process-steam pressures and temperatures under all conditions of electric load when old and new sections of a plant are joined together is another important application.

Advances in the art of combustion control have also contributed much to improvement in regulation of steam-pressure and temperature controls. There are so many applications of this equipment that its importance has assumed new proportions.

Steam-Generating Equipment

The modern steam generator bears little resemblance to the old-time boiler which was largely a vessel filled with water. Compared with its steaming capacity, the quantity of water stored in the drums and tubes was considerable. Along with the terms "boiler horsepower" and "per cent rating," the boiler itself has all but disappeared. To take its place have come elaborate designs of waterwalls, economizers, air preheaters, superheaters, and in some cases reheaters. Lack of water storage is compensated for by high steaming ability fortified by quick-acting feedwater regulating equipment and automatic combustion-control systems; all of these factors have helped to produce the present boiler unit with its very flat efficiency curve.

Contributing its share to this development has been parallel accomplishment in feedwater conditioning. Difficulties arising from deposits on the blades of high-pressure turbines, due to carry-over from the boiler, have made necessary the present-day

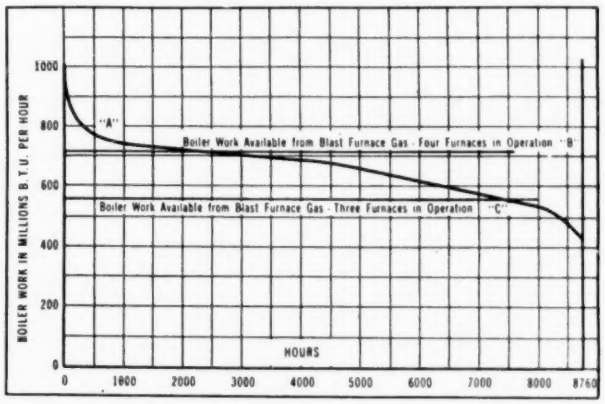

Fig. 8 Load-Duration Curve for a Steel Plant With Four Blast Furnaces

development of steam washers which are usually built inside the steam drum. However, it should be emphasized that universal use of these washers is not justified, especially where pressures are under 200 lb or where steam goes direct to process.

Local conditions affect the method of firing. The character of the coal and the size of the boiler unit are determining factors as to whether stokers or pulverized fuel shall be selected, and if the latter, whether the wet- or dry-bottom furnace shall be adopted. In some localities, natural gas and oil are cheap and abundant. Steel-mill practice dictates that excess blast-furnace or coke-oven gas receive priority over other fuels. Some boilers are arranged for three or four different fuels which come into service automatically according to some predetermined sequence. In general, where a multiplicity of fuels are to be used, pulverized-fuel firing is, for the solid fuels, the easiest method of accomplishing desired results. It is necessary that all fuels be burned in the same boiler furnace to avoid the expense of duplicate boiler equipment.

The fallacy of averages often leads designers astray in determining the size and use of equipment. This is well illustrated by Fig. 8 which is a load-duration curve for an active steel plant with four blast furnaces. In this case, the load values have been converted to heat requirement in boiler work, that is, the total quantities of heat that must be absorbed by the boilers, and are indicated by the curve marked *A*. The line *B* represents the average quantity of this heat that can be supplied by blast-furnace gas when four furnaces are in normal operation, and line *C*

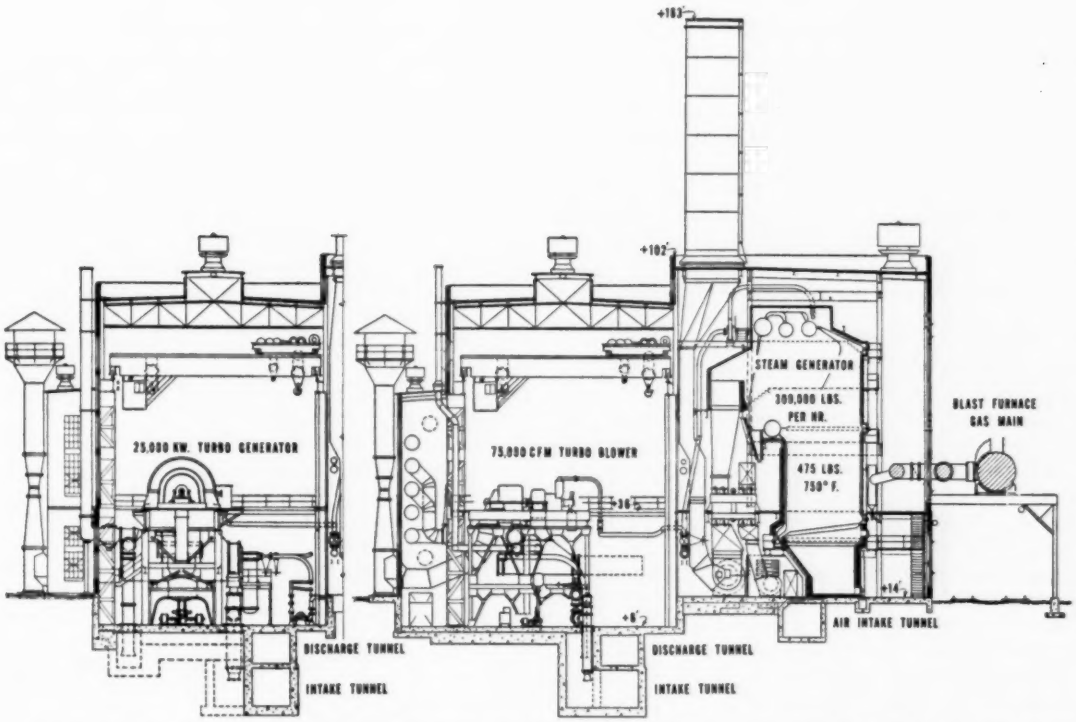

FIG. 9 CROSS SECTION OF NO. 5 POWER STATION, CARNEGIE-ILLINOIS STEEL CORP., SOUTH WORKS, CHICAGO, ILL.

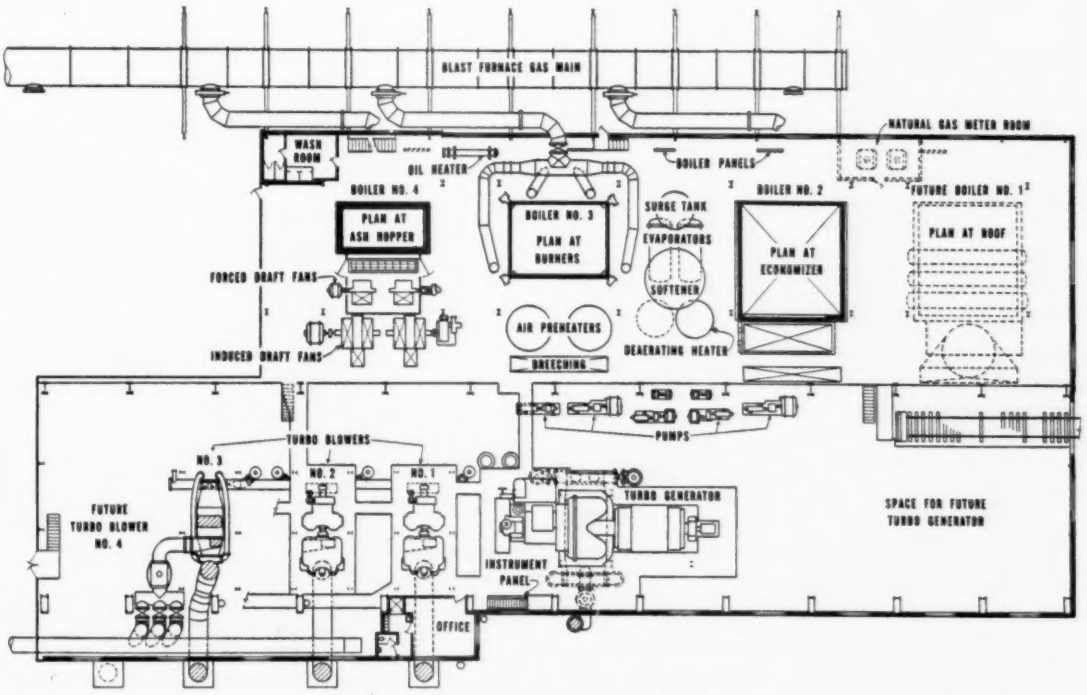

FIG. 10 PLAN OF THE PLANT SHOWN IN FIG. 9

when three furnaces are in use. It should be borne in mind that while lines *B* and *C*, covering averages, are necessarily straight lines the actual supply of gas from the furnaces is apt to fluctuate considerably. There are interruptions due to casting or furnace slips and variation in use of gas for heating purposes in the mill. In the diagram the areas under curve *A* and above lines *B* and *C* indicate the average amount of supplementary fuel which must be supplied, while, conversely, the areas below the lines indicate periods of nonuse of available gas.

An auxiliary-fuel supply must be available to supplement the blast-furnace gas and also carry the entire plant in case no gas is available. This requirement has been very strongly emphasized

in some of the steel mills in the last 4 or 5 years where operations were of such a nature that there was an active demand for process steam, although the blast furnaces were practically shut down and little or no blast-furnace gas was available.

In the case of industrial plants using steam for process work, while the average quantity of steam rejected by the generation of electrical load may balance the average requirements of industrial steam, the times at which these loads balance are apt to be seriously out of proportion and unless a very careful analysis is made the use of averages in determining these factors will be very misleading.

One of the largest industrial power plants recently completed is the No. 5 Power Station of the Carnegie-Illinois Steel Corporation at their South Works in Chicago. Figs. 9 and 10 show a cross section and plan, respectively, of this project which was placed in service last winter.

The building houses three boilers, each with a capacity of 300,000 lb of steam per hr at 450 lb pressure and 750 F temperature, one 25,000-kw condensing turbogenerator, and three 75,000-cfm condensing turboblowers. Space is also provided in the present building for one additional boiler, a future 50,000-kw turbogenerator and another turboblower.

Fig. 9 includes a cross section of the boilers which are of the four-drum bent-tube design equipped with convection-type superheaters, economizers, and air preheaters. Each boiler has two induced-draft fans and two forced-draft fans. A geared turbine drives one of each type of fan and a two-speed motor drives the other.

About 20 per cent of the total feedwater supply is make-up taken from Lake Michigan and treated by a hot-process, lime and soda softener. A deaerating heater and two closed feedwater heaters complete the feedwater-heating equipment.

An interesting feature of these boilers is the tangential firing designed to handle blast-furnace gas as primary fuel with natural gas and oil as secondary fuels when the bulk of surplus blast-furnace gas is being utilized for metallurgical purposes. Provision has also been made to use pulverized coal as secondary fuel in the future if and when the price structure warrants such a change. At each corner of the furnace is located one of the burner boxes consisting of the following: Three 11-in. × 14-in. burners for blast-furnace gas, two 6-in. diameter burners for natural gas, two $2^1/_2$-in. diameter burners for fuel oil, and two 14-in. × $4^1/_2$-in. burners for pulverized coal (future). There is a common windbox of cast iron and each burner has an individual louver damper which can be adjusted and clamped in a position to pass the correct amount of air for combustion over the complete operating range. Back of these individual dampers is the variable main damper which controls the air pressure in accordance with load requirements.

The boiler and auxiliaries are under the control of an air-operated system, the primary function of which is to supply fuel and air to the furnace in proportion to the steam demand.

A butterfly valve in the blast-furnace-gas supply line to the boiler responds first to the loading pressure set up by the master controller, which opens the butterfly valve to its maximum effective opening before any supplementary fuel is supplied. The position of the valve maintains pressure on the burners in proportion to demand regardless of fluctuations of pressure in the main. A normal pressure in the blast-furnace-gas supply main to the boiler plant is 20 in. of water. In order to avoid failure of the gas supply for metallurgical use, the regulating system is so set that should the pressure in the blast-furnace-gas main fall as low as a predetermined minimum of 14 in. the butterfly valve in the supply main to the boiler assumes a position which will not lower the pressure in the main below 14 in. Any additional fuel required to produce the requisite steam will automatically come from the auxiliary-fuel supply.

When the available blast-furnace-gas supply is insufficient for the steam demand, the secondary fuel normally brought into service next will be natural gas. Alternately, the natural-gas supply may be made the primary fuel by manual manipulation of the selector valves. In such case the blast-furnace-gas supply would be completely shut off.

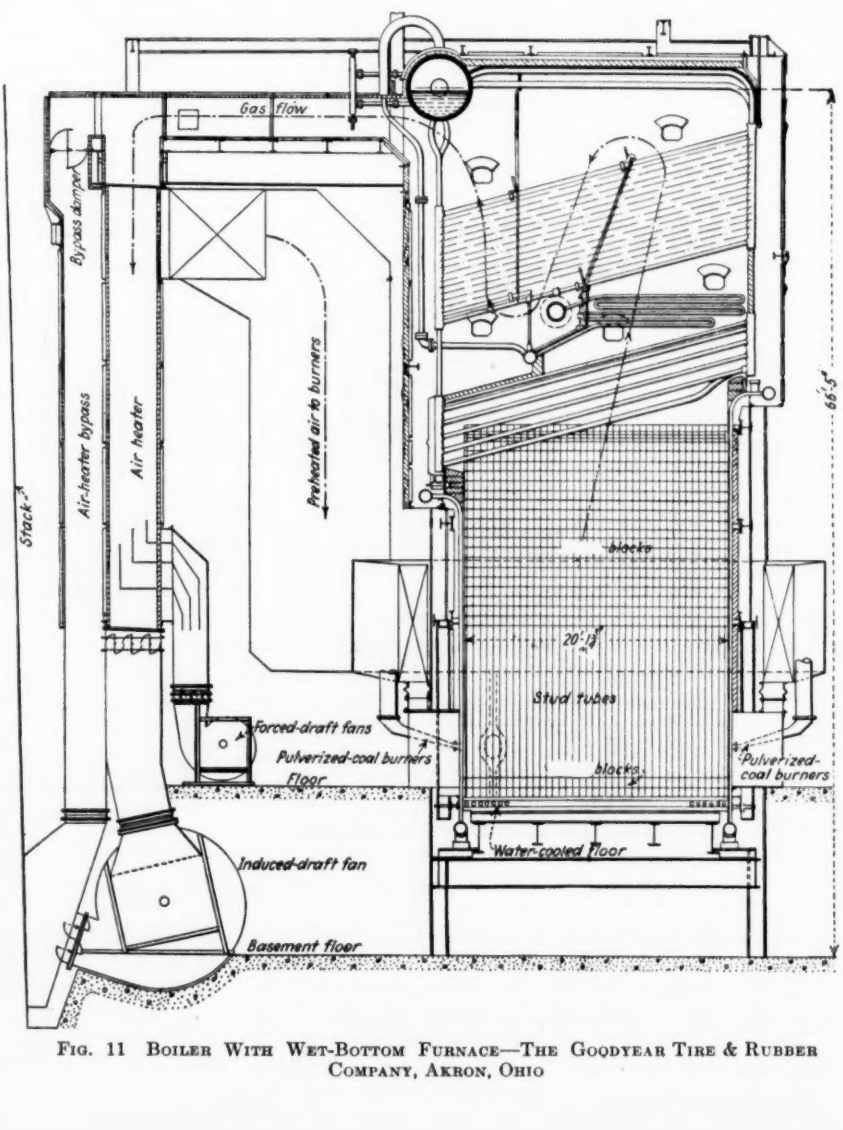

FIG. 11 BOILER WITH WET-BOTTOM FURNACE—THE GOODYEAR TIRE & RUBBER COMPANY, AKRON, OHIO

Normally the fuel-oil supply is closed off, but this fuel may be substituted for the natural gas as a secondary fuel or a supplementary fuel. Separate shut-off valves are provided in each of the two oil-supply lines and minimum stops are furnished on each of the oil-flow regulating valves. Each one of the latter controls a supply to four oil burners, one located at each corner of the furnace. By proper operation of the shut-off valves it is possible to bring first one set of four burners into service in response to the control loading-pressure change and after these burners are at their maximum capacity to cut in the second set of four burners. Thus, greater flexibility and good atomization of the oil over a wide range is afforded.

Another outstanding high-pressure boiler installation is that at The Goodyear Tire & Rubber Company at Akron, Ohio. This 800-lb 750-F boiler, the cross section of which is shown in Fig. 11, serves as the sole source of steam for a new 7500-kw back-pressure extraction machine previously mentioned in this paper, and is located in the space formerly occupied by four low-pressure boilers.

Due to the availability of Pittsburgh No. 8 coal, with its low ash-fusion temperature, a wet-bottom furnace was chosen. It is tapped intermittently from one outlet in the middle of a side wall. Satisfactory tapping at the rate of 4 to 5 tons per hr is obtained at a steaming rate of 150,000 to 350,000 lb per hr. The water-cooled furnace bottom has given no trouble from slag leaks. During three years of operation approximately seventy-five

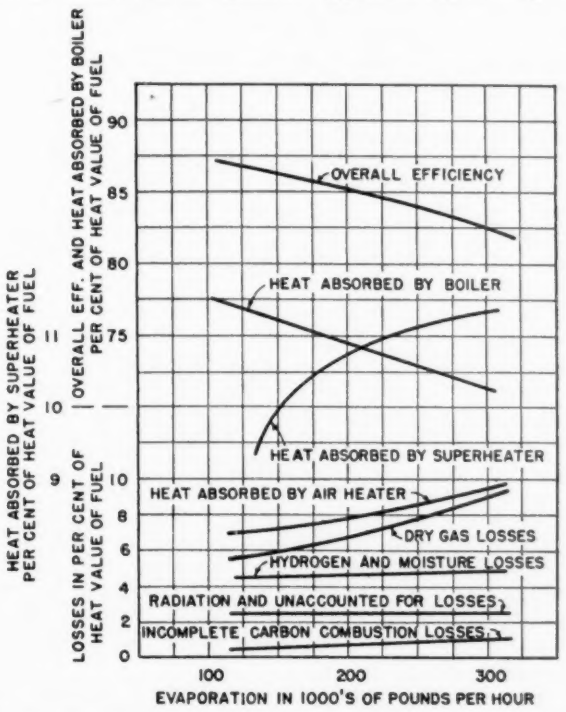

Fig. 12 Overall-Performance Characteristics of the Boiler Shown in Fig. 11

eroded side-wall blocks along the slag line have been replaced. Stud-tube construction is used on all four walls to a height of about 13 ft above the slag line of the furnace. The upper sections have smooth bare metal blocks. The large proportion of black radiating surface thus provided just below the boiler has prevented any trouble with slagging in the lower tubes of the boiler and the superheater. At maximum load the heat liberation is approximately 33,000 Btu per hr per cu ft of furnace volume and the mean furnace temperature is 2500 F.

Fig. 12 shows the overall performance of this steam generator based upon combined averages from one year's operation. The efficiency shown includes coal for banking, starting, steaming, and usual operation. The curves in Fig. 13 give interesting data

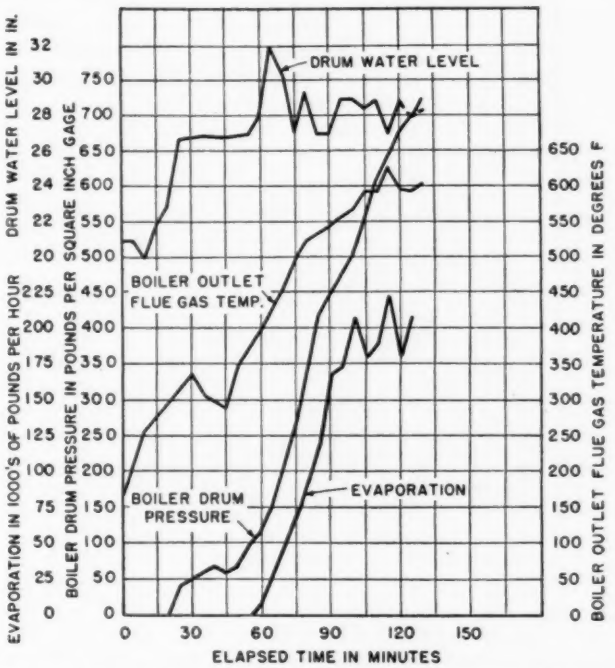

Fig. 13 Data Over 2-Hr Period While Putting the Boiler, Shown in Fig. 11, on the Line

taken over a 2-hr period consumed in putting this boiler on the line.

Self-Contained Boilers

During the last several years a new standardized steam-generating unit has come into use. Designed originally for the replacement demand in industries requiring small quantities of steam, its development has been such that today it is used in both industrial and central-station plants and for steam conditions ranging up to 700 lb and 850 F, and capacities up to about 250,000 lb per hr.

This boiler is generally of the two-drum type with the boiler tubes extended to enclose the furnace. It can be fired with oil, gas, or pulverized coal. Requiring no basement and small head room, it makes an ideal low-cost installation where a compact unit is needed to replace antiquated equipment. Due to the expansion and contraction of the furnace floor, the foundation requirements are relatively expensive but this is not a major item. The low draft loss simplifies the installation where only natural draft is available and saturated or moderate steam temperature is satisfactory.

Such a boiler fired with oil or gas develops from 80 to 82 per cent overall efficiency. An air preheater can be added to raise this to 84 or 86 per cent, but often it is not done as the increased draft loss necessitates the use of an induced-draft fan. This additional power cost reduces the saving to a point where, on small units, the greater investment often becomes unattractive. However, pulverized-coal firing requires some means of drying the fuel and an air preheater is often installed for this purpose.

In the paper-mill industry, several of these boilers have been used in connection with bark-burning stokers located in Dutch ovens surmounted by a capacious bark-storage bin as shown in

Fig. 14. The bark of hogged sawmill refuse containing about 50 per cent moisture is fed to the stoker. The fuel slides down the inclined grates, drying out rapidly as it reaches the burning zone. Combustion is completed in the main furnace. About 30,000 lb per hr of such fuel has been successfully handled in this manner. The ash and dust carried over the parapet wall and through the waterwall screen can be easily scraped or blown into the ashpit of the boiler proper. As a supplementary fuel, oil, gas, or pul-

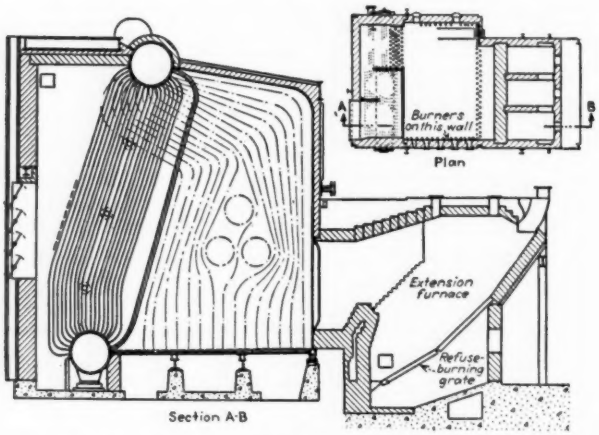

FIG. 14 SELF-CONTAINED BOILER WITH DUTCH OVEN

verized coal can be burned in standard register-type burners located in the front wall of the boiler furnace. Units of this type are in operation with steam-generating capacities as high as 80,000 lb per hr, 450-lb pressure, and temperatures in excess of 700 F.

A furniture plant using this type of boiler fired with refuse of kiln-dried birch and maple reports better than 12 per cent CO_2 on wood alone and 15 per cent CO_2 or better when using only pulverized coal. In this installation only a single furnace is used. The wood chips are introduced at the top of the furnace and on one side, so as not to interfere with the turbulence at the pulverized-coal burners. The secondary-air ducts admit forced draft near the bottom of the furnace so as to prevent the wood piling up on the floor. In this way much of the wood is burned in suspension.

While on this subject of combination coal and wood firing it may be of interest to note that in Sweden fine sawdust, bark, and shavings, which at times contain 50 to 60 per cent moisture, are burned on water-cooled inclined grates using primary air at temperatures as high as 650 F.

FORD MOTOR COMPANY

No paper on industrial power would be complete without reference to the River Rouge Plant of the Ford Motor Company. It is probably the largest industrial power plant in the world and it is also the largest single installation of 1200-lb equipment.

It was originally designed in 1920 for 240-lb steam. The original low-pressure generating plant consisted of four 30,000-kw turbines. An interesting item is that they were designed and built by the Ford organization. This plant was one of the original users of pulverized fuel and has since adhered to this method of firing.

During 1925 and 1926 four of the original 200,000-lb-per-hr boilers were rebuilt to give a capacity of 500,000 lb per hr and waterwalls, air preheaters, and radiant superheaters were added. Subsequent to 1929 this plant was rebuilt in several steps. In 1929 two of the old boilers were replaced with two 1350-lb 760-F generating units, each with a capacity of 700,000 lb per hr, and one 110,000-kw high-pressure condensing turbine was installed.

[a] From a statement by the Ford Motor Company.

TABLE 6 ANNUAL KILOWATTHOURS GENERATED BY THE FORD MOTOR COMPANY DURING THE LAST 15 YEARS

Year	Annual generation, kwhr
1923	260,000,000
1924	275,000,000
1925	424,000,000
1926	429,000,000
1927	377,000,000
1928	556,292,000
1929	702,210,000
1930	565,551,000
1931	385,902,000
1932	370,809,000
1933	302,615,000
1934	512,293,000
1935	657,892,000
1936	724,519,000
1937	825,202,000

In 1936 another of the old boilers was replaced by a 1350-lb 915-F boiler of 900,000-lb-per-hr capacity, and a 110,000-kw high-pressure, condensing, generating unit was installed, together with a 15,000-kw back-pressure turbine for supplying process steam. At present they are arranging for the replacement of the last of the original low-pressure boilers by a 1350-lb 930-F boiler with a capacity of 900,000 lb per hr, together with an additional 110,000-kw turbine.

Each of the 110,000-kw units has the high-pressure element mounted above the low-pressure turbine and the same arrangement applies to the separately excited 55,000-kw generators. In Units 1 and 2, the high-pressure turbine exhausts at 85-lb pressure and is reheated to 560 F by means of steam reheaters before entering the low-pressure cylinder. Higher initial temperatures in later units avoided this. Also, the generators on Units 6 and 7 will be hydrogen cooled.

The 15,000-kw machine generates all possible by-product power from process steam. The exhaust at 240-lb pressure goes to a battery of evaporators which generate 180-lb steam.

The boilers are of bent-tube design, fired with pulverized coal from a storage system which is supplemented by blast-furnace and coke-oven gas when available. About 4×10^9 cu ft of blast-furnace gas per month are normally consumed.

These new high-pressure units should produce a kilowatthour for less than 11,000 Btu. Table 5 covers the operation of the high-pressure boiler and turbine equipment from the time of the installation up to May 1, 1938. The outage of 336 hours on turbogenerators Nos. 1 and 2 was due to leaky tubes in the reheaters which utilize live steam at 1230-lb pressure. The no-load inactivity of the back-pressure unit No. 5 was augmented by building alterations.

The annual kilowatthours generated by the Ford Motor Company during the last 15 years are given in Table 6.

The figures in Table 6 serve as a barometer not only of the automotive industry but also of business in general. It is interesting to note that the output for 1937 was only slightly less than that generated by the Potomac Electric Power Comany and affiliate serving the metropolitan area of Washington, D. C.

OUTDOOR PLANTS

Semi-outdoor installations of boilers and steam-generating equipment have been receiving considerable attention for some time. Certain parts of the equipment of necessity must be enclosed so that operators may function, but in the main these in-

stallations may be called "outdoor plants." While the author personally questions the financial advisability of such developments except in warm climates, a recital of what has been done should be interesting. One of the inherent difficulties is the necessity for making repairs either to the boiler or turbogenerator during bad weather. This has become quite a problem.

In Schenectady, which has a rather cold climate, General Electric Company has a 20,000-kw mercury-vapor installation. In this plant the generating unit and the upper part of the boiler are entirely exposed. Other parts are under cover. This is a particularly favorable location for an outdoor plant, especially because of the large shop facilities which are in close proximity and which can be used for repair work.

The Utah Power and Light Company in 1936 placed in operation their Provo Station, designed as a semi-outdoor plant. The turbine room has a low ceiling and only the lower part of the boiler is enclosed. The water columns have separate enclosures. A waterproofed steel casing suitably insulated is provided for the upper part of the setting. The induced-draft fans are exposed and so are driven by totally enclosed motors which draw ventilating air from beneath the roof slab and vent downward to permit operation even though buried in snow. Special precautions were taken to prevent freezing in the water-column drum connections, feedwater regulating valves, and instrument piping.

This design is now spreading to industrial power plants, especially in the South. At their Sugar Land, Texas, Plant the Fort Bend Utilities Company has just placed in service an outdoor steam generator of 160,000-lb-per-hr capacity, fitted with an airtight steel casing, sealed at points of drum and header movement. The only housing provided is for auxiliary motors, control equipment, and operator's station.

Along this line there have been a fairly large number of synchronous condensers installed in the outdoor manner.

Unusual Boilers

Among the principal foreign boilers are the Loeffler, Velox, Benson, and Schmidt-Hartmann. The Loeffler and Velox are of the forced-circulation type; the Benson is in the so-called "once-through" class; and the Schmidt-Hartmann is the indirect heat-exchanger type. The only one of these now installed in this country is a Velox boiler operating in a plant of an eastern oil company.

The "Steamotive" boiler is being developed jointly by the Babcock & Wilcox Company, General Electric Company, and Bailey Meter Company. This unit is a complete small steam electric generating unit of relatively high efficiency and adaptable to many fields of industry. Two units, each having a capacity of 40,000 lb per hr, have been built to drive two 2500-hp turboelectric locomotives for a western railroad. They operate at 1500-lb pressure and 950-F temperature. Oil is used as fuel and the fuel-combustion rates reach very high values, namely about 400,000 Btu per hr per cu ft of furnace volume.

In the central-station industry the mercury-vapor cycle has received serious consideration and the installations at Hartford, Kearny, and Schenectady have provided valuable data for future designs. There are also a number of mercury-boiler installations in the industrial field, the most numerous being in connection with oil-refinery work, where the mercury unit is used as a heat carrier because of the possibility of very fine temperature regulation.

Fuels

As stated previously, the fuel selected depends largely on local conditions. By far the fuel most widely used is bituminous coal in pulverized form or on stokers. Bunker C oil and natural gas are available in many localities. In the steel industry blast-furnace and coke-oven gases are utilized when available. However, there remain several uncommon fuels and uncommon uses of ordinary fuels which are of interest.

Anthracite culm accumulates in the mining districts at the rate of millions of tons a year. A small quantity is burned in pulverized form, although its main use is on forced-draft chain-grate stokers or on hand-fired grates. It is low in volatile and has a high-ignition temperature. When burned in pulverized form one difficulty has been to secure sufficiently close regulation of the primary or carrier air to ensure a coal-air ratio approximating that required for maximum speed of flame propagation. Its flame is extremely susceptible to cooling until firmly established; therefore, the secondary air must be admitted to the furnace under careful control.

When burning this culm on forced-draft traveling-grate stokers, excessive sifting and carry-over to the boiler and even beyond, plus failure to follow rapidly fluctuating loads, have also retarded its popularity. In many cases it is necessary in order to secure proper operation, to mix the culm with No. 3 or 4 buckwheat.

Fig. 15 shows a direct-fired anthracite culm system in operation in a New Jersey paper mill. The boiler has been so successful that an additional unit is to be installed soon in another plant of the company. Culm containing as much as 15 per cent moisture and as little as $2^1/_2$ per cent volatile can be burned alone, unmixed with any other fuel and without other means for supporting ignition once the fuel has been ignited with the usual lighting torches.

A fan draws hot air through the pulverizer, dries the coal, and delivers it to the anthracite burners. As the air-coal ratio required for best pulverization is too high for good ignition, the burner arrangement is designed to remove about two thirds of the air in the coal-air suspension arriving at each burner and to divert this relatively clean air to the lower part of the furnace where it mixes with the secondary air entering through the front wall. In this manner the coal which drops through the vertical burners is suspended in a mixture containing the correct amount of primary air and will maintain stable ignition.

Culm containing moisture as high as 10 to 15 per cent has been dried satisfactorily by passing preheated air at temperatures of 350 to 400 F through the pulverizers. The power per ton consumed for pulverizing and firing at normal capacity of the system is about 35 kwhr as compared with 10 to 15 kwhr per ton of the usual bituminous coals. Maintenance cost on the mills is approximately 3c per ton. The overall thermal efficiency is about 3 per cent lower than that of a similar plant burning pulverized bituminous coal.

It may be of interest to note that economic conditions in England have forced the use of anthracite coal in the power industry. The large Tir John Station is using this fuel in pulverized form by means of the bin-and-feeder system. The cold boiler and setting is heated first with fuel oil. Preeconomizer air heaters are used to obtain primary-air temperatures of 700 F. Straight-shot vertical burners are installed.

Scattered through a number of our western states are approximately 2,500,000 million tons of lignite. Proximate analyses from two large sources of lignite are given in Table 7.

TABLE 7 PROXIMATE ANALYSES OF COLORADO AND TEXAS LIGNITE

State	Colorado	Texas
Moisture, per cent	27	35
Volatile matter, per cent	31	25
Fixed carbon, per cent	38	30
Ash, per cent	4	10
Heating value as received, Btu per lb	9100	7000
Ash fusion temperature, F	2000	2300

In Minnesota, the burning of lignite on traveling-grate stokers by the so-called "short-fire" method has proved successful. The fuel bed travels along undisturbed over the first zones of the stoker where surface ignition occurs and volatiles are driven off. Most

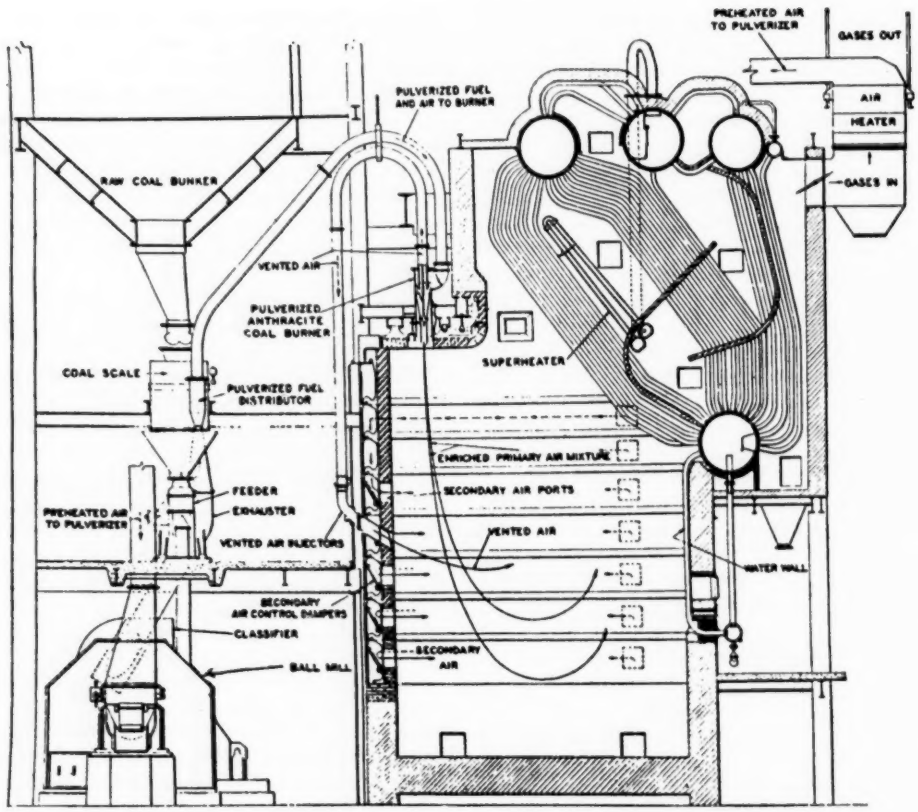

FIG. 15 UNIT SYSTEM FOR THE DIRECT FIRING OF PULVERIZED ANTHRACITE CULM

of the combustion takes place in suspension as the fuel reaches the blast zone, about half way along the stoker, where high air pressure lifts the fuel from the grate.

At Valmont Station in Denver the coal is burned in pulverized form and the flexibility of operation is much greater than with stoker firing. In this plant, four boilers, each with a capacity of 80,000 lb per hr, are equipped with air-cooled refractory walls, dry furnace bottoms, and burners of the down-firing type. The latest boiler with a capacity of 275,000 lb per hr, has water-cooled walls and a wet-bottom furnace.

The Texas deposit covers an area of 50,000 sq miles and the veins average 6 to 9 ft thick at depths of 50 to 150 ft. A number of small stoker-fired boiler plants use this fuel successfully, but at fairly low efficiency. About 12 years ago when the Trinidad Station of the Texas Power and Light Company was designed it was decided to burn lignite in pulverized form. The initial installation was so successful that the same method of firing was chosen when the plant was extended in 1931. Operating costs have been favorable compared with fuel oil and natural gas even in a region where these latter fuels have been unusually plentiful. The steam-heated driers plus the drying effect of the mill circuit reduces the moisture content to about 26 per cent. Forced-draft burners are used under straight-tube cross-drum boilers. The furnaces are water-cooled with dry bottoms. Steam is generated at 450-lb pressure and 750-F temperature. Natural draft is used which prohibits heat-recovery equipment beyond the boiler, but overall efficiencies of 75 to 78 per cent have been attained.

Another plant designed to use pulverized Texas lignite is the Comal Station near San Antonio, Texas.

Early in 1937 The Detroit Edison Company began to use in their Delray Power House surplus blast-furnace gas purchased from a neighboring manufacturing plant, the Great Lakes Steel Corporation. The gas is burned in conjunction with coal under three stoker-fired boilers as is illustrated in Fig. 16. As the gas dust and the coal ash may unite to form a mixture with a low-fusion point, resulting in serious slagging on boiler tubes, the gas is first washed and then is passed through an electric precipitator to reduce the dust loading to 0.05 grain per cu ft. Four burners, arranged for horizontal firing, are installed in the rear wall of each boiler. An intertube type of burner, protected against radiant heat when not in use, has proved satisfactory. As the combustion characteristics of coal and blast-furnace gas differ widely, a control system for combined firing was worked out for metering the gas to each boiler and also to proportion the gas and its combustion air. Elaborate precautions have been made to prevent explosions. Cleaned inert flue gas, cooled to 100 F, is used for purging the boilers and gas main. To protect men working inside the boiler, a water seal is provided in the gas main. No appreciable loss or gain in overall efficiency is chargeable to the burning of gas. The steam temperature is increased slightly. The use of gas results in an annual saving of 60,000 tons of coal, which is approximately 20 per cent of the total fuel requirements.

At the Louisiana Steam Generating Corporation, Baton Rouge, La., there are five boilers each with a capacity of 350,000 lb per hr of 620-lb 725-F steam. Natural gas makes up about 70 per cent of the fuel and the remainder is petroleum coke breeze and acid sludges. Bunker C oil is the stand-by fuel for use when there is no natural gas. Approximate analyses of the coke and acid sludges are given in Table 8. All five boilers are equipped to burn natural gas and fuel oil. Four can burn acid sludges in addition to natural gas and oil. Two boilers are able to burn coke breeze in addition to the other fuels. Normally, the procedure is

to burn coke breeze and natural gas under two boilers, acid sludges and natural gas under two boilers, and natural gas alone under the fifth unit. From flue-gas analyses there have been worked out for various fuel-burning combinations certain percentages of excess air which give the best combustion efficiency. The percentage of natural gas burned with other fuels varies from 50 to 90 per cent and is the only fuel controlled by the combustion-control system. The automatic fuel corrector adjusts the ratio of natural gas to total air in order to compensate for the quality and quantity of other fuels not under the control system.

In modernized kraft-paper mills, the old picturesque rotary recovery furnace with its rolling barrel 8 or 10 ft in diameter and 20 to 30 ft long, emitting fire and "black ash" at one end and wasting valuable heat up the stack at the other, is rapidly passing from the scene. For over 50 years this unique piece of equipment was the principal means of recovering valuable sodium compounds from the "black liquor." Black liquor results from cooking wood chips and "white liquor" (NaOH and Na_2S) in a large cylindrical digester under about 150-lb steam pressure. After 3 to 5 hr of cooking, the lignins in the wood are separated from the cellulose by action of the chemicals. The digester contents are then discharged into a diffuser where the cellulose is separated and washed prior to passing to other equipment for the manufacture of paper. The remaining liquid and the wash water form the weak "black liquor," which contains about 15 per cent total solids. On its way to the recovery furnace this liquid passes through multieffect evaporators where the solid content is raised to 40 or 50 per cent. On a dry basis these solids contain about 38 per cent carbon, 10 per cent oxygen, 7 per cent miscellaneous combustibles, and the remainder inorganic chemicals. The calorific value is 6500 to 6800 Btu per lb.

In burning the solids the inorganic chemicals are recovered in molten form. They are largely in the form of sodium carbonate (Na_2CO_3), with some sodium sulphide (Na_2S), reduced from the added salt cake (Na_2SO_4, sodium sulphate). This molten chemical is run into a dissolving tank filled with water to form a solution known as "green liquor." By the addition of lime in a causticizing operation, the "green liquor" precipitates calcium carbonate ($CaCO_3$) and forms "white liquor" for the wood-cooking process. Lime is recovered by burning the calcium carbonate in a kiln.

TABLE 8 ANALYSES OF PETROLEUM COKE AND ACID SLUDGES USED BY THE LOUISIANA STEAM GENERATING CORP.

Proximate analysis of petroleum coke:		
Volatile coke, per cent	11.06	
Fixed carbon, per cent	87.80	
Ash, per cent	1.14	
Sulphur, per cent	2.25	
Moisture, per cent	8.00	
Heating value, Btu per lb	15300	
	Lubricating acid sludge	Acid tar
Approximate analyses of acid sludges:		
Specific gravity	1.084	1.052
Moisture, per cent	39.680	47.510
Acidity of weak acid, per cent	32.580	32.210
Acidity of sludge, per cent	12.950	16.730
Weight, lb per gal	9.030	8.760
Heating value, Btu per lb	10940	9525

Until a decade ago the primary consideration of the kraft-paper industry was recovery of the chemicals in "black liquor," but developments in recovery furnaces accomplish also the generation of steam from the heat formerly wasted. Rates as high as 10,000 lb of steam per ton of pulp are not uncommon.

About 1925 the Wagner spray-type unit was introduced and enjoyed widespread use. "Black liquor" at about 65 per cent total solids is sprayed into the top of a vertical cylindrical furnace. Dehydration occurs during the fall through the furnace, and the remaining combustible with its chemicals are deposited on the smelter floor. Separation takes place and the chemicals flow out in molten form. A boiler behind the furnace absorbs heat from the gases for generation of steam.

The Murray-Waern system shown in Fig. 17 is a development involving a combination of heat-recovery apparatus and one or two rotary furnaces.

The Tomlinson furnace was first installed on a commercial scale at Quebec in 1934. Fig. 18 shows a 125-ton unit, generating 55,000 lb of steam per hr at 430 lb and 660 F. "Black liquor" at 220 F and containing about 55 per cent total solids and some suspended salt cake is delivered to the spray nozzle at a pressure of 50 lb per sq in. pressure. This nozzle produces a horizontal sheet of coarsely sprayed liquor which becomes partly dehydrated in its passage across the furnace and adheres to the opposite wall

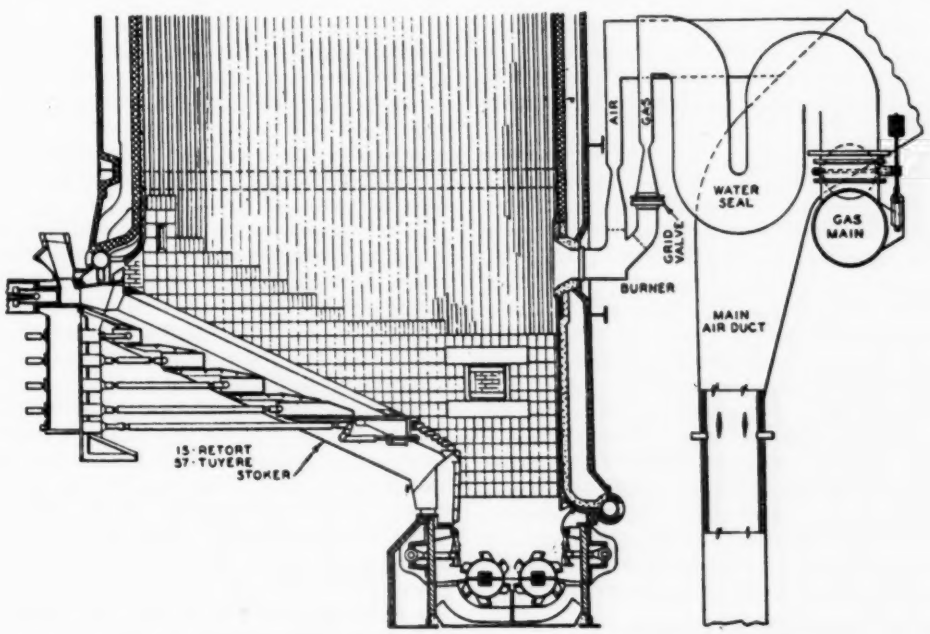

FIG. 16 ARRANGEMENT FOR BURNING BLAST-FURNACE GAS OVER A STOKER

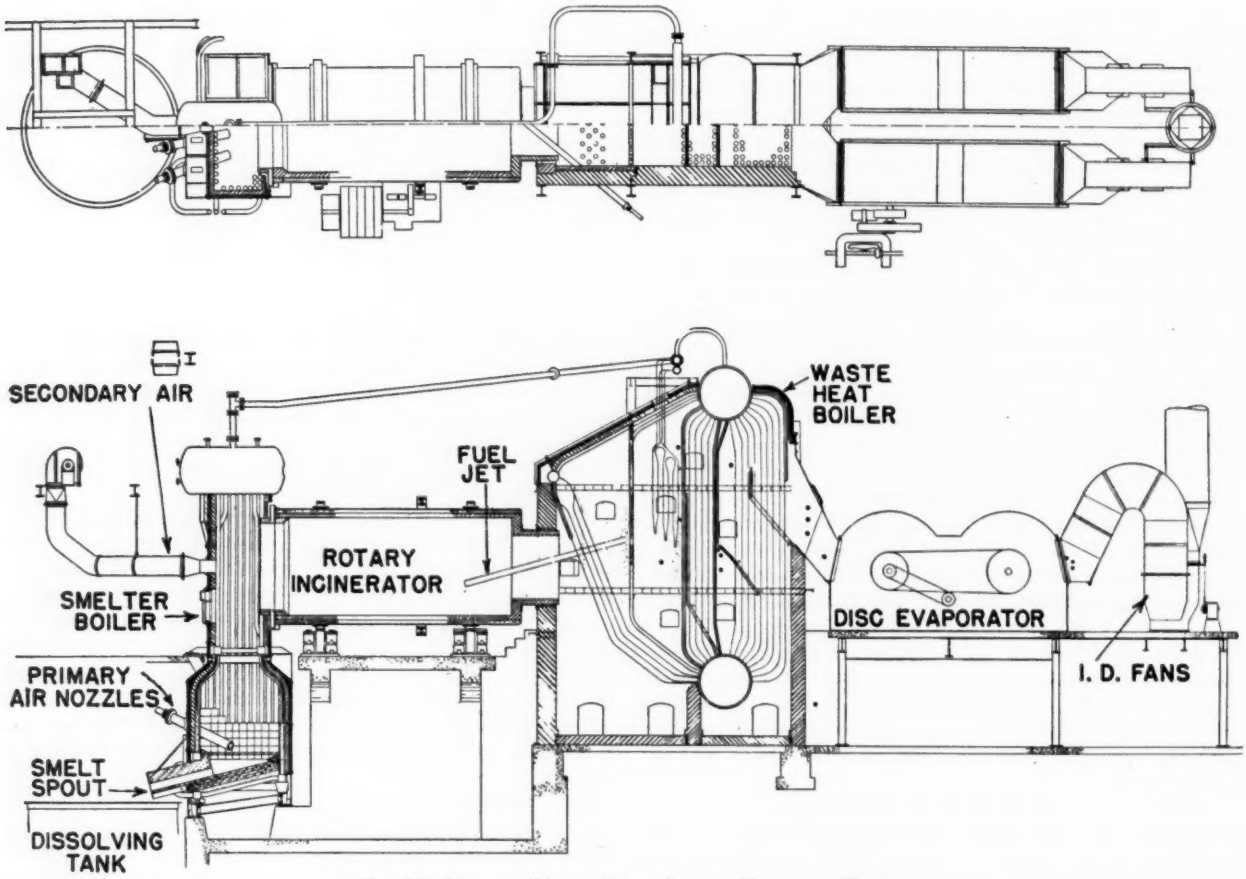

FIG. 17 MURRAY-WAERN BLACK-LIQUOR RECOVERY UNIT

in a partly wet condition. A vertical and rotational oscillating movement of the spray plate gives a paint-brush effect in its distribution of the wet liquor over the walls. Here, complete dehydration takes place as the char builds up to a thickness of 10 to 15 in. when, because of its weight, it falls to the smelter floor. Primary air is admitted near the fuel bed and secondary air higher up. As in all other types of smelter, the molten chemicals flow through a spout into a dissolving tank of water to form green liquor.

The unit shown in Fig. 18 involves a three-drum bent-tube boiler with a water-cooled furnace formed by studded walls covered with plastic chrome ore. Most of the boiler tubes are vertical and there are no baffles, thus affording easy removal of chemicals deposited on the tubes from sublimation in the smelter where the temperatures are between 2000 F and 2200 F. This type of unit lends itself to large capacities and to use with liquors from woods containing large amounts of rosin, such as southern slash pine. Results indicate that 60 per cent of the heat value in the black-liquor solids is absorbed by the boiler in the generation of steam. An air heater is standard equipment on these units since hot air has such beneficial effects in the combustion of this low-grade and high-moisture fuel. Frequently an economizer is installed to reduce heat losses, and sometimes a spray tower is used at the tail end to capture chemicals which may have escaped the boiler and heat-recovery equipment.

Another interesting feature pertaining to these furnaces is the fact that no ash remains in the smelter during the recovery cycle.

BOILER FEEDWATER TREATMENT

Coincident with the initial trend toward high steam pressures, which occurred over a decade ago, the problem of feedwater treatment attracted the attention of many able chemical engineers. The technical literature bears witness to the excellent progress that has been made in this important field. Without the accomplishments of these specialists, operation of the modern steam generator in many cases would be impossible. One of the great surprises that comes to managers of industrial plants facing expansion of the steam facilities is learning that water which was perfectly suitable for the old low-pressure boilers requires some special form of treatment for the new equipment. Yet no problem is more important to the engineer in this field than boiler feedwater treatment.

To compensate for the increased cost of equipment operating at higher steam pressures, it has been necessary to use fewer boilers designed for higher rates of steam generation per square foot of surface. Ratings of 200 or 250 per cent, once considered high, are now dwarfed by such average ratings as 500 to 700 per cent. At certain points, such as the front row of boiler tubes or waterwall tubes, the heat transfer may reach 150,000 Btu per sq ft per hr, which corresponds to about 5000 per cent rating. For ordinary carbon steel, the safe maximum continuous tube temperature does not exceed about 900 F. In a boiler operating at 1200-lb pressure, and assuming a heat absorption of 150,000 Btu per sq ft per hr, the temperature of the outer surface of the tube would be increased to 950 F if 0.01 in. of many types of scale were present on the inner tube surface. If such a condition were to exist, the tube would be likely to fail. This illustrates the necessity for using boiler waters free from scale-forming properties.

At these points of extremely high rates of steam generation, complex scale formation may develop. In this group, the one

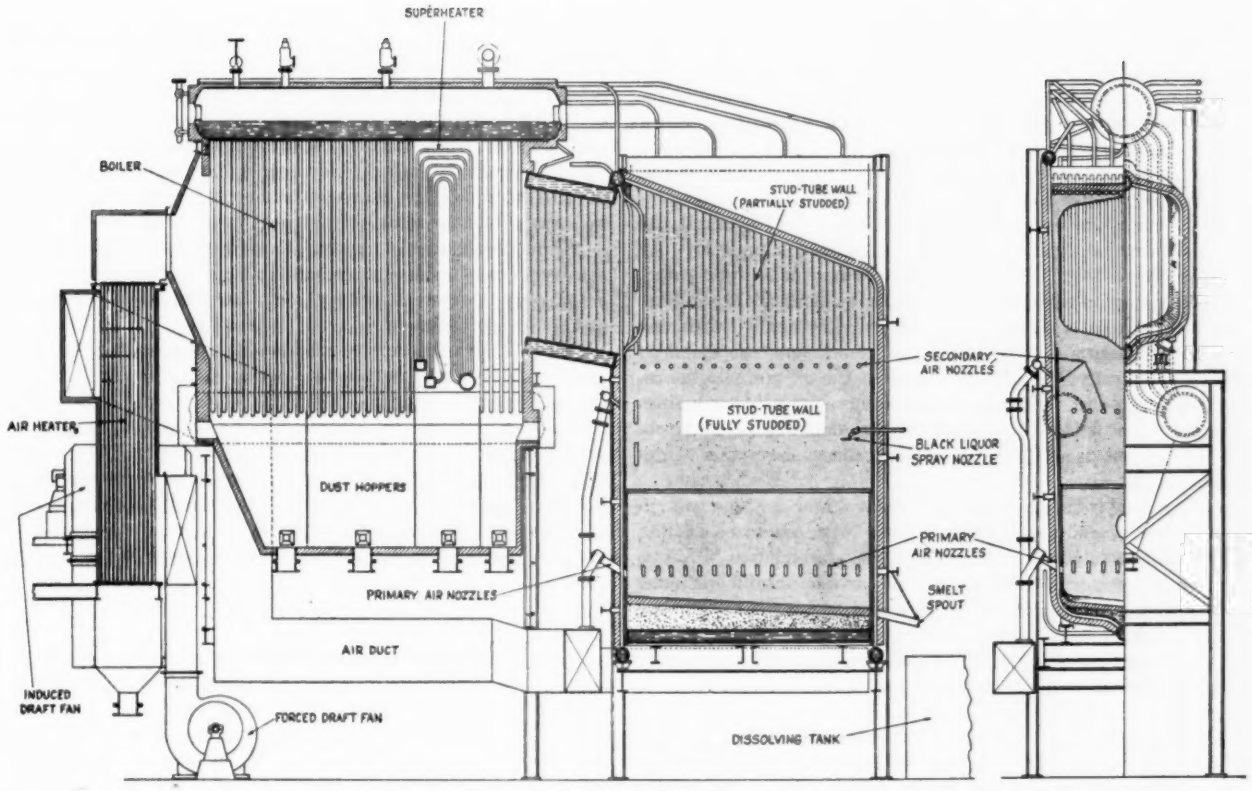

FIG. 18 TOMLINSON FURNACE WITH BENT-TUBE BOILER

which has given most difficulty is known as analcite, a complex silicate scale containing sodium and aluminum. Even the use of phosphate or other treatment cannot in all cases prevent the formation of this scale or remove it if it is once formed by the alkaline boiler water. Because of condenser leakage and evaporator carry-over, aluminum and silica cannot be kept out of the boiler water even if the feedwater consists entirely of condensate returns and evaporated make-up. The solution to this problem requires the cooperation of the boiler designer. Assurance of very rapid rates of water circulation at the localized hardest-worked sections of the boiler, plus satisfactory external and internal water treatment, is required to minimize the formation of this type of deposit.

With the elimination of scale it becomes necessary to protect the boiler metal from corrosion. The rate of reaction between the water and the steel is increased by the higher temperatures corresponding to the higher pressures. A thin coating of iron oxide integral with the surface of the boiler steel acts as a restraining influence and a protective barrier, thus prolonging the life of the thin boiler tubes. The iron-oxide coating will dissolve in highly acid or highly alkaline solution. The minimum caustic concentration which assures protection at boiler feedwater temperatures is that which corresponds to a pH of 9.6 at room temperature. For most operating conditions a boiler-water pH of 10.8 to 11.3 has been found satisfactory. In seams and at other points where restricted circulation and evaporation occur simultaneously, the concentration of alkaline solids may become very high. Under these conditions, and in the presence of silica or certain other agents, the steel may be subject to a selective attack at the grain boundaries which leads to intercrystalline cracking, better known as caustic embrittlement. Fusion welding of boiler drums has minimized this source of trouble by elimination of seams. The A.S.M.E. Boiler Operating Code requires the

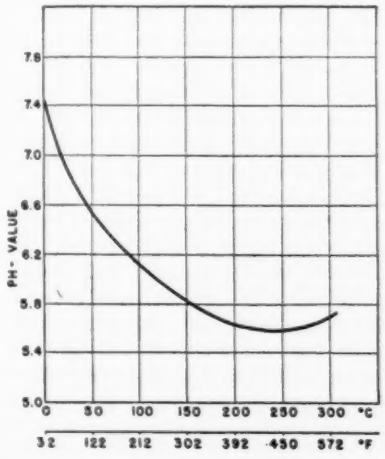

FIG. 19 RELATION OF pH VALUE TO TEMPERATURE FOR PURE DISTILLED WATER

maintenance of specific sulphate-carbonate ratios in the boiler water to inhibit caustic embrittlement. Considerable controversy has developed in regard to the adequacy of this protective treatment and other corrective measures have been suggested. These new treatments must, for the present, be regarded as in the experimental and developmental stage. It is probable, however, that some revision of the present A.S.M.E. Code may be forthcoming in the immediate future.

Many boiler feedwaters have a pH not far from the neutral point, or 7.0, and are treated to bring the alkalinity up to boiler requirements. Fig. 19 shows some interesting data on pure neutral distilled water and indicates why such untreated water in

a high-pressure boiler could be dangerous. At 0 C, the pH value is 7.44; it crosses the standard neutral point of 7.0 at 22 C, and reaches its lowest value of 5.58 at 250 C. Since the water contains no free acidity or alkalinity, its own acid and alkaline characteristics are balanced, i.e., it is neutral at each of these points. However, at the higher temperature, both the acid and the alkaline properties of the water are more than ten times as active as at room temperature.

Even when the boiler water contains sufficient alkalinity to inhibit corrosion, it is imperative to remove completely dissolved oxygen from the water if corrosion is to be prevented. The first step in removal of oxygen is mechanical deaeration, which is capable, with the most modern equipment, of reducing the oxygen content of the water to an amount too small to measure analytically. The last traces of the oxygen may be removed by the use of chemicals, the most popular being sodium sulphite. The latter should not be considered as a substitute for mechanical deaeration, but only as a secondary line of defense.

Raw waters found in this country vary over a wide range in their chemical analyses, but means have been found to condition most of them satisfactorily for high-pressure boilers. Make-up of even 100 per cent has presented no insurmountable obstacle. In deciding the form of water treatment to be employed, consideration must be given not only to providing the necessary protection for the boiler, but also to the complete inhibition of corrosion in the feedwater-treating system and equipment preceding the boiler.

The pretreatment of water in apparatus external to the boiler to make it suitable for feedwater make-up is most commonly accomplished by either the lime-soda process or the zeolite process, each of which has many modifications. The lime-soda process is more generally adaptable where the raw water is turbid or contains free acid, iron, or excessive hardness. It is adapted to the use of supplementary chemicals to accomplish various results. The lime-soda process may be carried out on either hot or cold water; since the reduction of hardness and the speed and efficiency of the process are greatly increased at higher temperatures, hot-process softeners are widely used. The less-complete degree of softening that is effected in cold water would, in many cases, be inadequate for the preparation of boiler feedwater. A recent development for treating relatively soft waters, with hardness not exceeding 3 ppm, is primary phosphate hot-process softening. This effects softening and coagulation in a single-reaction and settling tank, and zero hardness may be obtained. For very hard waters, similar results can be secured in two steps—the less expensive lime and soda in the first stage to remove the bulk of the hardness, and the economical use of phosphates in the second stage.

Zeolite systems are capable of reducing the hardness of water to a few parts per million and are suitable where the hardness varies considerably, since the softening reaction is more or less automatic and does not depend on instantaneous adjustment of chemicals to the quality and volume of the water. A clear and approximately neutral water supply must be provided for this treatment. It is sometimes combined with cold-process softening as a pretreatment and is frequently preceded by coagulation and filtration systems. The relative merits of chemical-process softening and zeolite softening will depend entirely on the operating conditions of the plant in question and the nature of the water supply. The size of lime-soda equipment is approximately determined by the quantity of water required, regardless of its hardness, although unusual problems may require additional settling capacity and special equipment. On the other hand, the size of zeolite systems is influenced by the hardness of the water, which determines the quantity of mineral that should be provided, as well as the volume of flow, which determines the total bed area of the softeners. The lime-soda process provides a water of high pH value which adequately protects equipment surfaces and minimizes the concentration of carbon dioxide. On the other hand, zeolite softeners deliver an effluent with a pH value below 8.0 and containing bicarbonates, so that carbon dioxide is evolved when the water is heated. However, some modification or combination of the chemical process and zeolite systems can usually be devised to satisfactorily treat most water supplies.

At the present time, a number of new types of synthetic zeolites are being developed, and radical changes are occurring in the art of water treatment, using these materials and older methods in various combinations.

Evaporators are generally used for high-pressure boilers where make-up constitutes only a few per cent. They produce substantially pure feedwater.

The type of apparatus and the process to be used in any particular case must be carefully analyzed to the end that initial and upkeep expense will be commensurate with the protection afforded. The engineers designing the plant should take cognizance of the need for careful investigation of the most satisfactory form of feedwater treatment which should be provided under a given set of conditions.

Evaporators

Years ago the use of an evaporator in connection with boilers was limited to seagoing vessels where distilled fresh water from seawater was used as make-up. The adoption of higher steam pressures coupled with a question as to the ability to successfully treat feedwater for the higher pressures led to the development of evaporators, and this trend has progressed to a point where evaporators of large sizes have been installed to produce low-pressure steam for process work. In such cases they are used as heat transformers generating low-pressure process steam and returning the clear condensate to the boiler-feed system. Notable installations of this sort were the evaporator plants at the Allegheny Steam Heating Company's Cecil Plant, installed in 1924; at the Youngstown Sheet and Tube Company, installed in 1928; at the Gulf States Steel Company plant, installed in 1928; and at Ford Motor Company's River Rouge plant. The Youngstown installation had a total capacity of 300,000 lb of low-pressure steam. The author believes these plants were among the earliest installations of this character.

At the River Rouge plant of Ford Motor Company, a 15,000-kw high-pressure turbine exhausts to a battery of three evaporators, generating vapor at 180-lb pressure for plant process. Most of the condensate is not returned. Process steam not supplied by the evaporators is generated in the old 240-lb boilers and delivered to the system through a pressure-reducing station.

Because of the high percentage of impurities in the raw boiler-feedwater for the plant of a large tire manufacturer, it was thought advisable to exhaust the turbine into an evaporator system rather than direct to process. The five evaporators operating in parallel produce 260,000 lb of dry vapor per hr at 180 lb per sq in. gage, when supplied with 270-F feedwater and 269,000 lb per hr of dry and saturated steam at 235 per sq in. gage. The evaporator feed is treated to prevent scale deposit rather than depend upon cracking. The tube surface has been maintained clean with a consequent steady rate of heat transfer. Results indicate that cost of vapor from the evaporators compares favorably with the cost of process steam from the old boilers.

Triple-effect evaporators are sometimes installed to supply steam demands that vary greatly. When more steam for process is required, the unit is operated on the double-effect principle.

With the adoption of the regenerative cycle and wider use of motors for auxiliary drives, the make-up requirements for

turbine-driven plants were reduced to 1 or 2 per cent. Moreover, the several extraction points on the turbines offered ideal conditions for the installation of single-effect evaporators between bleed points, with a lower-pressure feedwater heater acting as the evaporator condenser. General practice follows this arrangement today and nearly all of the 1200-lb installations in central stations use evaporators for small quantities of make-up.

In the new No. 5 Power Station of Carnegie-Illinois Steel Corporation, two evaporators were installed, each having a vapor capacity of 50,000 lb per hr. These units take steam directly from the boilers at 450-lb and 750 F and deliver vapor at 170-lb pressure to the low-pressure system. In this way the steam requirements in the old part of the plant were satisfied without the expense of adding new low-pressure boilers.

Developments in evaporator design include wide use of shells of welded-steel plate, efficient steam separators, arsenical copper or cupro-nickel steam-heating coils, and special designs of removable heads suitable for high pressures. Successful operation has resulted also from a new type of evaporator-drain pump so designed that a fixed level of water in the evaporator drain line is not required. This constant-speed pump adjusts itself automatically to capacity and head by means of submergence in the suction pipe, that is, by allowing the submergence to drop to a point where flashing in the eye of the impeller will occur in such a manner as to reduce capacity. This service is severe on the first-stage impeller. In some cases, vapor superheaters are used to remove superheat from the steam entering the unit and thus ensure dry steam for process use.

Electrical System

During the last few years it has become possible to improve the industrial power plant, from an operating standpoint, by means of recent developments in electrical equipment. The common use of metal-clad switchgear instead of the old open construction reduces the possibilities of service interruptions and also eliminates practically all of the life hazards. Furthermore, operation becomes simpler and the possibility of operating errors is reduced. Recent activity in the development of the air circuit-breaker for voltages up to 5000 may soon make it possible and practical to avoid entirely the use of oil for all circuit breakers within the station, thus greatly reducing the fire hazard.

All of the switching equipment, including auxiliaries, except that above 13,200 v, may now be metal-clad and located at any part of the station where space is available, and in large industrial plants the operating switchboard may consist of steel panels which are entirely dead-front and very compact in construction. For the small plant, the operating switchboard and the metal-clad switchgear may be combined into one structure, with the operating instruments located on steel panels forming the front of the circuit-breaker housings.

Considerable development has recently been made in the insulation of wire and cable. It is now possible to make use of cable insulation which can withstand higher temperatures than were formerly possible, and which is practically immune to the effects of moisture and various other formerly harmful substances.

Conclusion

One indispensable item in engineering of industrial plants is the economic result obtained, i.e., the return on the money invested. Most industrials, due to changes in production and processes, require returns of at least 25 per cent gross before embarking on an expenditure made solely on the score of economy. Conditions are somewhat different in the utility industry where there is a wide diversity of load and therefore a much better load condition. Consequently, utilities are not faced with changing processes which cause early obsolescence of equipment. While it is seldom found economical to replace steaming and power-generating equipment which is in reliable operating condition, there are cases where it is necessary to replace portions of the plant due to obsolescence or for other reaons and, in such cases, the replacement cost of this item should be credited to the total cost of the new development for providing both steam and power generation in order to arrive at the net cost of the power development to be justified.

Discussion

R. H. McLain.[2] In line with the excellent summation which the author has made in regard to electrical improvements in industrial plants, it should be pointed out that not only are air circuit breakers available up to 5000 v, but breakers of the type which formerly used oil are now adapted to use water and available up to 15,000 v. This still further reduces the fire hazard which the author mentioned.

It should also be interesting to know that transformers using a cooling medium which is noninflammable and nonexplosive are available instead of oil-cooled transformers. This development makes it still easier to use high voltage inside or alongside plant buildings in crowded spaces, without having to take precautions which were necessary in the case of oil-cooled transformers.

Joseph Pope.[3] Following are brief descriptions of several industrial power plants, in addition to some noted in the paper, with which the writer has had considerable personal contact. They are not all new but have never been much publicized.

The Ahmeek Mill power station of the Calumet & Hecla Consolidated Copper Company was built near a steam stamp mill, and replaced an old boilerhouse containing 16 hand-fired locomotive-type boilers of 210 hp at 155 lb per sq in. working pressure. Three 90,000-lb per hr boilers, fired by multiple-retort underfeed stokers, and fitted with integral economizers, were installed to supply steam at 425 lb per sq in. and 675 F total temperature in about equal amounts to a 7500-kw condensing turbine generator and to a 1250-kw geared back-pressure turbine generator, which exhausts through an accumulator to the old steam header at 155 lb per sq in. pressure. The accumulator does not function in the usual manner, the flow being straight through, but it does desuperheat the steam exhausted by the turbine and that by-passed through the reducing valve, and smooths out pulsations from the steam stamps. The 150-lb per sq in. pressure steam drives a triple-expansion condensing mill pumping engine, as well as the stamps. Exhaust from the stamps at 5 lb per sq in. operates a 2000-kw condensing turbine generator. These all were existing equipment. The accumulator acts as a direct-contact evaporator and requires the injection of feedwater, which concentrates and is blown off. There results a partial boiler feedwater make-up and conditioning action, since much of the steam appears later as condensate from the turbines and is fed to the 400-lb boilers. A combination straight-condensing and straight back-pressure turbine was selected rather than a single extraction unit because of less first cost and better over-all economy, under the expected load conditions. Stoker firing of coal was used instead of powdered coal, because of first-cost considerations, relative simplicity, character of coal available, and the severe climatic conditions under which it is stored.

A relatively recent addition to the power facilities of the Manville factory of the Johns-Manville Corporation consists of one 125,000-lb per hr integral-furnace boiler and one 2500-kw back-pressure-turbine generator. This boiler is fired by pulverized

[2] General Electric Company, New York, N. Y.

[3] Consulting engineer, Stone & Webster Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

coal, using two direct-firing mills, and supplies steam at 620 lb per sq in. and 650 F total temperature to the turbine which exhausts at 200 lb per sq in. into existing mains. This exhaust, and any reduced-pressure by-passed steam, flows through a tubular desuperheater, through which enough feedwater is automatically diverted to effect the desired temperature control. The boiler is fitted with an air preheater and forced- and induced-draft fans. The fans and feed pumps are driven by steam turbines, with steam and exhaust apportioned between the three pressures of 600 lb, 200 lb, and 5 lb to obtain reliability and flexibility of operation. The new plant was installed within an existing building, which originally housed six 200-hp 150-lb per sq in. pressure boilers, long out of use. It operates in conjunction with the older 200-lb steam and electric-generating system. The feed to the high-pressure boiler is mostly uncontaminated process drips diverted especially to the new plant. Make-up used principally in the older boilers is river water, clarified and then conditioned by Zeo-Karb.

Two plants which use small-sized anthracite for fuel, not culm, are the Baltimore refinery of the American Sugar Company, and the St. Nicholas steam plant of the Philadelphia and Reading Coal & Iron Company. Neither is exactly new, but there is scarcely a plant in that particular field, which is more modern. The Baltimore plant houses five bent-tube boilers of 12,060 sq ft area each, equipped with an additional lower drum and tube bank of 3160 sq ft, serving as an integral economizer. It was designed to burn dredged river coal, averaging in size 70 per cent through $^{3}/_{32}$-in. round mesh and all through $^{3}/_{8}$ in., with 8 per cent volatile, 75 per cent fixed carbon, and 17 per cent ash. When it was built, large stokers and water-cooled arches were not available, and each furnace was equipped with two forced-draft traveling grates of 318 sq ft combined area having front and rear sprung refractory arches. The boilers were provided with natural uptake draft and supplied saturated steam at 200 lb per sq in. pressure to engine generators and to the refinery direct. Efficiencies of 76 per cent at about 55,000 lb steam per hr per boiler and capacities of about twice that were obtained.

The St. Nicholas steam plant is a further development of the Baltimore idea adjusted to local conditions. The boilers, of which there are two, are very similar to the American Sugar Company's units in size and type, except that they produce saturated steam at about 400 lb per sq in. pressure. However, each boiler is fired with a single traveling grate of 425 sq ft area and equipped with one long flat suspended refractory rear arch, water-cooled side walls, and mechanical undergrate and uptake draft. The coal used is small, unmarketable fresh-mined anthracite from the St. Nicholas breaker of the same owning company. The coal is pumped with water to the steam plant through 1800 ft of pipe, and there separated and drained. Ash is removed by a continually running sluice or launder. Practically all the boiler feed is make-up. The steam output from the plant is distributed through long pipe lines at boiler pressure to the various operations of the company. It is reduced in pressure where used in old equipment. The steam load is extremely variable in character, there being wide differences between idle and operating mine shifts and violent swings occasioned by operation of steam-actuated mine hoists. The new plant handles these severe conditions in a satisfactory manner. Each boiler produces up to 125,000 lb steam per hr and swings equivalent to the output of one boiler are of normal occurrence.

The Kirk Power Plant of the Homestake Mining Company in the Black Hills of South Dakota, while of the same general character as a public-utility generating station, nevertheless belongs in the industrial-power classification. The main points of interest are that it is located a mile above sea level; all turbines are of the condensing type with forced-draft cooling towers employed to dissipate the heat from the circulating water; and the three 10,000-sq ft boilers operating at 415 lb per sq in. and 700 F total temperature are fired with Wyoming lignite, burned on forced-draft spreader-type stokers.

The boiler plant of the Franklin Sugar Company in Philadelphia is an example of the reconstruction of an old plant within an existing building. Forty-eight 250-hp boilers on two floors were replaced by five 1021-hp boilers, located on one floor and fired by pulverized coal, using unit mills. The boilers are fitted with individual economizers and forced-draft fans, but uptake draft is supplied naturally by a chimney 300 ft in height. Two of the boilers are equipped with superheaters and supply steam at 225 lb per sq in. to pressure-reducing turbine generators. The remaining three boilers furnish saturated steam at reduced pressure to the operations of the sugar refinery. When this plant was reconstructed twelve years ago it was particularly notable for its pioneering in the use of the direct-firing system of pulverized coal.

The Richmond Refinery Power Plant of the Standard Oil Company of California is thoroughly modern, in every sense of the word. It is new; it employs a high steam pressure and the latest methods of feedwater treatment; it burns several fuels, natural gas, fuel oil, and large quantities of refinery sludge; the piping systems are completely welded; and it is of semioutdoor construction. Three 125,000-lb per hr boilers are installed producing steam at 850 lb per sq in. and 750 F total temperature. They are fitted with furnace side and upper front waterwalls and tubular air preheaters. The air preheaters and the motor-driven vane-controlled, duplex-forced and induced-draft fans are located outside the building. The water-conditioning plant of original capacity sufficient to supply two boilers was of the two-stage type; a cold process for silica removal, followed by a phosphate hot process for softening. Subsequent enlargement of the treating plant has taken advantage of the newly available nonsiliceous base exchange type of softening.

There are three turbine generators, each rated at 4000 kw. They are designed for future possible exhaust at 25 lb per sq in. pressure and extraction at 125 lb, but initially the low-pressure stages carry no blading and exhaust is through the future extraction opening at the higher pressure.

The author has mentioned the three projected West Coast plants as examples of cooperation between utility and industrial interests. They are all in the general neighborhood of the plant just described and undoubtedly represent a recognition of the possibility of such situations. Of course the prototype of such a joint-interest plant is that of the Louisiana Steam Corporation, now the Gulf States Utilities Company, in Baton Rouge. In addition to the apparatus already in that plant, as described in the paper, there is now being installed equipment which will about double its former capacity. Two 500,000-lb per hr boilers, for the same working conditions as the earlier ones, are now ready for use, and two 25,000-kva turbine generators are rapidly nearing availability. These latter units are of the automatic extraction condensing type. Their actual capacity depends upon the division of maximum steam flow between extraction and condensation. This plant now has contracts for steam sales at 135 lb per sq in. pressure, totaling 1,331,000 lb per hr, and for electricity at 13,800 volts to the same purchasers, totaling 53,001 kw.

There is also being added to the plant of the Scott Paper Company, referred to in this paper, a 125,000-lb per hr oil-burning boiler to deliver steam at 600 lb per sq in. and 750 F total temperature to a 5000-kw dual-extraction, dual-admission condensing turbine generator. The extraction pressures may be automatically maintained at from 40 to 80 lb per sq in. and 17 to 20 lb per sq in., respectively. The second opening serves either to extract or to admit low-pressure steam.

Organization—Design for Modern Business

By FAIRFIELD E. RAYMOND,[1] CAMBRIDGE, MASS.

Questions of organization for large-scale enterprise are of increasing importance, since existing concepts applicable to single-unit organizations are becoming noticeably inadequate. More dynamic concepts appear to be necessary to comprehend those particular activities essential to a business and to provide adequate channels of coordination in an effort to humanize management. For each degree of specialization, in ascending from the smallest to the largest size of business, the direct channels of coordination following the lines of authority need to be supplemented by appropriate channels to make mutuality of interest effective. Decentralization, in contrast to centralized authority, may not only facilitate leadership, but also provide a means by broadening the organization structure to draw administrator and worker closer together, materially enhancing their unity of purpose. Recent developments point not only to an increasing functionalization of administration, but also to the reversal of the long-accepted pyramidal structure of management where the work group becomes the unit of management and the superstructure of organization must be justified on the service it renders these units. With increasing frequency the lack of constructive research in the field of organization has been remarked upon. In these times when the effectiveness of large-scale business is being challenged, is it not appropriate to seek for more comprehensive and possibly dynamic concepts of organization?

TO AN INCREASING extent executives are heard to express concern over what constitutes the economic size of a business enterprise. Do economic and social conditions warrant the mammoth corporations established in the last decade? In the textile field a cotton mill of 50,000 spindles has for some time been regarded as marking the optimum size of plant. Is management justified, however, in basing its measure of economic size on the efficient combination of production facilities alone? Are machines or process technology the sole determinants of minimum-cost operation, the apparent sine qua non of successful and profitable enterprise?

Unquestionably, the administrators of business have shown a high order of ability in dealing with their "inanimate material" (2).[2] Marked evidence of this is to be found in the existence of the large-scale enterprises of today. Nevertheless in establishing these multiunit organizations, the business leader has brought together an aggregation of human beings whose individual endeavor must be effectively coordinated and controlled, if the potential effectiveness, material and human, of the enterprise is to be fully realized and perpetuated. Should not management preferably adopt a criterion of economic size, based upon the character of that unit which can attain maximum results from its workers and plant with the simplest structure of management?

Has it not frequently happened that the smaller, less technically perfected enterprise, whose executives and employees are highly competent and cooperative, may take business away from the larger, efficiently equipped, but ponderous and impersonal industrial giant? May it not be that the 50,000-spindle textile mill excels because it achieves the most harmonious and effective coordination of its total personnel, the closest relationship between workers and top management with the maximum loyalty and minimum personal friction, without necessarily corresponding perfection in processing and equipment?

Thus enterprise may become just too big; yet present-day business conditions seem to favor a continuing increase in size. The test will be in whether human beings have the capacity to administer wisely large enterprise, to devise means for holding together the thousands of people in their employ, and to provide at all levels satisfying incentive and opportunity. The ultimate breakdown will in all probability occur, though possibly not initially manifest, in the failure of a top-heavy superstructure of management to promote and transmit leadership and to coordinate effectively its manifold and essential activities. Are we not faced with a serious challenge to existing concepts of organization if industry is to prosper on an even larger scale of operation? History repeats itself.

Historical Implications

Mankind has organized to a constantly increasing extent since the dawn of civilization. With the beginning of cooperative effort man set himself apart from the other creatures of the jungle with whom he had long struggled single handed for existence, and demonstrated the supremacy which comes with specialization and organization in the determination of his destiny. The inseparability of these two essentials cannot be too strongly emphasized. Any protracted lack of balance between them caused by the inescapable demands to maintain progress in civilization, on the one hand, and to establish commensurately effective methods of coordinating group endeavor, on the other, would bring about a social upheaval such as could thrust mankind back into its former jungle existence.

History now reveals (3) a direct lineage of modern military organization dating from the organization created by the primitive tribes of the "fertile crescent" in the valley of the Tigris and Euphrates rivers, to protect their crops and fields from floods, which proved also effective in repulsing invasion by the nomads of the neighboring deserts. For nearly five thousand years the basic concepts of organization have remained relatively little changed, though its forms have evolved through the ages in response to changing circumstance as the efforts of larger and larger groups of people have had to be coordinated.

The process has been largely one of trial and error where, in rather long cycles, economic and social conditions eventually surpass current ability to organize, causing the overextended unit to break up into its various homogeneous parts. Such a case is well illustrated (4) by the failure of the Greek States in the long run to hold on to their far-flung colonies, a precursor to the collapse of their independent civilization. Nevertheless today we see in Great Britain's ability to maintain her empire of world proportions the results of recent advances in organization.

Present Status of Organization

The relatively compact and unified chain of activities initially constituting organization has lengthened and broadened, expanding upward and outward as well in its evolution, until the indi-

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of authors, and not of the Society.

vidual responsible for the administration of the whole is so far removed from those who actually perform each constituent task that his personal influence of leadership is likely to be lost before it reaches the lowest level or the most remote corner of the enterprise. Similarly his sensitiveness to the needs and personal desires not only of these workers but also of the people with whom the enterprise may do business is impaired by the inevitable reinterpretation of conditions as reported back to him through intervening executives.

The complexity and rigidity of the consequent structure with its many standardized routines have increased the impersonal character of enterprise until any one member of the personnel at large has nothing tangible or satisfying for self-identification except the work before him. He has then, beyond his immediate superior, only the symbols of administration to which to attach his loyalties. Unless such conditions of superorganization can be rectified, another point of disintegration for large enterprise may be near at hand.

Need for Dynamic Concepts of Organization

Has not a totally new situation to be met in modern multiple-unit organizations, since the principles applicable to single-unit organizations are apparently quite inadequate? Aside from certain profound studies of the abstract essentials of organization, the chief emphasis has been placed so far on schemes for classifying activities and patterns or forms for coordination. All these are static and inflexible concepts becoming less and less applicable under the rapidly changing conditions of business today. Management is unquestionably in need of a truly dynamic concept of organization which fully explains and demonstrates the differences in relationship, methods of coordination, processes of functional development, and integration for each characteristic increase in size and complexity of business, and the corresponding changes produced in the factors conducive to leadership, in the responsibilities and duties of executives and their subordinates, and in the means for maintaining a spontaneous unity and purposefulness of the whole enterprise.

The lack of truly scientific research in the field of organization is to be greatly deplored. So is the lack of attention which executives give to acquiring a proper understanding of how to deal with problems of organization. Though such problems are of daily concern to them, top executives are, for the most part, immune to the need for further study; ingrained personal convictions and a pride in accomplishment, since organization is an inherent duty of administration, seem to stand in the way. More to the point are the facts that the abstract and intangible aspects of organization are abhorred and the more tangible and immediate problems of policy and operation are naturally given precedence. Thus, organization has remained an art, the basis of which has but slowly evolved through the centuries under the pressure of necessity.

Organization

The management of enterprise will always remain an art, drawing its foundations of technique from the natural and social sciences. Nevertheless management should be systematic and orderly, thus implying a need for a more scientific basis of organization. Since business is a collective undertaking, its organization may be briefly defined as the means for articulating its parts to constitute a whole for the harmonious fulfillment of a common purpose (5). It appears then that the fundamentals of organization could be disclosed through a realistic understanding, on the one hand, of the nature and relationship of those specialized activities essential to the satisfactory fulfillment of the expressed purpose, and, on the other, of what is required to insure their harmonious and unified functioning.

The first relates to the techniques of specialization and the second to those of coordination, the two inherent processes of organization. Through specialization each essential activity can be segregated and its distinctive character specified to provide a clear basis for the assignment of duty. At the same time the natural sequences of related activities may be determined to form a basis for the organization structure. Though this latter provides a foundation for coordination, it is only mechanical and lacks cohesiveness.

In collective human undertakings leadership is essential as the motivating force to crystallize the common interest and to unite the common effort. Though in all organization there must be a predetermined purpose to give explicitness to its intent, the inherent activities alone provide no vitalized basis to promote harmonious action. Coordination becomes effective only through mutuality, that subtle quality in organization which, under the influence of wise leadership, engages both the mental and emotional faculties of the group and holds it voluntarily steadfast to its purpose. Mutuality is manifest and operative in community of interest, harmonious understanding, and faithful cooperation (6). In these are to be found the determinants of the methods and techniques of coordination.

Thus there are both physical and psychological factors in organization. Its structure, therefore, not only should facilitate management in attaining the objectives of enterprise but also should provide a suitable medium for the exercise of leadership. The difference between successful and unsuccessful organization seems to lie in the fact that only certain arrangements of the physical structure for a given purpose and set of operating conditions permit the fullest realization of the psychological aspects. So it is in nature; all sorts of combinations of elements are conceivable but only certain ones are stable under the existing conditions. To comprehend organization fully it will be necessary to seek for those dynamic concepts of coordination which will mark the conditions favorable to stability and harmonious action where different purposes and stages of specialization prevail.[3]

Specialization

The starting point should therefore be with specialization, to inquire into what constitutes the natural and logical subdivisions of activities essential to the realization of the objective of business enterprise. In general, its objective may be stated as the rendering of a satisfactory service to the community in exchange for an adequate recompense for the costs and risks involved. The responsible head of an enterprise is always confronted by a similar question. The way in which he logically solves his business problem provides then an opportunity to explore the more fundamental question relating to the concepts of organization itself. Purpose in organization has external as well as internal aspects. Since the strategy of conducting the enterprise is a matter of entrepreneurship, present interest attaches solely to the process by which the problem of how to accomplish the ends of enterprise is solved.

The head of the business has two avenues of approach; he can either be an opportunist or he can use his intelligence and thus manage scientifically. The latter method is the only one with any rational basis and corresponds in essentials with the accepted process of scientific research. The seven basic steps which comprise this process are:

1	Careful planning	
2	Thorough preparation	
3	Conscientious performance	(observation)
4	Rational disposition of the facts	(analysis)
5	Precise evaluation	(synthesis)

[3] It is anticipated that the concepts expressed in this paper can later be extended to comprehend the essentials to the organization of military, religious, governmental, and other social institutions.

6 Preservation of results for reference
7 Constantly improved technique.

These steps in turn naturally derive from those recognized by psychologists as constituting the process of reasoning (7).

Accordingly, if the businessman is rational in carrying on his business undertaking, he will naturally:

1	Evolve a plan of action	(administration)
2	Gather together the necessary materials and tools	(purchasing)
3	Produce the goods which will supply the desired satisfaction or service	(manufacture)
4	Take the goods to those who wish to benefit by them in exchange for an adequate recompense	(distribution)
5	Exercise precautions to avoid failure of the venture	(protection from risk)
6	Figure out whether the undertaking was worth while, and	(control)
7	If worth repeating, study out how it may be done better.	(research)

In this fashion the major activities of a business may be logically accounted for in their natural sequence.

Functional Components

By stripping these descriptive statements of either their research or business connotations, the basic functional components to any rational human endeavor can be set forth. These become, adopting an arbitrary but sufficiently explicit terminology:

1 Plan 2 Procure 3 Perform 4 Dispose
5 Protect 6 Evaluate 7 Improve

Study has shown that these functional components are basic to any activity whether it be one of administration or a work unit in any operation cycle. Furthermore, as any major activity can be broken down in this fashion into its constituent functions, so also can they in turn be similarly subdivided. The process of specialization repeats itself until the last act in the sequence is either to exert a force upon a thing through a tool, if its consummation requires physical effort, or to exercise thought on a single proposition, if mental effort is required. The last act, however, is always reached in seven stages from the all-inclusive activity of enterprise.

Facilities

Though functional components can thus be revealed, the resulting activities cannot as yet be made explicit. From the descriptive statement of business other important primary activities are conspicuously absent. Naturally, the accomplishment of any task requires the use of certain facilities and only by recognizing that which must be dealt with can a subordinate activity be adequately defined.

These facilities derive directly from the productive agencies commonly spoken of as land, labor, and capital. Obviously the group to be organized supplies the men through whose present labor, physical or mental, each elemental task is performed; to these however must be added the people with whom the enterprise does business. Through the accumulation of past experience accepted methods are evolved. Land furnishes the natural resources in the form of raw materials (or power) by means of which goods or services are given tangible form. Capital, in turn, as the product of past surpluses of labor, provides the tools or machines to facilitate present labor or through money commands the product of others' labor.

Functional Definition

These facilities of money, men, methods, machines, and materials (8), together with the seven functional components, provide two series of coordinates making possible precise functional definition. Table 1 shows the expansion of the activity of conducting an enterprise into its major component activities and illustrates how in their appropriate relationship these activities become defined. On this pattern the functions of treasurership personnel, comptrollership, property management, and research

TABLE 1 FUNCTIONAL DEFINITION

MAJOR ACTIVITIES OF ENTERPRISE

(Phase Activity: Enterprise. Scale: III. Technique: Trading.)

		Money	Men	Methods	Machines	Materials
		Treasurership	Parties to Exchange	Management	Agencies of Trade	Commodity

among others of major importance take a definite place. Any one of these, in turn, may be defined by a similar expansion.

Such patterns have their use in setting forth the relationships basic to organization and in specifying the character of any activity. Their weakness lies in the present inadequacy of management terminology. Words themselves are of little consequence; it is the dynamic concept of an activity conveyed that has real significance. Within the precision of language, mutually exclusive definitions can be composed to give full expression, if need be, to the specific nature of given activities.

Functional Development

If the seven functional patterns of Table 1 presenting the full expansion of any activity, from its origin in enterprise to its final execution, are arranged in the logical sequence of functional definition, the functional development of that activity becomes manifest in the form of another pattern, Table 2, all in the plane of the facility with which it is concerned. Through functional development the specific character of the inherent act itself can be made explicit and it reveals in the functional transitions facts having a bearing on coordination. For instance, the activities based on the functions of procure and dispose provide the connecting links, up or down the line of action, respectively, between the activity of which they are a part and those adjacent of the same order. Procure, in administrative activities, reaches upward and outward to current external conditions, as is found in consumer research in connection with merchandising, Table 2. In perform activities, procure, such as inventory control as a part of manufacture, assures the correct inflow of the essential facilities. Dispose, in perform activities is concerned with the transmittal of the product of performance to its destination, as indicated by internal transportation in the case of production, Table 2. In administrative activities the dispose function is the means of directing all action, such as the merchandising authorization to those who are to put into effect an approved change to a new style or line of product. Furthermore from procure and dispose is derived the specific character of the principal activity because the perform function in no case becomes explicit until the kind of exertion can be specified at the final stage.

TABLE 3 STAGES OF FUNCTIONAL DEVELOPMENT

(Endeavor = business enterprise. Function = perform. Facility = materials or product.)

	The whole			Its parts	
Stages	Agency	Activity	Technique	Elements	Basis for coordinating parts

2	Executive Management	Manufacture	Method	Departments	Cycles of *Activity*
3	Operating Management	Production	Process	Work groups	Sequence of *Flow*
4	Supervision	Processing	Procedure	Individuals	Location in *Space*
5	Worker	Operation	Art	Actions of body	Period of *Time*
6	Limb	Motion	Skill	Effort	Synchronized *Rhythm*
7	Muscular Power	Exertion	Efficiency	Force	Economy of *Energy*

Functional Correlation

It is significant that the patterns of functional development, such as Table 2, in furnishing another plane of reference mark the stages in which all action takes place. These stages obviously correspond to the principal subdivisions of management and in so doing are characterized by the technique basic to the type of action occurring at each level of activity. See Table 3. Thus technique, column 4, provides a third coordinate for the proper alignment of specific activities defined by functional components and facilities, the basis for which is indicated in the last column of Table 3.

From a closer examination of the intent of action and the character of technique for each stage, significant groupings of the different stages in threes become evident. The first of the groups at the top of such a scale, service to society,[4] comprehends

[4] The first two stages preceding enterprise in this category have not been considered in this paper since the discussion has been purposely confined to the concepts basic to the organization of a business unit.

the activities of entrepreneurs in conducting enterprise as a profitable business venture, thus realizing the external objectives of organization. The second group, executive management (stages 2, 3, and 4), marks the stages in which the activities of enterprise are subdivided, facilitated, and undertaken in response to the internal objectives. The third group, execution of task, denotes the stages by which individuals comprising the organization perform the necessary acts, each with an efficient work cycle, in applying the requisite physical or mental effort.

Of note is the fact that the three stages which combine in each case, as well as the three resultant groups, have in the order of their occurrence the common characteristics of specialization, facilitation, and technique. The apparent unfailing repetition and its correspondence to the coordinates of rational endeavor would indicate that these three characteristics are of fundamental origin. Being the dimensions for designating explicitly any activity, it is but natural, in specifying respectively (*a*) its distinguishing features or parts, (*b*) the bonds uniting it with associated activities of the same order, and (*c*) the manner of performing its particular function, that they are the embodiment of nature, relationship, and behavior; the factors exclusively identifying any manifestation.

Functional Integration and Lateral Disintegration

A further inspection of the superimposed patterns of functional definition shows that in numerous instances occasion exists for the functional integration of service and staff activities on the basis of common techniques, to minimize duplication of managerial effort, to promote uniformity, and to bring about a more homogeneous organization. Thus a separate functional structure paralleling the primary one of operations can be reared for such activities as technical research and engineering, comptrollership or accounting, office management, quality control, and the like. It is important to note that integration causes the establishment of superimposed activities which have characteristics identical to others at the corresponding higher levels of supervisory, executive, or administrative management.

Integration may, however, go to such extremes as eventually to divorce a group of functional activities from the original enterprise where they become a distinct enterprise of their own, hiring out their services instead.

Coordination

With this sketchy, though nonetheless significant picture of the dynamics underlying specialization, the problem of coordination can be more readily approached. The author has long felt that too much emphasis has been laid on the application of fixed types of organization, such as line, line-and-staff, functional, and committee, without recognition of what really constitutes effective coordination and of the natural processes of structural evolution with the increasing complexity of organization.

Authority and Accountability

Though specialization discloses the functional relationship of all activities and the technical basis for their correlation, human nature is not so constituted as to undertake voluntarily the separate activities of an endeavor in any such logical order without some impelling force. In initiating an undertaking, the individual or group immediately assumes the responsibility for its successful outcome, from which derives directly the sole right to determine how the objective is to be obtained. In the case of an individual this right, in view of his own interests, gives him the supreme authority to carry out his undertaking as he sees fit within the confines of his expressed objective, subject only to the moral obligation incurred toward those in the community with whom he necessarily must deal. In so doing, if

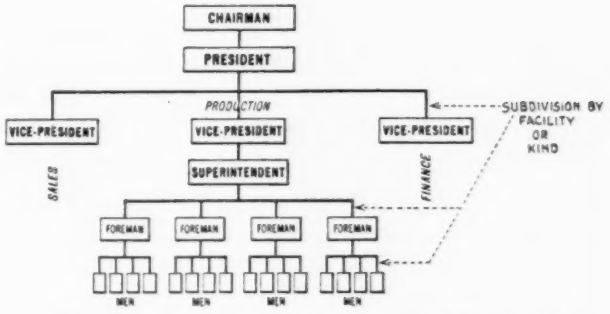

Fig. 1 Lines of Delegation for Supreme Authority

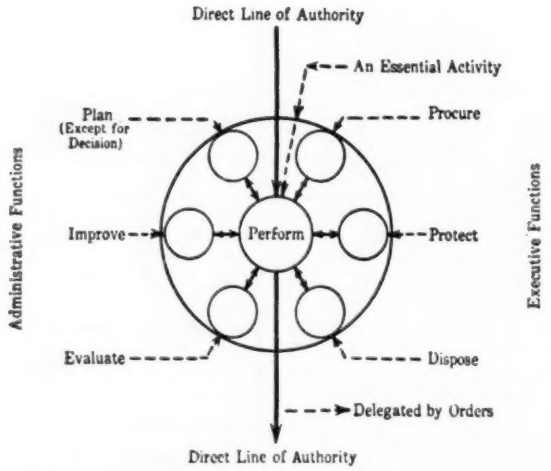
he is unable to perform every activity himself, he must delegate to those in the group he employs the authority for their separate actions. In the other case of a group, the same holds true except that, to become coherent and operative, it must delegate the supreme authority for action, resident in its combined membership, to its chosen leader. Here lies the distinction between an organization to operate and an organization to own or to attain any other objective which in its common interests has brought the group together.

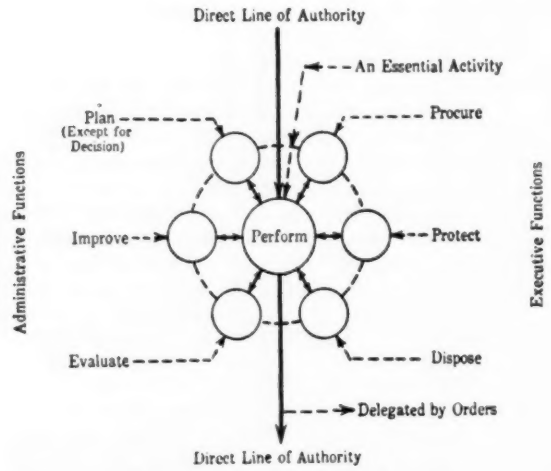
Accordingly, the delegation of authority occurs upward from a group free to determine its own purpose and downward from its leader to those he designates as responsible for the performance of each essential activity. Furthermore, since failure to satisfy fully the obligations incurred in undertaking responsibility exacts its irrevocable penalties, authority, if it is not to be unrestrained, must be accompanied by complete accountability. When clearly defined on the basis of specialization, authority and accountability provide together directive and controlling forces throughout the organization, making for unity and harmony of action. Therefore, the lines of delegated authority, as tracing the natural subdivisions of responsibility, provide the primary channels for coordination.

Lines of Delegation



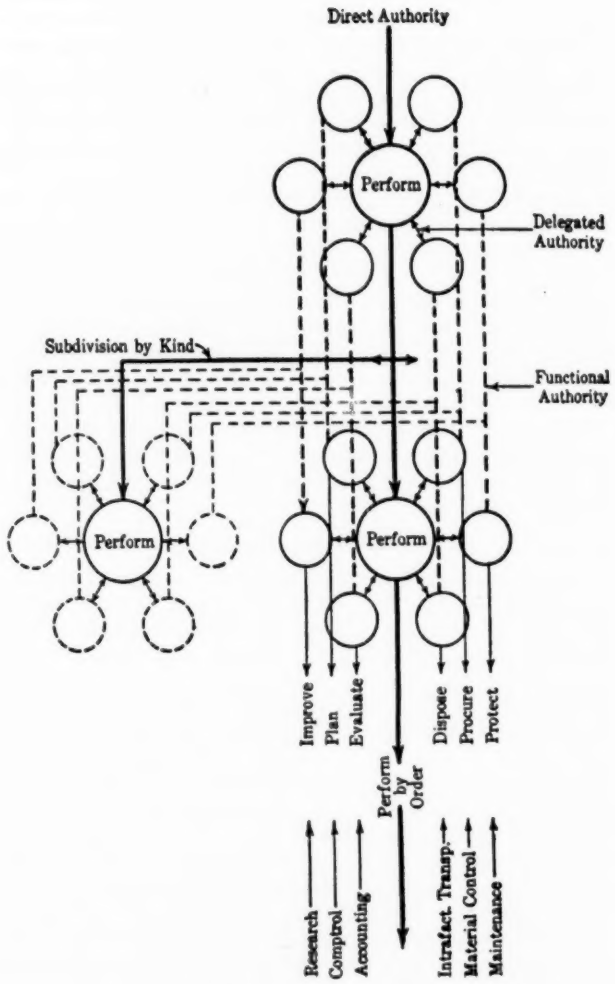
These lines of flow for authority and accountability necessarily conform to those manifest in the functional relationships inherent in specialization as a result of the requirements for orderly and efficient operation. Since the magnitude of no undertaking as yet has become so great that the complete pattern of functional development is evidenced in organization structure, on what basis then are the lines for the delegation of authority established and how completely do they facilitate coordination under varying degrees of specialization? An examination of typical structures of organization will be of value in exposing the techniques of coordination, where the delegation of authority is conditioned by the character of the activities which from their importance should be given individual status.

Undifferentiated Delegation



The simplest of all structures represents the subdivision of supreme authority purely in response to the number of units required, each unit composed of men functionally self-sufficient and of a size (9) conducive to effective leadership. The eventual number of levels is merely a mathematical function of these two factors, and obviously the units can only be distinguished on the basis of space or territory occupied, since all have identical objectives.

Simple Vertical Delegation



The first differentiation comes when the objective of any subdivision is conditioned, though unaltered in intent, by specific relationship to one of the *facilities* of men, methods, machines,

(a) OPERATING SPECIALIZATION (LINE)

(b) INTERNAL FUNCTIONALIZATION (STAFF)

(c) COMPLETE FUNCTIONALIZATION (SERVICE)

FIG. 2 LINES OF DELEGATION FOR FUNCTIONAL AUTHORITY

materials, or money. Subdivision occurs then according to either territory (as just shown), process, equipment, product, or markets. A second type of differentiation may be caused by subdivision according to *kind:* that is, the specific nature of one of these agencies such as passenger automobiles, trucks, tractors, or the like. The third type occurs when *functional specialization* takes place at any point and the line of supreme authority subdivides into separate lines of delegated authority supreme within their particular technique. This accounts for the usual top structure of enterprise where each unit or any of its subdivisions is still functionally undifferentiated and self-sufficient. See Fig. 1. In these three cases as well, the simplicity of the structural relationships amply facilitates leadership as the coordinating medium.

Functional Delegation, Internal

If, on the other hand, the need for further technical specialization requires functional development, the structure of coordination takes on more specific forms as the magnitude of the constituent activities increases. In the first place, when the work of the unit becomes more than one man can perform, activities divide according to duties of an administrative character and of execution. See Table 4 and Fig. 2(*a*). Obviously, this is the usual case where the man responsible for results retains the policy-forming and control functions of administering the unit and delegates the various duties of execution to subordinates. Should no greater functional specialization be required, the activities of execution subdivide either by facility or kind as previously described. Here again strict line authority provides the basis of harmonious action.

Lateral Delegation

In the second place, if functions such as procure and dispose are of sufficient importance to be set apart, as for instance material control or internal factory transportation in production, service units are created having distinct status only within the realm of the level of activity to which they are associated. See

TABLE 4 BASIS OF FUNCTIONAL DIFFERENTIATION

Constituent function	Relation	Character	
Plan	Staff	Administration	Cycle of one action. ↓
Procure	Service	Execution	
Perform	Line		
Dispose	Service		
Protect	Service		
Evaluate	Staff	Administration	
Improve	Staff		

Fig. 2(*b*). A clear delegation of functional authority has here taken place, supreme however, only within the corresponding technique.

Similarly, a planning or records clerk may be added to take over such routine duties of the executive, creating a staff unit of like character. In fact, the lateral delegation of authority may apply to all the constituent functions, except that, if he is to retain any vestige of responsibility, the executive must never be divorced from his essential acts of decision.[5]

Likewise, the executive may delegate laterally his responsibilities toward men, methods, machines, materials, and money employed by his unit, but in respect to men he must retain the full exercise of leadership or else lose all human influence.

Though these service or staff units are responsible and operative through the executive head only, they have occasion for informal contacts in carrying out their duties with those concerned with the other constituent activities of the whole unit. To facilitate coordination, the executive may provisionally authorize their dealing directly with the other associated functional or operating units in an unofficial capacity, with the final authorization of a particular action following the regular lines of authority. If desirable, a blanket but revocable authorization may be given to act in regard to all routine matters without further recourse to the executive. Since more than two people become involved in such transactions, with the possible impairment of mutuality, channels of coordination other than that of line authority must be at least informally established.

Functional Delegation, External

In the third place, efficient operation may require a similar functional development, at all lower stages, to the point of focusing on the individual executing each task. Complete functionalization, as in Fig. 2*c*, then takes place where all activities of the same character at each level are delegated to form a service or staff division, having supreme functional authority, for the benefits gained from uniformity in technique. When it is essential that such functional divisions serve other branches of the enterprise to minimize duplication, functional integration takes place, as evidenced particularly in personnel. Where functional activities now lie entirely outside the chain of operating units, the mutuality of interest, previously present in a common endeavor, has been destroyed and formally recognized channels of coordination must be established to reinstate, through structural facilitation, the incentives for harmonious association (10).

[5] That is, in respect to the formulation of policy, the approval of action, and the review of accomplishment.

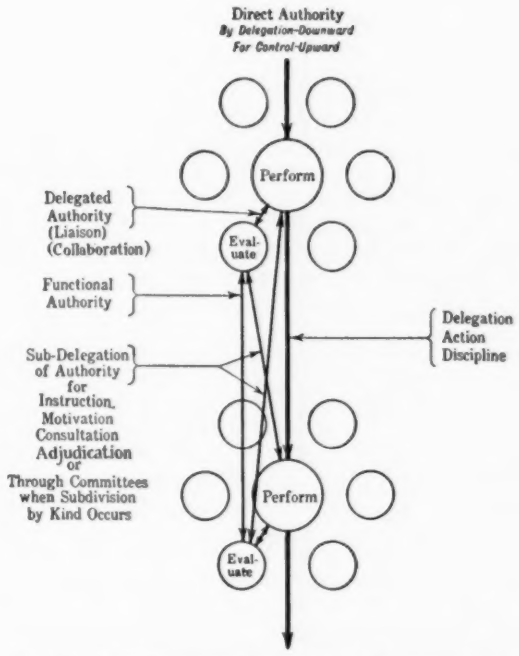


FIG. 3 SUPPLEMENTARY CHANNELS OF COORDINATION
(For contact and communication between operating and functional units, or operating and service divisions.)

Otherwise the conflict from having two masters is likely to prevail.

Facilitating Coordination

Thus with functionalization the need becomes extreme for lines of contact and communication supplemental to those of supreme authority. Authority, of course, supplies the primary means for harmonious action in that it conveys the sole right to undertake a specific action on condition that a satisfactory accounting of results follows. Hence, orders pass down the line of authority and reports ascend providing an effective bond for purposes of direction and control.

The channels thus provided for the flow of supreme authority, since it embodies the common objectives of the organization, are adequate for the exercise of leadership in fostering all aspects of mutuality. The lines of specifically delegated authority are equally effective channels of coordination since the primary

Usual Sequence of Occurrence

From Subordinates

objective remains unaltered though restricted in application to some one facility of a specific kind.

With functional authority, regardless of the manner of delegation, new and supplemental objectives are introduced, applicable only within the realm of its own technique. As long as functional activities form natural subdivisions of the common endeavor, leadership can still maintain mutuality, provided it encourages informal associations along paths of natural routine (11). When functional activities are given individual status, authority and leadership must be supplemented by other channels of coordination to maintain mutuality of interest.

Factors of Coordination

To supplant structurally the incentive for mutuality destroyed by functionalization requires an understanding of the means by which it is made operative. See Table 5. Its component, community of interest, is apparently fostered by liaison and collaboration, where two units turn to each other for advice and information, and work out upon the request of one a proposal for some action by the other which is of consequence to both. The second, harmonious understanding, is derived from instruction and motivation where one learns from the teachings of the other and each is stimulated to better performance by mutual criticism and suggestion. The third, faithful cooperation, is effected through consultation and adjudication where one unit takes the other into its confidence to secure advance agreement, by mutually formulating and accepting a plan of common action, and to assure fair disciplinary treatment in the event of conflict or complaint.[6]

Supplementary Lines of Coordination

Accordingly, supplementary channels for contact and intercommunication should be established along the natural lines for liaison, collaboration, instruction, motivation, consultation, and adjudication, as in Fig. 3. The first two are most likely to flow over the lines of laterally delegated authority. The second two will pass over the line of subdelegated authority from the functional unit associated with primary authority to a subordinate operating unit. The third two will operate over the line of discretionary authority between the primary unit and a subordinate functional unit, where the subordinate operating executive, in view of effectiveness, waives his right to be a party to the deliberations, reserving as always his responsibility of final decision. Thus, acceptance or disciplinary action in the end must pass over the lines of operating authority to the lower unit and then laterally to the functional unit. Between integrated functional units all six types of contacts regarding uniformity of technique are contained in the line of supreme functional authority. When interdepartmental contacts of a regularly recurring nature are essential, these channels may be effectively formalized by the establishment of a committee (12).

Facilitating Leadership

The longer and more intricate the chains of specialized activities become, the more ponderous and impersonal the organization, especially when all authority is concentrated at the top. Centralization has its advantages in unity and uniformity but is lacking in flexibility and spontaneity of action. It is, therefore, more effective in the coordination of functional divisions than of operating units, particularly when the latter are far removed from the administrative center.

Since operating units are in continual contact with new situations and constantly changing circumstance, they are more effective when authority is decentralized. Their responsible heads, being then close to the scene of events, are more sensitive to the required course for effective and prompt action and can preferably be held accountable for objective results, instead of efficiency of operation alone. Leadership, thus, is spread out over the whole organization and no longer suffers dilution in being transmitted from the top (13).

The point where the decentralization of authority should occur depends upon the determination of the level where constructive action takes place in the direction of the specific objectives of the endeavor and what constitutes adequate freedom under the conditions prevailing, in so far as all contributory prior activities can be departmentalized and rendered upon request as services to the operating units. Basically the decentralized operating unit should be self-sufficient and autonomous, provided its objectives are in no way at variance with those of the enterprise. Primarily, executives, supervisors, and employees should be concerned only with the intelligent, resourceful, and efficient attainment of results. This means, however, an alertness by all in anticipating and meeting the exigencies of each situation with a full understanding of the human, technical, and economic factors involved.

Thus the superstructure of organization could be compressed into a purely motivating, coordinating, facilitating, and evaluating medium. The opportunities for attaining such an organization lie in the understanding of how functional integration will provide a broadening of the structure of enterprise without loss of technical efficiency, and yet narrow the spread between administrator and worker for the fuller and more direct exercise of leadership.

Recent Developments in Business Organization

It appears that the influence of an executive will reach effectively through only three levels of the organization. Similarly the layers of personal insulation (14) dilute the interests of the man at the bottom in reaching further upward with consequent distortion in being relayed to the top. In fact, a new concept is becoming manifest where the work group under a foreman is regarded as the basic unit of management. All the superstructure of management in this case must be justified upon its efficiency in serving these work units. A similar development has appeared in sales organizations.

A corresponding change is being wrought by functional integration in administrative organization (15). Usually the major operating branches of enterprise stem directly from the administrative officer. However, with constantly increasing personal demands, some administrators are surrounding themselves with what may be termed an administrative council, the members of which are the former top operating executives, relieved of all their executive duties. Administration is thus also being forced to functionalize. From the character of administration as now understood, functional integration in its full application would indicate that the administrative group should comprise those executives concerned with (*a*) public and industrial relations (personnel and publicity), (*b*) technical development (research and engineering), (*c*) comptrollership (control information and reports—internal and external), (*d*) law, (*e*) finance (working funds and property), and (*f*) operations (purchasing, manufacture, and sales). This development presupposes that the administrator be himself a practical economist, an organizer, and above all a leader of men.

Accordingly, if decentralization together with functional integration continues to develop in this direction, business enterprise will become substantially, if not in fact, a group of separate enterprises, mutually dependent, serving each other

[6] Note the correspondence of the separate actions with the essential qualities of a leader, i.e., he should be a planner, a technician, a commander, a coordinator, a trainer, an energizer, and a critic. See Bibliography (7), chapter 12, p. 157.

efficiently in carrying out their common business objective and, above all, far better adapted to the fostering of individual initiative and leadership. Thus one way has manifested itself to extend the limits of optimum size in response to the continued growth of large-scale enterprise and at the same time effectively to humanize management.

Practical Aspects of Organization

The remaining aspects of organization are of a practical nature since they are concerned with making the structure operative, and derive their basis of application from the concepts which have been thus far described. Though deserving of equal treatment from the standpoint of immediate utility, space limitations permit only their brief mention to complete the present consideration of the dynamics of organization.

Departmentation is the process by which essential activities are effectively grouped to meet the needs of an enterprise. Aside from natural functional relationships, it is largely governed by the magnitude of operations and the frequency of occurrence. In the upper executive categories where coordination of policies and programs is of primary concern, activities which are naturally associated or complementary in kind should preferably be combined. In the lower categories, groupings should conform to similarity of technique or skills (16). The number of activities so grouped should not exceed that of the direct personal contacts which the executive in charge can effectively maintain (17).

In smaller enterprises the coordinating and facilitating stages may combine with either that of general management or operations, because the more direct personal contacts possible eliminate the need for their formal recognition. In the largest enterprises the stratification manifest among the stages in functional development accounts for the pyramidal structure of holding companies where their subsidiaries in descending order are concerned with the affairs of entrepreneurship, functional services, and specific operations.

The point, where specialization by functional activities should supplant that based on primary authority, occurs when two or more men, simultaneously doing the whole job, can instead do separately different portions of the job, giving a consequent increase in effectiveness, with no other change having taken place (18).

Assignment to duty comprehends the fitting of available personnel to the established departmental units in satisfying the requirement that "the man equals the job." Though one individual may be given responsibility over activities of various kinds, it merely means that he acts in different capacities at different times. Coordination is only affected to the extent that between the temporarily associated activities the single executive in charge himself provides the essential connecting link, and that otherwise separate external channels may become identical until with another individual a reassignment occurs. Though the degree of specialization is reduced, functional definition derived from it serves to clarify relationships in specifying an individual's duty and thus avoids conflicts in authority.

The character and amount of work assigned to an individual, directly and implied, whatever the necessary degree of specialization, should be governed by what fairly constitutes a full day's occupation, with due regard for the physical, mental, and nervous strains involved and for their frequency and severity under periods of peak as well as normal load. Assistance, which is the first step toward further specialization, should be granted before a point is reached where the work becomes so exacting as to impair the effectiveness of the human being (19).

Through systemization, the application of organization to method, standardized processes may be established to relieve an executive or supervisor of unnecessary repetitive detail in directing the regular work of his department, so that he may be free to devote his attention chiefly to exceptional situations, the checking of performance, or the anticipation of the needs for improvement. What happens is that, by planning once in advance, the administrative functions of a constantly recurring nature, for all activities standardized, are dispensed with until circumstances require change.

Routinization, in turn, is a similar standardizing of procedures. Technique is, of course, the standardized practice of an art based on the underlying sciences.

Complete mechanization, the extreme of systemization, contemplates not only the transfer of operator skill for the mechanical performance of work but similarly the incorporation of devices to perform the allied procure and dispose functions as well.

Pulsating Air Velocity Measurement

NEIL P. BAILEY,[1] NEW BRUNSWICK, N. J.

This paper includes an analysis of the weaknesses of three methods of air velocity measurement, that is, (1) the hot-wire anemometer, (2) the Thomas or Callandar meter, and (3) nozzles, orifices, or pitot tubes used with liquid manometers, and the author points out that these methods give unreliable results when the air flow is pulsating. After analyzing the influence of plenum chambers he then describes a modified proportional flowmeter in which the pressure change of a nozzle, orifice, or pitot tube produces an *air* velocity through a small orifice which is always proportional to the instantaneous velocity of the main air flow; therefore, by measuring volumetrically the *air* that passes through the small orifice, the average velocity of the main air flow can be determined. Included in the paper are test results obtained with this meter on a $3^1/_4 \times 4^1/_2$-in. single-cylinder C.F.R. internal-combustion engine.

IN A few simple cases, quantities of air are metered by direct volumetric measurement, but in general it is necessary to determine the velocity of flow. This is usually done in one of three chief ways, namely, by (1) the hot-wire anemometer, (2) the Thomas or Callandar meter, and (3) nozzles, orifices, or pitot tubes used with liquid manometers. The hot-wire anemometer indicates the velocity by the rate of heat loss from a heated wire in the air stream. In the Thomas or Callandar meter, heat is supplied at a known rate and the resulting temperature rise of the air stream is used to determine the velocity. When nozzles, orifices, or pitot tubes are used with liquid manometers, the energy necessary to produce the velocity is measured and used to calculate the velocity.

With suitable precautions, any one of these three methods will give accurate results when the velocity being measured is steady and without fluctuations, but when the flow is unsteady or pulsating in nature these accepted methods of velocity measurement are all subject to serious errors. If any method of measurement is to indicate the true average air velocity, it must depend upon some phenomenon that is influenced only by the average velocity, regardless of the variations of the instantaneous velocity above and below this average value. Since this is not true of the rate of heat transfer involved in the hot-wire anemometer and the Thomas heat meter or of the energy content involved in the use of pitot tubes, nozzles, and orifices, they do not conform to this requirement.

No mechanically induced air motion is free of velocity fluctuations, and in reciprocating engines and compressors the flow is decidedly of a periodic nature. The importance of the need for accurate flow measurement under such periodic conditions makes it seem worth while to analyze the weaknesses of existing methods of velocity measurement, and to present recent developments made in a general method of velocity measurement that was originally presented in 1934.[2]

Hot-Wire Anemometer

The hot-wire anemometer[3] is essentially an electrically heated wire of small diameter that is placed in the air stream. From the applied voltage and current, and the temperature coefficient of electrical resistance of the wire, its temperature may be determined. With the heat input and temperature known, the forced convection film conductance can be calculated after a radiation correction is made.

If this film conductance for wires were a linear function of air velocity, the hot-wire anemometer would yield the true average air velocity for any condition of flow. Unfortunately it varies as the air velocity u to the 0.41 power for small wires and as the velocity to the 0.58 power for large wires.[4] If it be assumed that on the average, the film conductance varies as $u^{1/2}$, it follows that the rate of heat loss at any instant is proportional to $u^{1/2}$ and to the temperature difference between the wire and the air.[3,5] Except for low pulsation frequencies and very small wires, the heat capacity of the wire will tend to maintain a constant wire temperature.[6] In some special work in the study of boundary-layer velocities the temperatures of the very small wires used partially follow the velocity variations, but in general equipment, the temperature difference between the wire and air may be considered as unvarying. It follows that the average rate of heat loss is proportional to the average value of $u^{1/2}$, and the velocity calculated would be the square of the average value of $u^{1/2}$. If this velocity is designated as the indicated velocity it is defined by

$$u^{1/2}{}_{ind} = \frac{\int_0^t u^{1/2}\,dt}{t} = \text{average value of } u^{1/2} \ldots\ldots [1]$$

This is the same as the average velocity for steady flow, but when the velocity is fluctuating it is something quite different. This definition gives a maximum deviation from the average and this difference decreases as the apparatus becomes more delicate and highly refined.

Thomas Meter

With the Thomas or Callandar meter the weight per second of air flowing is found by determining the rate of adding heat necessary to produce a small temperature rise in the entire body of air flowing. Knowing the temperature rise, the rate of adding heat, and the specific heat of the air, the rate of flow may be found. This seems like a positive and safe method of measuring air flow under any conditions of velocity variation until the individual heat-transfer steps involved are analyzed.

Since all the air approaching the heater is assumed to be at the same temperature, the first thermometer will indicate the correct initial air temperature regardless of the velocity fluctuations present. In the heating element, which is usually an electrically heated wire grill, the temperature rise of the air passing is small compared with the large temperature difference that must exist between the heater and the air. This temperature difference may then be considered constant for all the air passing, regardless of velocity variations.

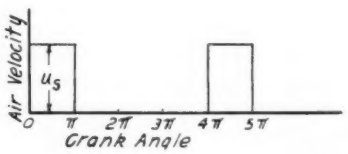

Fig. 1 Simplified Intake Wave of a Single-Cylinder Engine

A convenient method of discerning what happens in this heater is to follow an increment of air through it. If any unit of air has a velocity u, the rate of heat transfer to it as it passes the grid will be proportional to $u^{1/2}$ as in the hot-wire anemometer. The time that this portion of air is in contact with the heater varies inversely as its velocity or as $1/u$. It follows that the heat received by the element of air and consequently its temperature rise are proportional to the product of film conductance and time of contact, and will vary as $u^{1/2}/u$ or as $1/u^{1/2}$. This means that the temperature rise experienced by any portion of air as it passes the heater will vary inversely as the square root of its velocity. This may be expressed mathematically as

$$T_{air} - T_1 = K/u^{1/2} \quad [2]$$

where T_{air} is the temperature of any portion of the air as it leaves the heater; T_1 is the initial temperature; and K is a factor which depends on wire size and temperature, and air properties and temperature. For any practical thermometer, thermocouple, or resistance thermometer sizes and pulsation frequencies, the temperature T_2 indicated by the thermometer after the heater will be steady.[6] Its value will be such that there will be no net heat transfer between it and the air stream. Since the film conductance of the thermometer varies as $u^{1/2}$, it follows that

$$\int (T_{air} - T_2) u^{1/2}\, dt = \int_0^t \left[T_1 + \left(\frac{K}{u^{1/2}} \right) - T_2 \right] u^{1/2} dt = 0 \quad [3]$$

From this, the temperature rise indicated in the Thomas meter is

$$T_2 - T_1 = \frac{Kt}{\int_0^t u^{1/2}\, dt} \quad [4]$$

If u_{ind} be the velocity indicated by the meter, it would be calculated from the temperature rise $(T_2 - T_1)$ as

$$u^{1/2}_{ind} = K/(T_2 - T_1) \quad [5]$$

From Equations [4] and [5]

$$u^{1/2}_{ind} = \frac{\int_0^t u^{1/2}\, dt}{t} = \text{average value of } u^{1/2} \quad [6]$$

It is evident that the Thomas meter, like the hot-wire anemometer, averages $u^{1/2}$; consequently, this indicated velocity is seriously in error when the flow is pulsating.

Pitot Tubes, Nozzles, and Orifices

When air flow is measured by a pitot tube, orifice, or nozzle, the energy necessary to create the flow velocity at any instant is proportional to u^2 and this is measured as a pressure by a liquid manometer. Except when the manometer is of such a length as to oscillate in synchronism with the pulsation frequency, the manometer reading is proportional to the average value of u^2. Consequently, the effective velocity u_{eff} calculated from the manometer reading is given by

$$u^2_{eff} = \frac{\int_0^t u^2\, dt}{t} = \text{average value of } u^2 \quad [7]$$

Again, the pitot tube, orifice, and nozzle when used with a manometer do not give the correct average velocity when the flow is pulsating.

Pulsation Errors

The possible magnitude of the errors involved in the use of existing methods for air velocity measurement when the flow is

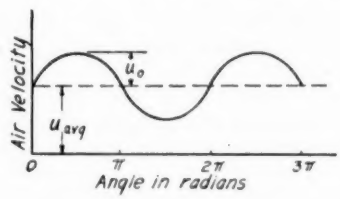

Fig. 2 Pulsating Air Flow

pulsating or periodic may be dramatized by assuming the intake air to a single-cylinder four-stroke-cycle engine to be as simple as shown in Fig. 1. For such a velocity wave

the average velocity is $u_{avg} = \pi u_s/4\pi = u_s/4$

the indicated velocity is $u_{ind} = [(\pi u_s^{\frac{1}{2}})/(4\pi)]^2 = u_s/16$

the effective velocity is $u_{eff} = \sqrt{[(\pi u_s^2)/(4\pi)]} = u_s/2$

or

$$u_{avg}/u_{ind} = 4$$

and

$$u_{avg}/u_{eff} = 1/2$$

This means that the hot-wire anemometer or the Thomas meter would give an indicated value one quarter the average, and a pitot tube, orifice, or nozzle would give an effective value two times the average.

A more comprehensive picture of these errors may be presented by representing any pulsation as an equivalent sinusoidal variation as shown in Fig. 2. The instantaneous velocity for such equivalent pulsation is given by

$$u = u_{avg} + u_0 \sin\theta \quad [8]$$

and the pulsation may be defined as

$$\text{Pulsation} = u_0/u_{avg} \quad [9]$$

For the hot-wire anemometer and Thomas meter

$$\frac{u_{avg}}{u_{ind}} = \frac{u_{avg}}{\left[\dfrac{\int_0^{2\pi} (u_{avg} + u_0 \sin\theta)^{\frac{1}{2}}\, d\theta}{2\pi} \right]^2} \quad [10]$$

$$= \frac{1}{\left[1 - \frac{1}{16}\left(\frac{u_0}{u_{avg}}\right)^2 - \frac{15}{1024}\left(\frac{u_0}{u_{avg}}\right)^4 \ldots\ldots \text{approx}\right]^2} \quad [10a]$$

and for the pitot tube, orifice, and nozzle

$$\frac{u_{avg}}{u_{eff}} = \frac{u_{avg}}{\left[\frac{\int_0^{2\pi}(u_{avg} + u_0 \sin\theta)^2\, d\theta}{2\pi}\right]^{1/2}} \quad [11]$$

$$= \frac{1}{\left[1 + \frac{1}{2}\left(\frac{u_0}{u_{avg}}\right)^2\right]^{\frac{1}{2}}} \quad [11a]$$

These variations are shown in Fig. 3.

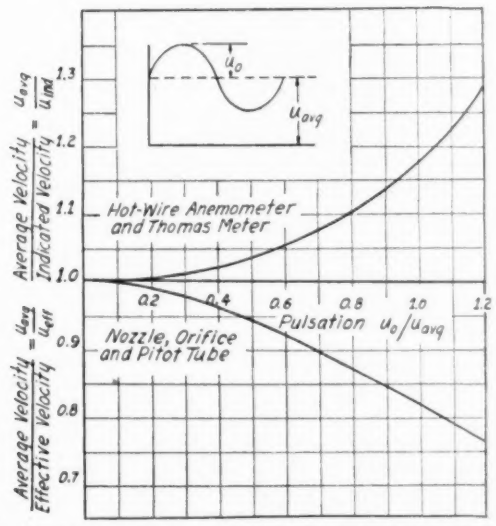

FIG. 3 PULSATION ERRORS FOR SINUSOIDAL VELOCITY VARIATION

The measurement errors for the idealized air intake of four-stroke-cycle internal-combustion engines are summarized in Table 1. The air velocity is assumed to be sinusoidal during the intake strokes and zero at other times.

TABLE 1 IDEALIZED PULSATION ERRORS FOR INTAKE AIR OF INTERNAL-COMBUSTION ENGINES

Engine type	u_{avg}/u_{eff}	u_{avg}/u_{ind}
Single cylinder	0.45	4.60
Two cylinders	0.76	2.30
Four cylinders	0.90	1.15

Errors of this magnitude are not realized in practice because of the reduction of the intake manifold, but Table 1 does illustrate the possible magnitude of pulsation errors.

PULSATION REDUCTION

The usual method used to reduce the pulsation in the air flow to reciprocating machines is to draw the intake air through a plenum chamber where the elastic action of the air in the tank reduces the velocity fluctuation in the air entering the chamber through the orifice or nozzle. The air dome on the discharge of a reciprocating liquid pump fills this same function.

If a reciprocating machine draws a pulsating flow from a plenum chamber with an instantaneous velocity V, the mass per second of air leaving the chamber is

$$\text{mass per second leaving} = c\rho VA \quad [12]$$

where ρ is the mass density of the air, A is the orifice area, and c is its coefficient of discharge. The mass per second being stored in the tank of total volume S is $S(d\rho/dt)$, and, since the air conforms to the general gas equation $PV = WRT$ and the temperature may be considered constant for the small pressure changes involved

$$\text{mass per second stored} = \frac{S}{gRT}\frac{dP}{dt} \quad [13]$$

where P is the instantaneous pressure in the tank at any time t.

If u is the instantaneous velocity of the air entering the plenum chamber through the intake orifice, a change in this velocity du will produce a change in the plenum chamber pressure of

$$dP = -\rho u\, du \quad [14][7]$$

For an intake orifice area a and coefficient of discharge c, the mass per second entering the chamber is

$$\text{mass per second entering} = ca\rho u \quad [15]$$

Since the mass per second entering the plenum chamber must leave or be stored

$$ca\rho u = c\rho VA - \frac{S}{gRT}\rho u\frac{du}{dt} \quad [16]$$

or for equal discharge coefficients

$$V = u\frac{a}{A} + \frac{S}{gRT\,AC}u\frac{du}{dt} \quad [17]$$

From Equation [17] it may be seen that u differs from $(A/a)V$ by a term which depends upon $u(du/dt)$. This term represents three physical differences between the velocity wave drawn by the engine and that entering the plenum chamber. The amplitude of oscillation is decreased, the time of maximum velocity is shifted, and the wave is distorted by the introduction of harmonics. Since the actual velocity wave drawn by a compressor or engine contains many harmonics, and since each harmonic has its amplitude and phase angle changed and is distorted, a completely general solution of Equation [17] is out of the question.

However, as will be verified later, the maximum possible effect of a plenum chamber may be predicted from a simple approximate solution of Equation [17]. Any wave form drawn from the tank may be represented by an equivalent sinusoidal variation that has the same value of V_{avg}/V_{eff}, or by

$$V = V_{avg} + V_0 \sin\omega t \quad [18]$$

When only the change in amplitude and the phase displacement are considered, and all distortion due to harmonics is ignored, the velocity wave entering the plenum chamber may be represented by

$$u = u_{avg} + u_1 \sin\omega t + u_2 \cos\omega t \quad [19]$$

Substituting Equations [18] and [19] into Equation [17], ignoring all harmonic terms in $u(du/dt)$, and solving for u_{avg}, u_1, and u_2, gives

$$u = \frac{A}{a}V_{avg} + \frac{V_0\, aAg^2R^2T^2c^2}{S^2u^2_{avg}\omega^2 + a^2R^2T^2g^2c^2}\sin\omega t - \frac{V_0 gRTcAS u_{avg}\omega}{S^2u^2_{avg}\omega^2 + a^2R^2T^2g^2c^2}\cos\omega t \quad [20]$$

[7] To obtain solvable equations, the entering and leaving densities are assumed equal. The only place where the variation in density is numerically significant is in the rate of change of mass in the plenum chamber $Sd\rho/dt$.

This may be simplified to

$$u = \frac{A}{a} V_{avg} + \frac{(A/a)V_0}{\sqrt{\left(\frac{Su_{avg}\omega}{agRTc}\right)^2 + 1}} \sin\left[\omega t - \tan^{-1}\frac{Su_{avg}\omega}{agRTc}\right] \quad [21]$$

If the tangent of the angle of phase displacement is defined as

$$\beta = \frac{Su_{avg}\,\omega}{agRTca} = \text{plenum factor} \quad [22]$$

Equation [21] becomes

$$u = \frac{A}{a} V_{avg} + \frac{(A/a)V_0}{\sqrt{(\beta^2 + 1)}} \sin\left[\omega t - \tan^{-1}\beta\right] \quad [23]$$

By the same method used in Equation [11]

$$\frac{u_{avg}}{u_{eff}} = \frac{1}{\left[1 + \frac{1}{2}\left(\frac{V_0}{V_{avg}}\right)^2\left(\frac{1}{\beta^2 + 1}\right)\right]^{\frac{1}{2}}} \quad [24]$$

and since from Equation [11]

$$\frac{1}{2}\left(\frac{V_0}{V_{avg}}\right)^2 = \left(\frac{V_{eff}}{V_{avg}}\right)^2 - 1 \quad [25]$$

Equation [24] then becomes

$$\frac{u_{avg}}{u_{eff}} = \frac{1}{\sqrt{\left[1 + \frac{(V_{eff}/V_{avg})^2 - 1}{\beta^2 + 1}\right]}} \quad [26]$$

This equation gives the maximum possible value of u_{avg}/u_{eff} for air flowing into a plenum chamber having a plenum factor β (Equation [22]) when the air flowing to the engine has pulsation represented by V_{avg}/V_{eff}. This plenum-chamber action is

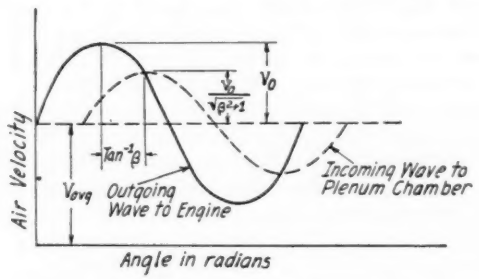

FIG. 4 THE EFFECTS OF A PLENUM CHAMBER ON AIR VELOCITY WAVES

illustrated graphically in Fig. 4, which shows the incoming and outgoing air waves reduced to the same orifice-area basis. From Equation [17] when $du/dt = 0$, the maximum or zero slope value of the incoming wave occurs at an angle $\tan^{-1}\beta$ later than the maximum value of the outgoing V wave, and the equivalent amplitude is reduced to $V_0/\sqrt{(\beta^2 + 1)}$. The effect of the harmonics that were ignored in the approximate solution of Equation [17] would be to produce a distorted wave with the same average value but having a higher maximum value and also a smaller u_{avg}/u_{eff}.

Fig. 5 shows the maximum possible values of intake u_{avg}/u_{eff} plotted against the plenum factor β for different values of initial V_{avg}/V_{eff}. It is interesting that a plenum chamber having a factor of $\beta = 5$ will reduce the pulsation error as far as it is practically feasible. Further gains in pulsation reduction would be too slight to justify the necessary increase in plenum-chamber size.

Applying this conclusion to an internal-combustion engine of N cylinders, each having a displacement P, turning n revolutions per second, Equation [22] may be written

$$S = \frac{\beta ac\, u_{avg}\, gRT}{\omega\, u^2_{avg}} \quad [27]$$

For a four-stroke-cycle engine, the cubic feet of air per second is

$$acu_{avg} = (N/2)nP\epsilon$$

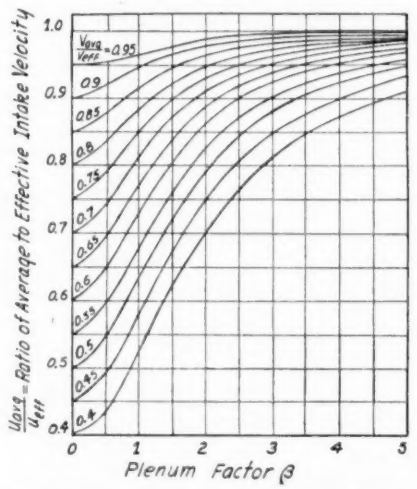

FIG. 5 PULSATION REDUCTION IN PLENUM CHAMBERS
(V_{avg} and V_{eff} refer to air drawn from the plenum chamber, while u_{avg} and u_{eff} refer to resulting air flow to the plenum chamber.)

where ϵ is the volumetric efficiency. Also, $\omega = (nN/2)2\pi$; $\beta = 5$; $\epsilon = 0.7$; $R = 53.3$; and $T = 530$ F, abs. For an average intake-orifice velocity ($u_{avg} = 100$ fps)

$$S = \frac{\beta(N/2)nP\epsilon gRT}{2\pi(nN/2)u^2_{avg}} = \frac{\beta gRT\epsilon}{2\pi\, u^2_{avg}} P = 50\ P \text{ (approx)} \quad [28]$$

This is the size usually recommended[8] for such plenum chambers, and for a two-cylinder engine for example, Fig. 5 shows that an initial $V_{avg}/V_{eff} = 0.76$, as given in Table 1, would be reduced to a $u_{avg}/u_{eff} = 0.985$. This would represent a minimum pulsation error of 1.5 per cent. However, if the engine speed is reduced one half and the plenum chamber and intake orifice are not altered, u^2_{avg} of Equation [29] will be reduced to about one fourth. From Equation [28]

$$\beta = \frac{2\pi(u_{avg})^2\, S}{gRT\epsilon P} \quad [29]$$

This would give a plenum factor $\beta = 1.25$ instead of 5, and from Fig. 5, for $V_{avg}/V_{eff} = 0.76$, u_{avg}/u_{eff} would be 0.875, which would represent a minimum possible measurement error of 12.5 per cent. This illustrates the need for proportioning a plenum chamber and its orifice for the exact conditions of use, and also the danger of depending on a simple rule that specifies only the volume of the chamber.

AN AVERAGE-VELOCITY METER

If any instrument is to measure the true average velocity of air when the flow is pulsating, it must be actuated by some phenomenon that is always directly proportional to the instantaneous

[8] "Power and the Internal Combustion Engine," by W. E. Dalby, Longmans, Green & Company, New York, N. Y., 1931, p. 111.

velocity. In 1934 the author proposed[3] a modified proportional flowmeter in which the pressure change of a nozzle, orifice, or pitot tube produced a water velocity through an orifice always proportional to the instantaneous air velocity. By collecting the water that passed through the orifice, the average air velocity was determined.

Subsequent work with this meter has emphasized the need for the elimination of the flow of water through a small orifice, and this has resulted in the evolution of the instrument shown in Fig. 6. In it the pressure drop across the intake orifice *1* causes an instantaneous air velocity through the small orifice *2* that is always equal to the air velocity through *1* as long as the pressure in *3* is maintained equal to atmospheric. This pressure is maintained by admitting water from storage *6* through the valve *5* at such a rate as to maintain the water levels in the glass tubes *3* and *4* always equal as they rise. If the time required to draw a certain volume of air from the annular space between tubes *3* and *4* is found, the average velocities through orifices *2* and *1* may be found.

For satisfactory operation, tubes *3* and *4* should be large enough to give a flat meniscus and so proportioned that their capillary heads are equal. Their lengths should be sufficiently great to lower the natural oscillating frequency of the water columns well below the minimum pulsation frequency of the air flow being measured. The orifice area *2* needs to be very small in comparison with the tube sizes to cause the water level to rise

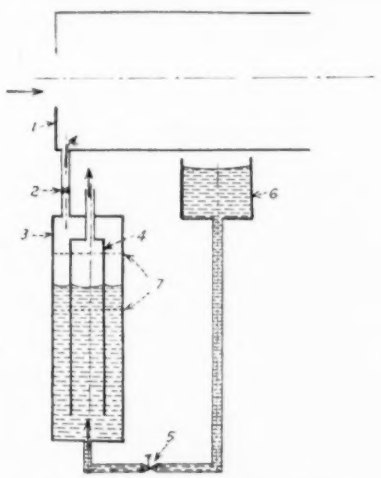

FIG. 6 AVERAGE VELOCITY METER

slowly enough to make it possible to maintain the two levels the same throughout a run, and also to minimize air-friction losses in the rubber tubing leading to the instrument.

This meter is, in effect, a combination of proportional flow and positive-displacement meters. With it the true average velocity may be determined directly for any conditions of pulsation with either intake or discharge orifices or nozzles, and when it is used in conjunction with a manometer, the value of V_{avg}/V_{eff} may be found. Fig. 7 shows the calibration curve of the experimental instrument now in use. During its development it was checked by velocity determinations where the wave shape was produced artificially and was known accurately. Using a trapezoidal wave through an intake orifice it gave $V_{avg}/V_{eff} = 0.912$ and the value calculated from the wave shape was 0.898. For a similar wave through a discharge orifice at the same frequency of two cycles a second it gave $V_{avg}/V_{eff} = 0.898$ and the calculated value was 0.895.

The accuracy of the present meter is within 2 per cent, and its

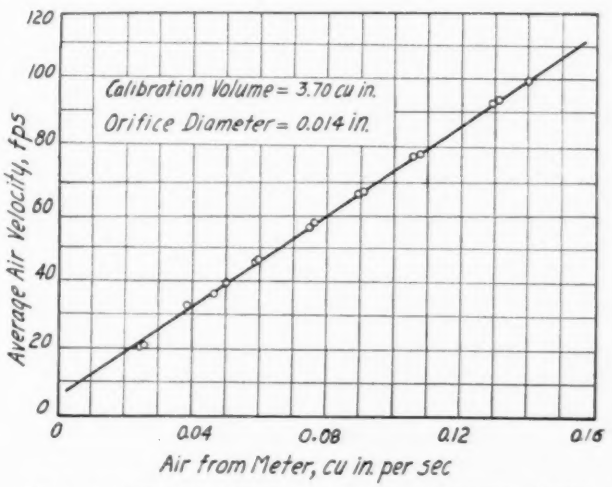

FIG. 7 CALIBRATION CURVE FOR AVERAGE VELOCITY METER

operation requires approximately the same degree and type of skill as an Orsat gas analyzer. Starting with the water level below the lower calibration mark, water is admitted at the correct rate to keep the levels equal in the two tubes. From the time required for the level to rise from the lower to upper calibration mark *7*, the average velocity may be found from the calibration curve. It is calibrated against a liquid manometer under steady-flow conditions where the average and effective velocities are equal.

EXPERIMENTAL VERIFICATION

To illustrate the operation of the average-velocity meter and to check the predicted action of a plenum chamber, tests were made on a $3^1/_4 \times 4^1/_2$-in., C.F.R., single-cylinder internal-combustion test engine operating at variable speed and a compression ratio of 5 to 1. Since a single-cylinder four-stroke-cycle engine draws air of distorted wave shape for one stroke and none for three strokes, it represents about the worst possible condition of operation for the average velocity meter. It also has an intake air-velocity wave with a wide variety of harmonics and represents the greatest variation from the simplifying assumptions made in the solution of Equation [17] and shown in Fig. 5.

When the air to the engine was drawn through a $^7/_8$-in. diameter orifice directly in the $1^1/_4$-in. intake to the engine, the values of V_{avg}/V_{eff} shown by Table 2 were found.

When the intake air was drawn through a plenum chamber $2^1/_2$ ft long with a total volume of 1.98 cu ft and a $^7/_8$-in. diameter intake orifice, the values listed in Table 3 were obtained.

Theoretical values of u_{avg}/u_{eff} calculated from the results of Tables 2 and 3, using the curves of Fig. 5, are given in Table 4. In Fig. 8 the test and theoretical results are shown graphically.

Fig. 8 brings out several points of interest. The increase in pulsation of the engine intake air shown by the decrease of V_{avg}/V_{eff} as the engine speed is increased might seem contradictory until it is remembered that an increase in speed results in a sharper-topped suction wave. It is not surprising that the theoretical values of u_{avg}/u_{eff} exceed the test values by as much as 0.085 when it is remembered that the case tested varies a maximum amount from the conditions assumed when solving Equation [17]. As the initial-velocity variation becomes less marked and more symmetrical, results would more closely correspond to test results.

SUMMARY

From the foregoing it seems safe to conclude that conventional methods of air velocity measurement are unreliable when the

flow is pulsating. This trouble may be at least partially eliminated by a properly designed plenum chamber, but there are possibilities of plenum-chamber errors not previously mentioned. Some of the apparently unproductive development work[9] of the past four years has emphasized the fact that when any dimension of the plenum chamber or intake system is such as to produce resonance of any one of the principal harmonics of the suction-velocity wave, a plenum chamber may be a menace instead of an aid.

An incorrect length of rubber air hose to an instrument or a wrong water-column length may produce resonance and the difficulty of knowing the harmonic frequencies present in an engine suction wave increases this danger. In general, it is desirable to keep all air paths short enough to have natural frequencies above any harmonic present and to use long water columns to keep their resonance frequencies very low.

Since plenum chambers have a knack of introducing unsuspected errors and since they are not feasible when testing large engines, the author believes that the average velocity meter shown in Fig. 6 used with nozzles or orifices directly in engine-intake pipes can fill a definite need.

NOTE: $S = 1.98$ cu ft; $a = 0.00418$ sq ft; $c = 0.61$; and $T = 530$ F, abs.

The coefficients of discharge of nozzles vary so little that no fear has been felt in using the steady-flow values under pulsating conditions. The work done to date[9] on the effects of pulsation on orifice discharge coefficients indicates that here also, the steady-flow values may be used with safety. The apparent discrepancy between the average velocities V_{avg} and u_{avg} in Tables 2 and 3, when $^7/_8$-in. diameter orifices were used in both cases, resulted from the methods of installing them. When the plenum chamber was used the coefficient of discharge was assumed to lie between 0.60 and 0.61; however, Table 2 is for a $^7/_8$-in. diameter orifice used in a $1^1/_4$-in. diameter pipe and here, as in steady flow, the coefficient ranged from 0.52 to 0.56.

However, there are enough such questions to be answered that plans for the future include the investigation of orifices, nozzles, and pitot tubes. It is also planned to refine the present instrument, which is now just an accumulation of glassware, into a rugged instrument that will require less operating skill.

Discussion

J. F. ALCOCK.[10] This paper is of great interest to the writer since, having studied the problem for some years, he has arrived at an entirely different solution. In this the fluctuation difficulty has been eliminated by using the pressure drop across a viscous resistance for flow measurement. Because at any instant the pressure drop is directly proportional to the flow, the root-mean-square error disappears and pulsation has no effect.

In this viscous-flow meter the resistance element is a honeycomb of long narrow triangular passages, formed by winding alternate layers of plain and corrugated strip metal on a core, as in the "Amal" flame trap but with smaller and longer passages. The strip is of nickel silver and the passages are 0.017 in. wide. The theoretical critical velocity in these passages, for air under atmospheric conditions, is about 270 fps, but the highest velocity so far used in practice is about 22 fps, although the resistance is linear up to at least twice this figure. There is a small square-law resistance component, due to entry losses, which is automatically corrected by making the downstream manometer connection face upstream and vice versa, thus giving a small reverse kinetic head.

There are, to prevent clogging of the meter exhaust element, two air cleaners, one oily to trap dust and the other dry to trap any oil blown over from the first cleaner. Felt pads are fitted in the tubes between the meter and the manometer. This raises an interesting point. In the early tests it was found that, although the resistance characteristic on steady flow was quite linear, the readings on pulsating flow were incorrect (generally on the low side). It was suspected that the air flow in and out of the manometer tubes, due to the pressure changes in the meter and to the elasticity of the air in the tubes, was responsible. The matter was examined theoretically for a simplified pulsating flow in which the velocity was n times the mean for $1/n$ of the cycle,

[10] Ricardo & Company, Limited, Consulting Engineers, Bridge Works, Shoreham-by-Sea, Sussex, England.

with no flow in between. The capacity of the tubes was assumed to be so large, and the orifice connecting them to the meter so small, that there was negligible cyclical pressure variation therein. The resistance of the manometer correction orifice was assumed to be square-law.

This investigation showed that the pressure in the manometer tube is not, in general, the true mean pressure in the meter. Thus there is an error which is expressed by the formula

$$\frac{\text{True flow}}{\text{Apparent flow}} = \frac{n}{1 + (n-1)^2}$$

For $n = 2$ (and for other wave forms having no odd harmonics) the error disappears. The meter reads high for $n < 2$ and low for $n > 2$. At $n = \infty$ the error is equal and opposite to the root-mean-square error of the orthodox orifice meter. Thus the latter would, for example, record fairly accurately the gas discharge from a machine gun.

If, however, the connection from meter to manometer is viscous, this manometer connection error disappears for all values of n, hence the felt pads. Their exact resistance does not matter provided that it is large enough to swamp incidental square-law resistances in the connections.

Another source of error with square-law connections is that they often have different resistance coefficients for inflow and outflow, thus acting as imperfect nonreturn valves. This cannot happen with a viscous resistance element.

These connection errors would not apply to the author's meter if the air volume above the water is large enough to render negligible the cyclical pressure changes therein. The accuracy of the viscous meter on pulsating flow has been checked by tests on single-cylinder four-cycle gasoline engines in series with a gasholder, and on the delivery of a Roots blower delivering at 6 lb per sq in., where the pulsations are extremely violent owing to the absence of compression in the blower.

Under these exceptionally severe conditions, the maximum discrepancy found was 2 per cent, which is within normal meter tolerances, except over one narrow range of engine speed in the first test, where the error reached a maximum of 8 per cent low. Here the engine volumetric-efficiency curve showed the presence of a strong pipework resonance. A smoothing receiver of only four cylinder volumes reduced the error to 3 per cent. Since the reading was low the error was probably due to the velocities being outside the viscous range of the manometer connections; recent modifications have increased this range. In any case it is generally desirable on other grounds to avoid resonances of such magnitude.

These meters have been used in internal-combustion-engine research for some years. One advantage for such work is that the cyclical variations of pressure drop are less than with a square-law meter. Thus on a single-cylinder four-stroke engine the effective pressure drop during the suction stroke is only four times the mean pressure drop as against sixteen times with a square-law meter. Thus for a given degree of engine throttling, a larger head and, therefore, a less sensitive manometer, can be used. For the same reason, the sensitivity at reduced flows falls off less than with square-law meters.

COLIN CARMICHAEL.[11] The accurate control of air-fuel-mixture ratios in aircraft engines during flight is of paramount importance in securing maximum performance, particularly in regard to economy at cruising speed.[12] The impossibility of applying existing laboratory test methods to the measurement of air supply in flight has led to investigations of indirect means of estimating air-fuel ratio, such as the analysis of exhaust gases. The accuracy of such methods is admittedly of a low order, as indicated by the scattering of test points in the investigations reported. A direct method of air measurement that does not involve cumbersome apparatus should therefore be welcomed with enthusiasm by aircraft engineers in particular, as well as by automobile, railroad, and marine engineers who have to make tests in a limited space.

Since the author's average-velocity meter requires no provision for pulsation reduction, an orifice or nozzle fitted in the carburetor intake is all that is required. It would appear, if the orifice is so proportioned that the average air velocity at wide-open throttle is about 100 fps, the reduction in volumetric efficiency will be little more than 0.5 per cent. Simultaneous measurements during the same period of time of air flow and fuel flow will afford a ready and accurate check on mixture ratio and enable the correct setting to be made as quickly as possible.

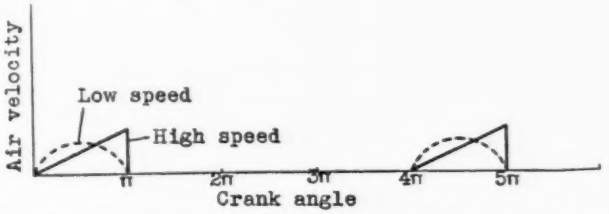

FIG. 9 SIMPLIFIED INTAKE WAVES OF A SINGLE-CYLINDER ENGINE AT LOW AND HIGH SPEEDS

While the manipulation of the author's instrument appears relatively simple after a little practice, it would seem desirable and perhaps quite feasible to introduce some means of maintaining automatically the two liquid levels equal.

Some of the author's discussion has centered around the probable shape of the velocity wave drawn by the engine. It would appear that Equation [17] is a tool which could be used for an investigation of wave shapes and volumetric efficiency, and how they are affected by speed and valve timing. In this case A is the piston area, a is the instantaneous area through the valve opening, S is the instantaneous cylinder volume and V is the instantaneous piston velocity. A step-by-step integration is of course necessary, for which purpose Equation [16] may be rewritten

$$du = \frac{gRTAdt}{S}\left(\frac{V}{u} - \frac{ca}{A}\right)$$

the coefficient of discharge at the piston area being unity. The instantaneous values of velocity through an area of the valve being known, the mass flow and velocity in the pipe may be calculated.

When the velocity is low the wave shape in the pipe will tend toward that of the piston-velocity wave for as long as the valve is open. As the speed increases, with normal timing, the restriction in the early part of the stroke due to slow opening of the valve will decrease the velocity, but later in the stroke the momentum acquired earlier will cause the velocity to exceed that corresponding to the piston velocity. The resulting curve at high speed might be simplified to a triangular wave Fig. 9, instead of the approximate sine wave found at low speed.

R. B. SMITH.[13] The problem of pulsating flow is an important, yet extremely difficult one to attack rationally, for the reason

[11] Assistant Professor of Mechanical Engineering, Rutgers University, New Brunswick, N. J. Mem. A.S.M.E.

[12] "Interrelation of Exhaust-Gas Constituents," by H. C. Gerrish and Fred Voss, N.A.C.A., Technical Report No. 616, 1938.

[13] Development Engineer, Elliott Company, Jeannette, Pa. Jun. A.S.M.E.

that we are none too sure of our fundamental premises. To be specific, the Saint Venant or Bernoulli equation, which has been employed by the author and his contemporaries, is merely a special formulation of Newton's equation as written by Euler. Now as is well known in hydrodynamics, the acceleration term may consist of both a time derivative and a space derivative. Upon the supposition that we are dealing with substantially steady-state flow, the time derivative is neglected and the integration of the equation yields, with special restrictions, the Saint Venant or Bernoulli equations.

For the extreme variations that may be met in the field of pulsating flow, there exists some question in the writer's mind regarding the legitimacy for neglecting a time differential. It is not inconceivable that an error of very serious magnitude may result and, in view of this fact, it would appear that the burden of proof rests upon the author.

In attacking the problem experimentally, the author has, in principle, attempted to approximate the total flow by a sampling scheme which embodies a means for positive-displacement calibration. Unfortunately, the size of the sampling orifice is such that we have very nearly the calibration of a kinetic meter with a capillary tube. Inasmuch as the flow relations for these two conditions are different, this would appear to offer some difficulties. For instance, referring to Fig. 7, it is evident that the Reynolds number of the sampling device varies from 0 to about 500. This performance lies in the region where there is a rapid variation of orifice coefficients with Reynolds' number, with the result that only slight variations in fluid viscosity should have theoretically at least, considerable effect on the instrument calibration.

Author's Closure

It is fortunate that the discussion of this paper includes Mr. Alcock's description of the viscous meter used in the experimental laboratories of Ricardo and Company. This viscous-flow meter, designed for high-precision laboratory use and the kinetic meter, described in the paper and designed for portable use in the field, represent two extremes in the approach to this problem. Mr. Alcock's reference to, "Another source of error with square-law connections is that they often have different resistance coefficients for inflow and outflow, thus acting as imperfect nonreturn valves," is a very important point to be remembered in the design of kinetic meters such as the one discussed in this paper.

Professor Carmichael's discussion of Fig. 9 is a very good explanation of the increase in the pulsation in an engine intake as the speed increases. This increase in pulsation is illustrated in Fig. 8 and is intimately associated with the important variations of volumetric efficiency of an engine. His suggestion that the manipulation of the instrument be made more nearly automatic is fully agreed to by the author.

From the physical point of view, the neglect of the "time derivative" referred to by Mr. Smith is concerned with the neglect of the compressibility of a gas, which results in Bernoulli's approximate equation. When a gas undergoes an acceleration, the displacement of any surface is made up of the motion that results from the actual acceleration of the gas plus the motion which is a result of the compression of the gas. If s represents the total displacement at any surface, ρ is the gas-mass density and t represents time, the inertia force on a unit volume is $-\rho(\partial^2 s/\partial t^2)$. This inertia force at any point x may also be expressed in terms of the deformation and the bulk modulus of elasticity E, as $E(\partial^2 s/\partial x^2)$.

The resulting force–balance equation is

$$E\left(\frac{\partial^2 s}{\partial x^2}\right) - \rho\left(\frac{\partial^2 s}{\partial t^2}\right) = 0 \quad \ldots\ldots\ldots\ldots [30]$$

Solving Equation [30] for the case of a velocity ($u_0 \sin \omega t$) drawn from one end of a uniform path, the velocity wave entering the other end at a distance l ft is

$$u_l = \frac{u_0 \sin \omega t}{\cos \sqrt{(\rho/E)}\omega l} \quad \ldots\ldots\ldots\ldots [31]$$

While the dangers of resonance in air paths were discussed in the summary of the paper, it may be worth while to give some quantitative limits. The amplitude of the entering-velocity wave will be approximately 2 per cent in error when $\cos\sqrt{(\rho/E)}\omega l = 0.98$, or when $\sqrt{(\rho/E)}\omega l = 0.2$ radian. For air at atmospheric conditions, Table 5 shows the path lengths that will result in approximately 2 per cent distortion for various frequencies.

TABLE 5

Pulsation frequency in cycles per sec	Path length in ft for 2 per cent wave distortion
1	35.6
10	3.56
100	0.356

As long as these limits are observed in the construction of equipment, there is nothing to worry about when gas compressibility is neglected.

Mr. Smith's second question about the viscous effects in small orifices and tubes is one of relative magnitudes. The pressure drop through any tube is partly viscous and partly dynamic. In very long tubes of small diameter the viscous pressure drop predominates, but in short tubes the situation is different. The orifices used in the meter are in reality short tubes, since construction limitations make it necessary to have the metal-wall thickness approximately equal to the diameter or 0.014 in. For a tube the acceleration pressure drop is $(\rho u^2)/2$, where ρ is the mass density and u is the air velocity. The viscous pressure drop is $8\mu l u/R^2$ where μ is the viscosity, l the tube length, and R the tube radius. The ratio of dynamic to viscous pressure drop is $\rho u R^2/16\mu l$ and, for a length of 0.014 in., a radius of 0.007 in. and an air velocity of 10 fps, this ratio is 2.4.

Since 10 ft a sec is the minimum velocity tested for Fig. 7 and most test work is at higher velocities, where the ratio is much greater, it is not surprising that no viscous temperature change in the calibration curve has ever been detected.

The Effect of Pulsations on Orifice Meters

By S. R. BEITLER,[1] COLUMBUS, OHIO

The paper describes three test setups made for investigating the effects of pulsation on orifice flowmeters for the measurement of gases. Arrangements are described for subjecting meters to pulsation from either the inlet or outlet side and determining the error in measurement.

The work so far is admittedly just a start toward a possible solution of the problem of metering pulsating flow, but the results show the extent and seriousness of the problem and point the way for further research which is of vital interest to the measurement industry.

THIS PAPER is written, with the hope that the restatement of one of the important unsolved metering problems will lead to a more complete study of it and, possibly, to its solution. It has been known for a long time that an orifice meter, or any other type of differential-head meter, cannot be used with accuracy if the flow is not steady but is pulsating. While this fact is known, no method of compensating for it has been developed, and the problem in general has been dodged by all of the experimenters on fluid flow.

The last published work on this subject was that of Judd and Pheley presented to the A.S.M.E. in 1922.[2] In the discussion of this paper, and in another paper[3] presented to the Society, John L. Hodgson presented a theoretical analysis of this type of flow and some suggestions for elimination of the effects which were interesting but which as yet have had little practical application. As a result most of the standard measurement instructions state that pulsations must be eliminated before a flowing fluid can be measured by a differential-head meter.

In the standards of the V.D.I.[4] the following statement is made: "The discharge equations apply only for steady flow. . . . . In particular there should be no pulsations in the flow. . . Very little investigational work has been done to determine the error due to nonsteady flow: This error therefore cannot be corrected."

The A.S.M.E. Fluid Meters committee states:[5] "Measurements of a pulsating type of flow are very likely to be in error, particularly if a head-type meter is used."

The foregoing statements show that the existence of the errors is well known and that it has been accepted as a limitation of the measurement of fluids with head-type meters. It has meant that practically no meters have been installed to measure the flow to steam engines, for instance, and their use has been limited in the measurement of the discharge of reciprocating compressors and pumps.

There are certain places, however, where measurements must be made close to reciprocating devices and in a great many cases meters have been installed, with a knowledge that, while the resultant measurements will not be exactly correct, they are better than no measurements. Such practice, however, is unsatisfactory and has resulted in a great deal of discussion of methods which might be used to eliminate the errors.

The natural-gas companies are much interested because of the fact that they must, in many cases, measure the gas close to either the outlet or inlet of compressor stations. It is important at times to make these measurements in order to detect leakage between stations and, if this leakage is a small percentage of the total flow, the measurements must be accurate. Because of the fact that some measurements were known to be slightly erroneous two of these companies decided in 1936 almost simultaneously, to make some investigations into this phase of measurement.

Two test setups were made, one by the United Fuel Gas Company at their Kenova compressor station, near Kenova, W. Va., and the other by the Ohio Fuel Gas Company at Brown compressor station near Mt. Vernon, Ohio. After some of the results from the experiments at these stations were analyzed, it was felt that some data should be secured with a simple setup, and a thesis was arranged under the direction of the author at Ohio State University. All of these test plants were constructed early in 1937 and investigations have been continued intermittently on them ever since. While no positive results as to methods of eliminating the error have been found, yet it is felt that the results show more of the nature of the problem and point the way toward a solution.

It was the intention in all of the installations first to find the magnitude of the error introduced by pulsations and then if possible, to devise some method of eliminating it. However, it has been found that there are so many permutations to the determination of the errors that it has not been possible to spend much time on elimination.

It has been shown by previous experimenters that the amount of error is dependent on the quantity of fluid being measured, the resistance and capacity between the disturbance and the meter, the frequency and the amplitude of the disturbance, and the viscosity and density of the fluid.

The three test setups gave quite a wide variation in these items and covered a broad range of conditions.

Test Apparatus

The general arrangement of all test stations was the same. That is, there were two orifice plates in series in a line between the suction and discharge headers of the compressors. These orifices were connected up with the proper gages so that they could be used as measuring devices. Arrangements were made in the test line so that it was possible to have pulsationless flow through either one or both of the meters, by setting up critical-

Discussion of this paper closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

flow conditions, either through a valve or through another orifice, between the source of the pulsation and the meter. With this arrangement it was possible to check the orifices against each other with steady-flow conditions, and then to make the same checks with one meter subject to pulsations and the other to steady flow. The pulsations could be obtained either on the outlet side of the orifice, i.e., from the suction of the compressor, or on the inlet side of the orifice, from the discharge of the compressor. Since the two meters were measuring the same fluid a comparison of the indicated flow determined the effect of the pulsations. The method of first checking the two orifice meters against each other on steady flow eliminated the chance of any error creeping in, due to difference in the primary and secondary elements of the meter. In calculating the flow through the meters the proper computations were made, taking account of pressure,

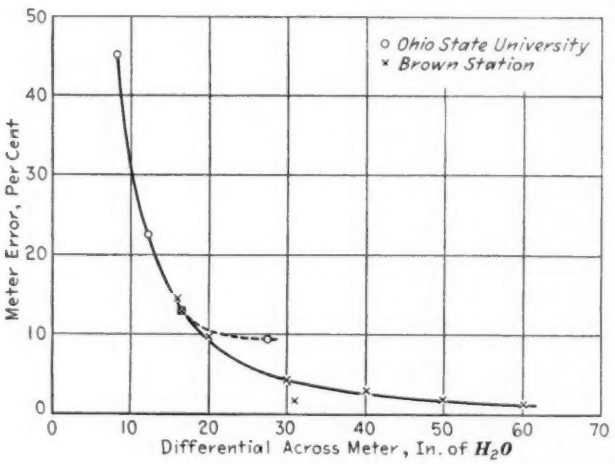

FIG. 1 ERROR CAUSED BY PULSATION ON INLET SIDE OF ORIFICE METERS
(Diameter ratio of orifices = 50 per cent.)

temperature, expansion of the gas through the orifice, and deviation of the gas from Boyle's law.

The station at Kenova had seven compressors, five 1350-hp 88-rpm twin double-acting, and two 1000-hp 125-rpm twin double-acting. The suction pressure at this station averaged about 100 lb per sq in. and the discharge pressure about 325 lb per sq in. Though the suction pressures varied from this amount considerably at times, the discharge pressure was fairly constant. The 4-in. test piping was connected directly to the discharge header and arranged so that the test flow could be discharged into either the inlet or outlet of some wet-type gas scrubbers in the suction lines of the station. The meter piping was made up according to the recommendations of report No. 2 of the Gas Measurement Committeee of the A.G.A. Orifices of from 0.25 to 2.50 in. diam were used in the tests.

The station at Brown had ten compressors, six 160-hp 190-rpm twin double-acting, three 170-hp 200-rpm twin double-acting, and one 80-hp 190-rpm single double-acting. The suction pressure was about 25 to 50 lb per sq in. and the discharge pressure about 170 lb per sq in., varying at times from 150 to 190 lb per sq in. The gas for the test line was taken from the discharge line of one of the 160-hp compressors just before it entered the station discharge header and the test line discharged directly into the suction header of the station. Meter piping and orifices were the same general design and size as used at Kenova.

In Robinson Laboratory the 3-in. test line was the direct discharge of a 12-in. and 7.5 × 9-in. two-stage double-acting compressor running at 300 rpm. The line discharged directly into the atmosphere and was arranged so that a tank with a volume of 54 cu ft or one of 3 cu ft could be placed between the compressor and the meter line. The only orifice size used up to the present was one of 1.5 in. diam.

DISCUSSION OF RESULTS

Most of the tests have been made with the pulsations on the inlet of the meter though a few have been made at Kenova with the pulsation on the outlet side. Because of this, the first part of the discussion of results is limited to meters on the discharge of the compressor, that is, to those subject to pulsations on the inlet side of the orifice plate.

Pulsations on Inlet Side. The first question which was raised was what was the total error produced by pulsations on meters of similar size at the two stations. Fig. 1 indicates this comparison. No tests were run at Kenova using a varying head on the meter and so no comparison on this basis can be made. In the case of the tests at the University and at Brown it has been necessary to make some extrapolations to determine the curves as drawn, but they seem to indicate that the errors produced by the pulsations at these two stations were about the same when

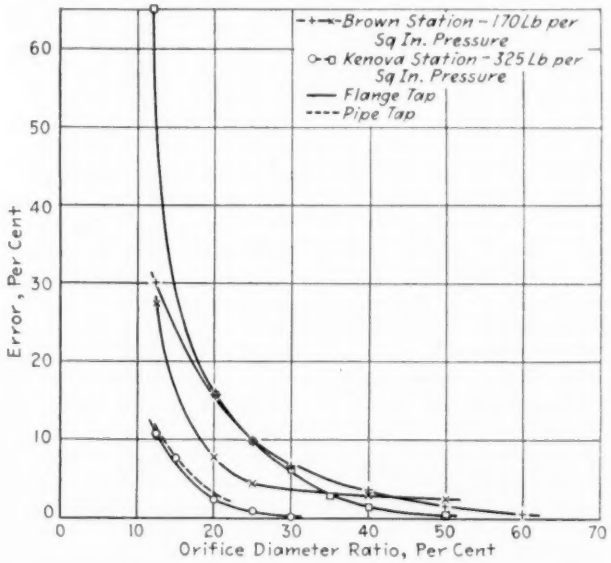

FIG. 2 ERROR CAUSED BY PULSATION ON INLET SIDE OF ORIFICE METERS
(Various values of diameter ratio at constant differential head.)

orifices of 50 per cent diameter ratio were used. It will be noticed that this error was relatively small, that is, about 1.5 per cent when the differential on the meter was 60 in. of water but that, as the differential head decreased, the error increased rapidly to about 45 per cent at an 8-in. differential head. The error of the meter was positive, that is, it made the meter read high. Some other tests which were not so complete showed the same effect. This investigation seemed to show that the effect of pulsation for any fixed condition was a function of $1/h^{1.75}$ or $1/Q^{3.5}$, where h = the head and Q = the quantity of flow. This indicates one important fact, and that is that, for a given meter, the error due to pulsation will be small if the quantity flowing is large, but that the error will be large if the flow is small; a decrease of one half in the flow will increase the percentage of error twelve times.

The next effect investigated was that of changing the diameter ratio of the orifices keeping the differential head practically constant. Fig. 2 shows some of the results of these tests. Each of the curves represents the average of the runs on several dif-

ferent orifices under approximately the same conditions. It will be seen that except for the general tendency there was no similarity of results even when the conditions seemed the same. All of the errors were different in absolute value, and the slopes of all of the curves were different. It is quite possible that this was due to the fact that different compressors were running at the time of the tests or that the valves in the discharge header were set differently so that the frequency and amplitude of the pulsations were not the same. Since these test lines were actually by-pass lines on operating stations it was impossible to control the conditions exactly and conditions for one run may have differed from another.

It will probably be necessary, before the investigation is ended, to make some tests in which the complete discharge from a compressor station is piped through a test line to determine the effect of this type of flow. However a great deal of valuable information can be secured by using the setup at the University where the complete discharge of the compressor can be sent through the test line and where conditions can be controlled within the limits of the pressures available.

The question as to the effect of frequency and amplitude of the pulsations is not answered by these tests for two reasons. The first of these is the lack of any device to indicate these values accurately and easily and the second is the fact previously mentioned, that it was impossible to control them.

Pulsations on Outlet Side. One other question which has been raised often, and which has not as yet been answered is the one

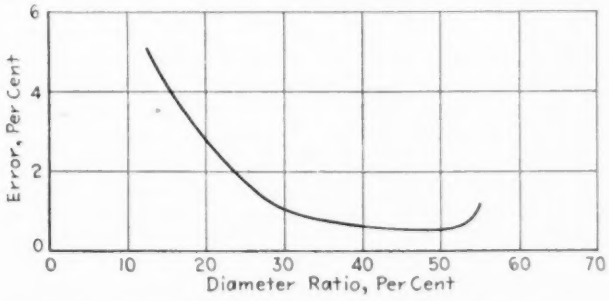

FIG. 3 ERROR CAUSED BY PULSATION ON OUTLET SIDE OF ORIFICE METERS

(Various values of diameter ratio at constant differential head.)

as to whether or not pulsations on the outlet of the meter (this is the type encountered in metering steam to a steam engine, or in metering the gas flowing to a compressor) would have the same effect as do those on the inlet. A series of tests at Kenova was made to determine the effect of suction pulsations on the meter. The results of these tests for different diameter ratios are shown in Fig. 3. It will be noticed that this curve has approximately the same shape as have those in Fig. 2 except for the fact that the end of the curve for the higher ratios seems to be turning up. This, however, is based on the results of the tests of one orifice only and does not prove that the curve has this shape.

It will be noticed that the absolute errors for this curve were much less than for those in Fig. 2. This may be accounted for by several factors. First, the nature of the pulsation was different due to the fact that the inlet valves of a compressor are open during the full suction stroke while the exhaust valves are open for only a portion of the discharge stroke, so that a much different wave form was obtained. Then the differential head on the orifice was somewhat greater during these tests, though the mass flow was about the same. Also there is always the possibility of a different condition in the line due to differences in operating conditions in the station. Some of these will be acting in all cases however, and it is predicted that the errors on the suction side of compressors will be less than on the discharge side. This line of reasoning will not apply to steam engines, however, because of the fact that the earlier cutoff of engines makes the pulsations even worse than the discharge pulsations of a compressor.

One discrepancy which appeared in this series of tests for a meter with pulsations on the outlet of the orifice plate, was the fact that the errors were positive and the dead-end reading of the differential, i.e., the reading when the inlet valve to the meter was closed so that there was no flow, was above zero. At several other stations in which observations had been made of this phenomenon the dead-end reading was below zero.

Pipe-Tap Meters. All of the tests described so far had to do with orifice meters with flange taps. Another question which was raised was whether or not the effect on pipe-tap meters would be the same. This question was answered by a series of tests the results of which are plotted in Fig. 2 as the dotted curve. It will be seen that the results of these tests were practically the same as the results plotted as curve No. 4 of Fig. 2, which were obtained at the same time and under the same conditions at Kenova. This shows that for the same mass flow and the same pulsation conditions the effect was the same on either type of tap.

Pulsation Elimination. Several elementary changes were tried to eliminate the effects of the pulsations. It is well known that resistance or capacity or both between the meter and the source of pulsation will help to eliminate the error by decreasing the pulsation. It is not practical to use too much pressure drop for most pulsation elimination because of the expense involved. Since the function of the compressor station is to produce a high pressure in the flowing gas, if much of this pressure is dissipated to get accurate measurements then the cost of measurement will be excessive. In order to determine what pressure drop would be required to completely eliminate errors due to pulsations several series of tests were run at both of the gas-measuring stations, throttling the gas flow between the compressor and the meter until the error was eliminated.

In general it was found at both stations that a pressure drop of from 2 to 14 lb per sq in. was required to eliminate the error and that the larger pressure drops were required by the smaller orifices. The results of these tests were inconclusive, however, due to the fact that they were inconsistent. In some cases the errors would be eliminated with little pressure drop and in other cases the error would never be completely eliminated, but would reach a constant value which did not decrease with increase in pressure drop. These inconsistencies were probably due to the fact that the throttling device disturbed the flow conditions to the orifice enough to create some error of measurement which the straightening vanes did not eliminate.

The effect of capacities was measured at the University and on the tests with the pulsations on the outlet of the meter at Kenova. At the University the 54-cu ft volume in the discharge line completely eliminated the pulsations, while the 3-cu ft volume eliminated most of the effect of them. When the inside of the 3-cu ft volume was treated acoustically the pulsation error was eliminated.

At Kenova tests were run with wet-type gas scrubbers between the meters and the compressors and these eliminated the error completely.

Another idea tried at the University was that of adapting the pressure taps of the secondary element to eliminate the effect of the pulsations. A large number of different types of pressure taps, with volumes, restrictions, combinations of restrictions and volumes, and acoustical treatment were tried and in all cases it was found that these devices increased the error. It would appear from these tests that the best pressure connection is the shortest and straightest one.

At the start of the tests it was felt that a good indicator to tell

when pulsations were present would be of great value and an attempt was made to design such an instrument. This consisted of a volume connected to the line in the plane of the pressure tap of the meter through a small orifice meter, which gave the dead-end flow condition mentioned previously. If pulsations were present the orifice meter would indicate a flow and this indication had some relation to the severity of the pulsations. Readings were taken on this instrument when the tests were being made for meter errors. It was found that when the readings on this instrument were below a certain value there were no errors due to pulsations. However the instrument is too sensitive to changes in line pressure, and it is very easy to blow the measuring liquid out of the manometer. An attempt is being made at present to design an electrical instrument which will not be so difficult to use and which will give a more complete picture of the pulsations.

While the results of the work done so far do not seem to have shown any definite remedy for the problem of measuring pulsating flow yet they are of great value, in the opinion of the writer, for several purposes. The first is that they show that those interested in measurement realize the problem and are working on it. They show the extent and seriousness of the problem and point the way to possible solutions which look promising.

To gain the greatest value from this work it will be necessary first to develop a device for measuring the pulsations more accurately and easily and then to continue the tests in conjunction with this device, to determine the causes of the errors and what must be done to eliminate their effects. To do this will require a great deal more experimental work, which is not the function of any one company, but which should be done by the measurement industry as a whole because all of the industry should be vitally interested in it.

Acknowledgment

This work would not have been possible were it not for the support and initiative of the two companies mentioned and the men interested in their measurement problems. A great deal of the credit for the work done by the gas industry goes to T. H. Kerr of the Ohio Fuel Gas Company and D. A. Ketcham of the United Fuel Gas Company, under whose authorization the work was done. The major part of the actual field research work, however, has been done by Edward Sackett and J. E. Overbeck and to them the most credit is due. A. M. Hutchison also cooperated. The work at the University was done by John Eagle and W. A. Daberko, and H. S. Bean has assisted with his advice.

Discussion

Howard S. Bean.[6] Probably the fact that pulsations in a fluid stream may cause considerable error in the indications of any device used for metering the rate of flow, particularly meters of the differential-pressure type, has been known about as long as fluid metering has been studied. It may seem a little strange at first, therefore, that more fundamental work on this problem has not been done. The answer to this is found when we come to consider all the possible factors and variables particularly as they occur in present-day pipe-line systems.

In all of the tests considered in Professor Beitler's paper, the effect of pulsation was to make the observed meter indication high. This is in the same direction as that generally reported by other observers. Various writers have offered mathematical explanations of the reason the indications of a meter subjected to pulsating flow are high. While it would be possible to state the essence of these explanations with few mathematical terms it would require considerable space which it seems hardly necessary to take here.

In 1931 the writer made a survey for the Measurement Committee of the American Gas Association to see how the problem of metering pulsating flows of gas was being handled by different companies in the fuel-gas industry. A report of this survey appeared in the October, 1935, issue of *Western Gas* (now published under the name *Gas*). In this report the suggestion is made, and it has been repeated many times since, that the most promising method of attacking and solving the pulsation problem would be first to build a pulsometer with which both the frequency and amplitude of the pulsation waves can be detected and measured. Then by comparing the indications of this pulsometer with the errors in the indications of orifice meters under various conditions, it would be possible to determine under what conditions the effects of pulsations may or may not be serious. Since that report was written, it has been suggested on various occasions (but originally by F. C. Morey[7]) that a suitable pulsometer can be constructed by using a piezocrystal as a pickup or pulsometer responsive unit. By introducing suitable amplification in the form of vacuum tubes the very small emf produced across the crystal by the pulsation waves can be made to operate a chronograph pen. The time element could be superimposed on such a chart, in several ways.

The writer is gratified to see from his concluding remarks, that Professor Beitler is apparently attacking the pulsation problem along these lines, although he does not give any statements about "the device it will be necessary to develop for measuring the pulsations more accurately and easily . . . . ."

C. A. Dawley.[8] Professor Beitler's paper refers to the effect of pulsations on orifice meters, by which he means fixed-orifice meters with variable head. His statement, that no method of compensating for the error produced by pulsating flow has been developed, is substantially correct for this type of meter.

In some meters of the variable-orifice, fixed-head type (Area Meters, Class 2.3, Fluid Meters Committee Report), pulsation compensators have been developed and applied to handle such severe pulsations as are met with in measuring the flow of compressed air to rock drills and similar service. Complete compensation can be effected for any one kind and degree of pulsation within reasonable limits. The same compensation will not fully compensate for some other degree of pulsation, but a meter compensated for an average degree of pulsation will have a much smaller error on some other degree of pulsation than will an uncompensated meter.

The method of compensation comprises the use of a definite restriction or damping of the motion of the meter indicator in the downward or decreasing direction, and a greater restriction, definitely related to the first, to motion in the upward or increasing direction. The same method of compensation may be applied to a water-column manometer used with a fixed orifice. It is simple in construction but so highly complex in theory as to defy mathematical analysis. The proportions must therefore be determined empirically.

The writer would define pulsating flow as flow that varies rapidly from maximum to minimum rate in recurring cycles (not necessarily identical). The common examples are the flow of fluid to a reciprocating pump, engine, compressor, or tool, or the flow of fluid from a reciprocating pump or compressor. The reasons why such flow produces error in head meters follow:

1 Head varies as the square of velocity, and average head is therefore not proportional to average velocity.

2 No manometer will reliably indicate even the average head when the head is fluctuating rapidly.

3 Complications of pressure and density variations (pressure waves), set up by velocity variation, are likely to give spurious manometer readings; and

4 There may be actual reversals in the direction of flow or "alternating currents" of gas flow, as in the discharge lines of a gas compressor.

Figs. 1 and 2 of the paper show the error on the discharge or outlet flow from one or more compressors. Fig. 3 shows the error on the suction or intake flow to a battery of compressors. In Fig. 3 the errors are small for orifices with diameter ratio larger than 30 per cent. No data are given as to comparative heads and rates of flow on the various orifices, but it is likely that the greater error of the smaller orifices may be due to the comparatively small pipe-friction losses, relative to orifice heads, when the small orifices were used.

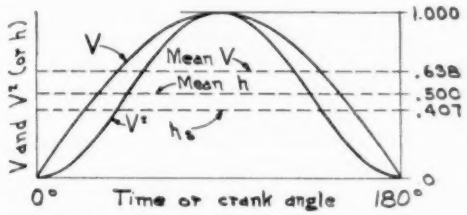

FIG. 4 THEORETICAL ERROR ON FLOW TO ONE DOUBLE-ACTING CYLINDER

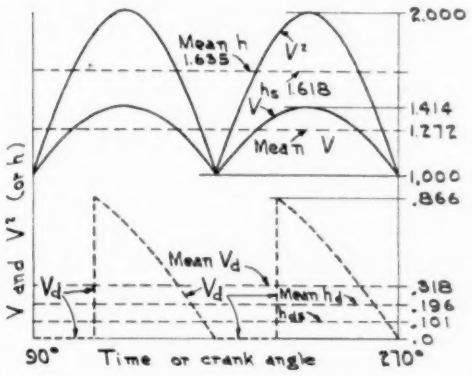

FIG. 5 THEORETICAL ERROR ON FLOW TO TWIN DOUBLE-ACTING UNIT

Most of the compressors were twin or two-cylinder units, double-acting, and presumably with cranks at 90 deg. It is interesting to compare the results reported with the theoretical error on the flow to one double-acting cylinder and to a twin unit with two such cylinders. Assuming simple harmonic motion, the piston velocity varies as the sine of the crank angle. Assuming flow in the intake pipe proportional to the piston velocity, taking the crank velocity as unity and the head produced at an orifice in the intake pipe as unity, when the piston velocity is equal to the crank velocity, we get for a single cylinder the curves shown in Fig. 4. In these curves velocity and velocity squared (or head) are plotted against time or degrees of crank angle. The mean velocity for one stroke is 0.638 and the mean head is 0.500. If the same flow took place at uniform velocity, the head h_s would be the square of 0.638 or 0.407. The ratio of the head for harmonic flow to that for steady flow is 0.500/0.407 or 1.23, and the square root of this head ratio is 1.11. In other words, a flow of this kind produces a theoretical excess indication of 11 per cent.

When two such cylinders are driven by cranks at 90 deg, the composite velocity of the two pistons at the same instant is shown by V in the upper part of Fig. 5. The value of V varies only from 1.000 to 1.414 and the value of V^2 or h from 1.00 to 2.00. This is a far closer approximation to uniform flow than that from a single cylinder. The mean velocity for 180 deg of crank travel is 1.272 and the mean head 1.635. If the same flow had taken place at uniform velocity, the head h_s would have been 1.618. The ratio 1.635/1.618 is 1.01, and the square root of this ratio 1.005. In other words the theoretical error in measuring this flow is about 0.5 per cent. This compares closely with the values shown in Fig. 3 of the paper on the larger orifices.

The discharge flow from a compressor shows much wider variations as indicated by the dotted curve V_d in the lower part of Fig. 5. The velocity curve depends on the ratio of compression The actual velocity in the outlet pipe is likely to depart more widely from the theoretical than is the case with the inlet flow. Curve V_d is based on the assumption that discharge occurs during 60 deg of crank travel or 25 per cent of stroke. For 180 deg of crank travel, the mean velocity is 0.318 and the mean velocity squared or head h_d is 0.196. If the velocity were uniform, the head h_{d_s} would be the square of 0.318 or 0.101. The head ratio for this curve as compared with steady flow is 0.196/0.101 or 1.94, and the square root of this is 1.39. In other words, this flow would give an error of 39 per cent in excess of true flow. This figure should be taken with a grain of salt as it represents an orifice directly on the compressor outlet without the benefit of any smoothing action from capacity, pipe friction, and the pressure drop of the orifice itself. It does indicate plainly that the measurement of compressor discharge is far more severe than measurement of the intake flow.

Most of the results shown in the paper are not for the flow of a single compressor, but for a by-pass from the delivery main to the suction main of a battery of compressors. It would seem that more significant conclusions could be drawn by using the entire flow of one or more compressors. The above calculations would suggest that measurement made at a little distance upstream on the intake main would show comparatively small pulsation errors. The pipe line has large capacity which, combined with the fluid friction of the line, provides good steadying action. The combination of capacity and resistance in the proper proportions is the best way of reducing pulsation.

R. E. SPRENKLE.[9] The revitalization of the pulsation-flow problem is indeed most interesting not only to the potential users of metering equipment as applied to pulsation-producing prime movers, but to the meter manufacturer as well. That a need for more information along this line still exists is quite evident when it is considered that in a great many industrial plants there are compressors, steam engines, pumps, ice machines, and other reciprocating units which are pulsation producers to which units the flow of fluids should rightfully be measured, in order to obtain best over-all plant economy. At the present time, such measurements cannot be undertaken with surety unless special precautions in the way of throttling orifices and volume enlargements are used, and in many instances such devices cannot be employed because of the impracticability of their application.

While Professor Beitler's paper draws no conclusions from his test, this should not be wondered at because the work involved has merely gotten under way and much yet remains to be done. In fact, the paper really is a progress report of the development stage in this project, more of which it is hoped will follow in the future,

[9] Mechanical Engineer, Bailey Meter Company, Cleveland, O. Mem. A.S.M.E.

as soon as definite work and conclusions have been reached regarding any phase of this important subject.

It is interesting to note among several of the elementary things tried out that the enlargement, restriction, or the use of additional volume, or combination of such changes in the connecting piping between the primary and the secondary, serves not to reduce the effect of pulsation in so far as the meter error is concerned, but rather to augment such meter error. This is borne out by our own experience in that we have found throttling of the connecting piping between the metering orifice and the meter register does not dampen pulsation but only tends to give a false picture of the actual conditions.

There are several preliminary results which appear on the surface to be the reverse of expectations. One of these is a decrease of meter error with increasing differential, and another that smaller amounts of throttling were required for larger-diameter-ratio orifices. It is further noted, particularly with regard to the second example just stated that the results were somewhat inconsistent and therefore no final conclusions could be made.

It is hoped that this work can continue to a point where definite and correct conclusions can be drawn from the test work. Further, and this is the most important, the real answer is the accumulation of sufficient data which will enable one to prescribe definite means for the elimination of pulsations from the metering system so that the flow through the primary element will be of the normally turbulent type unaffected by pulsations. If and when such knowledge becomes available, industry will be well served by this research.

Author's Closure

Mr. Bean has suggested the use of piezoelectrical devices for the measuring of the pulsations. A device of this type has been developed and is being tried at this time. Considerable data have been taken with it but, as yet, the results have not been completely analyzed nor has the practicability been proved. However, the results to date look very promising.

Mr. Dawley has spent considerable time calculating the errors due to the pulsations and has arrived at some interesting conclusions. However, it is the author's opinion that Mr. Dawley has not taken into account the fact that the rapid fluctuation of static pressure has a greater effect on the error due to pulsation than has the change in flow. Professor Judd in his 1922 paper seems to have proved this conclusively. The author's results to date seem to indicate the same thing. For instance, Mr. Dawley has calculated that the error on a meter in the suction of a two-cylinder, double-acting compressor with the cranks 90 deg apart would be about 0.5 per cent.

The author in December, 1938, investigated a small compressing station having one two-cylinder, double-acting compressor with the following results: A meter placed about 50 ft from the compressor suction read about 50 per cent higher than did one placed about 5000 ft from the compressor discharge. This error was cut to less than 10 per cent by throttling between the compressor and the suction meter, so that at least 40 per cent of the difference in these meter readings was due to pulsation on the suction meter. The fact that the error is so much greater than the calculated error seems to indicate that it will be impossible to calculate it, even approximately, until there is a more complete knowledge of the causes of the error.

As pointed out by Mr. Sprenkle and in the paper, the attack on this problem is just started and there is yet an enormous amount of work to be done. It is hoped that the statements made will stir up more interest and lead to a more rapid solution of the problem.

The Effect of Size and Shape of Cut Upon the Performance of Cutting Fluids When Turning S.A.E. 3140 Steel[1]

By O. W. BOSTON,[2] W. W. GILBERT,[3] and L. V. COLWELL,[4] ANN ARBOR, MICH.

This paper gives the results of detailed experiments to determine the influence of each of several classes of cutting fluids on tool life when turning a steel with different sizes of cut. The tests were divided into three series: In the first, two cuts were used having the same area, in one case the depth was equal to eight times the feed, and in the other the depth was equal to twice the feed.

In the second series of tests the feed was kept constant while the depth was varied over a considerable range to give cuts of different area. All cutting fluids were tested for each combination of depth and feed.

In the third series of tests the depth was kept constant while the feed was varied to give a series of cuts of different area.

Lastly, all data are correlated to show the influence of each type of cutting fluid as a function of the size and shape of cut, as a function of the cutting speed for a given tool life, and in terms of the volume of metal removed per tool grind.

THE OBJECT of these tests was to determine the influence of several types of cutting fluids on tool life and cutting speed when varying the size and proportion of the cut in turning annealed S.A.E. 3140 steel, with a constant tool of high-speed steel.

It has been shown[5] that various types of cutting fluids materially affect the value of the cutting speed for a given tool life when turning an annealed S.A.E. 2345 steel and an annealed S.A.E. 3140 steel.

The Tests

There were three series of tool-life cutting-speed tests involved in this investigation. In the first series, each of the cutting fluids was used on deep thin and shallow thick cuts having the same area. In the second, the depth of cut was varied while the feed was kept constant, and in the third, the feed was varied while the depth was kept constant.

For each test, the tool life was measured with a stop watch and checked by noting the increase in power on the wattmeter chart. The tool life consisted of the time required from the start of the cut until the tool failed. Total failure was evidenced by the wiping off of the cutting edge of the tool. The edge broke off and produced a burnished band on the shoulder of the cut. At this time there was a decided increase in the power consumed as indicated by the wattmeter. In some cases, a preliminary failure was noticed, at which time a burnished streak would appear on the shoulder of the cut. This indicated the breaking down of a part of the cutting edge, but it did not change the quality of the machined surface, and did not cause an appreciable increase in power consumption, so that all tools were allowed to run until total failure occurred.

Cutting Tools. The cutting tools used consisted of $^3/_8$-in. square tool bits of the 18-4-1 type of high-speed steel. These bits were ground and used in a special tool holder which had a back slope of 10.5 deg. The tools themselves had working angles as follows: 8-deg back rake, 22-deg side rake, 6-deg end and side clearance, 6-deg end-cutting-edge angle, 15-deg side-cutting-edge angle, and $^3/_{64}$-in. nose radius, as used on monel metal.[6]

Equipment. The equipment used in the tests has been described previously.[5,6]

Constant Area of Cut. In the first series of tests, the area of cut was held constant at 0.00125 sq in., while the ratio of depth to feed was varied. In one set of tests, the depth was equal to eight times the feed; (depth 0.100 in. and feed 0.0125 in. per revolution). In the second set of tests, the depth was equal to twice the feed; (depth 0.050 in. and feed 0.025 in. per revolution).

The cutting-speed tool-life curves are shown in Fig. 1 as straight lines on log-log paper for each of the cutting fluids and for each of the two cuts. These results show again that the line for each cutting fluid for the deep cut with the light feed is higher than that line for the same cutting fluid obtained with the shallow cut and heavy feed. That is, a higher cutting speed for a given tool life is obtained when the ratio of depth of cut to feed is high, with other factors remaining constant. The cutting speed for a 40-min tool life V_{40}, for dry cutting, is 68 fpm when the depth is twice the feed, but is 83 fpm, or 22 per cent higher, when the depth is eight times the feed, for the same area of cut. Similarly, V_{40} for the highest curve of each group is 83 fpm for the lower group, and 101 fpm, or 22 per cent higher for the upper group. The cutting-speed tool-life lines for both cuts are higher when an oil or emulsion is used, and in both cases these curves are higher and are more nearly horizontal than are those curves for dry cutting.

In the upper group of curves, in which the depth was eight times the feed, it is shown that dry cutting gives the shortest

tool life for any given cutting speed, or the lowest cutting speed for a given tool life. For high speeds, that is, values of tool life up to approximately 30 min, the sulphurized-base oil *SB* gives the highest cutting speed for any tool life, but inasmuch as it has a steeper slope than the lines for the other cutting fluids, it crosses the curves for the three emulsions and falls below them for values of tool life in excess of 50 min. The 1:50 emulsions of

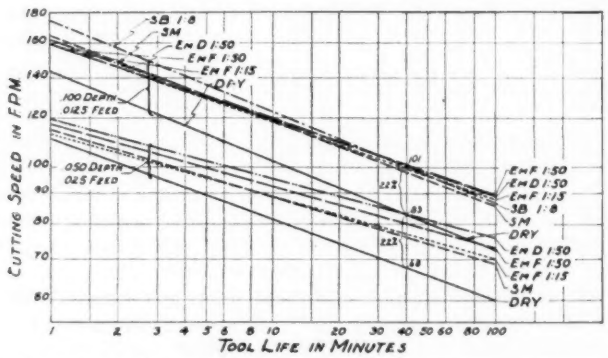

FIG. 1 THE INFLUENCE OF CUTTING FLUIDS ON CUTTING SPEED

TABLE 3 EQUATIONS OF UPPER GROUP OF CURVES OF FIG. 1

SB	$VT^{0.152} = 175$ — (87.0 fpm)
SM	$VT^{0.142} = 165$ — (86.0 fpm)
EmD 1:50	$VT^{0.130} = 162$ — (89.0 fpm)
EmF 1:15	$VT^{0.130} = 160$ — (88.0 fpm)
EmF 1:50	$VT^{0.125} = 159$ — (89.5 fpm)
Dry	$VT^{0.147} = 143$ — (72.5 fpm)

The values in parentheses represent the cutting speed for each oil for a tool life of 100 min, for which case the emulsion *EmF* 1:50 gives the highest value, and dry cutting the lowest. Equations for all of these curves are summarized in Table 5.

For the lower group of curves in Fig. 1, when the ratio of depth to feed is two, for which the depth is 0.050 in. and the feed 0.025 in. per revolution, several differences from the results noted above are observed. Emulsion *EmD* 1:50 produces higher speeds than those for *EmF* 1:50. Otherwise the relative values of speed produced by the several cutting fluids remain in the same order, although they are spread over a greater range. For a tool life of 1 min the cutting speed is increased from 111 for dry cutting to a maximum of 119 for *EmD* 1:50 or 7 per cent. This emulsion produces cutting speeds higher than those obtained with any of the other cutting fluids for all values of tool life. For a tool life of 100 min the cutting speed for this emulsion is 26.6 per cent higher than that for dry cutting. Emulsions, in general, are superior to the sulphurized mineral oils, except for values of tool life below 8 min. The thin emulsion, *EmF* 1:50 gives speeds higher than those for the thicker emulsion *EmF* 1:15. This seems to indicate that cooling is of greater value than lubrication. The equations for each line for the shallow thick cuts, showing the constant which equals the cutting speed for a 1-min tool life, as well as the cutting speed for a 100-min tool life, in parentheses, are given in Table 4.

TABLE 4 EQUATIONS OF LOWER GROUP OF CURVES OF FIG. 1

EmD 1:50	$VT^{0.097} = 119$ — (76.0 fpm)
EmF 1:50	$VT^{0.105} = 117.5$ — (72.5 fpm)
EmF 1:15	$VT^{0.104} = 113$ — (70.0 fpm)
SM	$VT^{0.113} = 115$ — (68.5 fpm)
Dry	$VT^{0.133} = 111$ — (60.0 fpm)

TABLE 5 SUMMARY

(A summary of experimental results as represented by cutting-speed tool-life equations when turning S.A.E. 3140 steel annealed with high-speed-steel tools of the form 8-22-6-6-6-15-3/64, with various cutting fluids, at different combinations of feed and depth. The number of cubic inches of material removed per grind for a 100-min tool life is shown also for the various cuts and cutting fluids.

$VT^n = C$, in which V = cutting speed in fpm and T = tool life in minutes)

Variable Depth at Constant Feed. In the second series of tests, the depth of cut was varied from 0.0125 in. to 0.200 in., while the feed remained constant at 0.0125 in. per revolution. These tests were run dry, with the emulsion *EmF* 1:50, and the sulphurized-base oil *SB*. See Figs. 2–8, inclusive, and Figs. 17, 18.

The experimental data of the variable-depth tests are shown plotted on log-log paper in Fig. 2. For each depth of cut with a constant feed of 0.0125 in., cutting-speed tool-life curves were obtained with three cutting fluids, namely dry, *EmF* 1:50, and *SB*. The three lines at the top of the figure represent the cutting-speed tool-life relationship for each of the three cutting fluids

(Three values of tool life when cutting with *EmF* 1:50. From Fig. 2.)

when the depth of cut was 0.0125 in. Dry cutting, as represented by the solid line, is lowest. For values of tool life below 40 min, the sulphurized-base-oil line is higher than that for the *EmF* 1:50 emulsion. These two lines cross, however, so that for values of tool life above 40 min, the emulsion gives higher cutting speed for any tool life. Similar results are observed by the intermediate set of curves for the depth of 0.035 in. Again, the sulphurized-base oil *SB* is highest for values of tool life up to 40 min, at which point it crosses the curve for the emulsion. The lines for the 0.100-in. and 0.200-in. depths of cut are shown grouped at the bottom of the figure. The lines for the 0.100-in. depth are slightly higher than the respective lines for the 0.200-in. depth. The short-dash lines for the sulphurized-base oil are highest for the shortest tool life for each depth. They are steeper, however, than the lines for the emulsions, and so for tool-life values in excess of 30 min, the emulsion gives the highest cutting speed for any value of tool life. It is interesting to observe that the curve for the emulsion for the 0.200-in. depth is even higher than that for the emulsion for the 0.100-in. depth of cut when the tool life is in excess of 30 min. The tool-life lines for dry cutting for the two greatest depths appear to cross at a tool life of 200 min. At this point the cutting speed would be the same for both cuts.

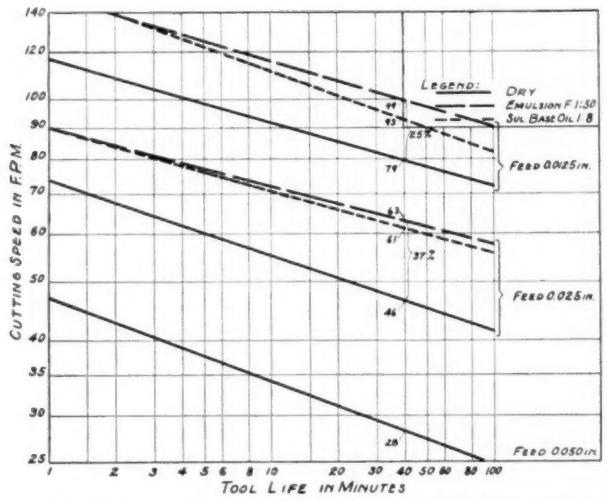

FIG. 9 SHOWING THE RELATION BETWEEN CUTTING SPEED AND TOOL LIFE

(Turning S.A.E. 3140 annealed steel; feed varied for a constant depth of cut of 0.200 in.; three cutting fluids. Shape of high-speed-steel tools, 8-22-6-6-6-15-3/64.)

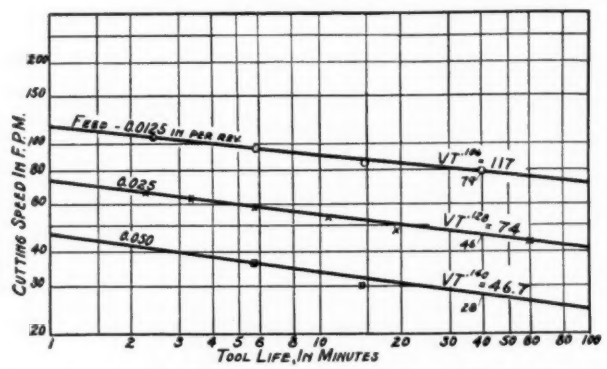

FIG. 10 CUTTING SPEED VERSUS TOOL LIFE WHEN CUTTING DRY

(Three feeds; constant depth of cut of 0.200 in. From Fig. 9.)

When the depth of cut is increased, with the feed remaining constant, the length of cutting edge in contact with the material being cut is increased. If the cutting tool had no nose radius and a straight cutting edge, the length of cutting edge would increase directly with the depth of cut, and the unit linear loading of the tool cutting edge would not be increased. This would lead to the assumption that, if the cutting tool could absorb all the heat generated in each small unit of length of cutting edge, the depth of cut would not influence the cutting speed for a given tool life. The heat developed in the tool is concentrated at the nose of the tool. When the radius of the nose is increased, the length of cutting edge is increased and the average chip thickness is decreased, thereby increasing the allowable cutting speed as the heat is dissipated over a greater length of cutting edge. These assumptions indicate that a maximum-possible depth of cut should be used. This has several practical limitations. There is a decided tendency for deep thin cuts to produce excessive chatter, which may make their use objectionable. Also, when turning small-diameter stock and using deep cuts, the extreme condition will be reached, in which the point of a tool will be at the center of the rotating work and the back of the cutting edge will be at the outside diameter of the work, so that the cutting speed will vary along the cutting edge and be a maximum at the outside diameter. Failure would occur probably at the point of this outside diameter, due to the highest cutting speed.

The advantage of varying the depth of cut is shown in Fig. 3, when cutting dry, where the depth is varied from 0.0125 in. to 0.200 in., with the feed remaining constant at 0.0125 in. per revolution. The cutting speed for a 30-min. tool life V_{30} is reduced as the depth is increased in multiples of the lightest depth, as follows:

$$1f = 200 \text{ fpm}, 3f = 140, 8f = 86, \text{ and } 16f = 80 \text{ fpm}$$

When the depth of cut exceeds 0.100 in., its influence on tool life is less, and if the two lowest lines were extended to tool-life values greater than 100 min, tools cutting at a depth of 0.200 in. would have a longer life than those cutting at 0.100 in. for the same cutting speed. This indicates that, when the depth of cut exceeds eight times the feed, a further increase in depth will not reduce the tool life to any great extent.

The cutting speed in feet per minute is plotted as ordinates against depth of cut in inches as abscissas on log-log paper in Fig. 4. There is a uniform decrease in cutting speed for each constant tool life of 1, 10, and 100 min, until the depth of cut reaches 0.100 in. For larger depths, the lines tend to flatten out, indicating that the increased depth beyond 0.100 in. has little effect upon the cutting speed and, therefore, is a desirable proportion of cut.

When using the sulphurized-base oil *SB* and varying the depth of cut, Fig. 5 shows that the greater depths produce the most advantageous cutting condition, in that the cutting speed is reduced at a slower rate than the depth is increased. The results were similar to those obtained with dry cutting except that the addition of the cutting fluid tended to make the increased depths even more desirable. In Fig. 6, the cutting speed is plotted against depth of cut for tool-life values of 1, 10, and 100 min. These curves tend to be concave upward and more horizontal as the depth of cut exceeds 0.035 in. The curve shown in Fig. 6 for a 1-min tool life did not flatten out as much as the curve for a

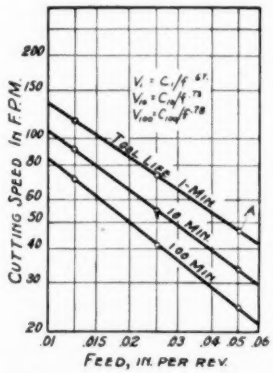

FIG. 11 RELATION BETWEEN CUTTING SPEED AND FEED WHEN CUTTING DRY

(Three values of tool life; depth of cut of 0.200 in. From Fig. 9.)

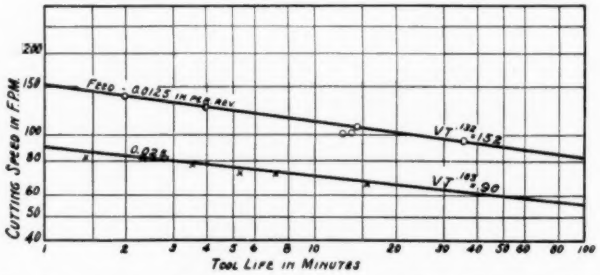

FIG. 12 CUTTING SPEED VERSUS TOOL LIFE WHEN CUTTING WITH *SB* OIL

(Three feeds; constant depth of cut of 0.200 in. From Fig. 9.)

100-min tool life. For the latter, the tool and the cutting fluid had the capacity to carry away the heat generated, regardless of the additional depth of cut, after the depth had exceeded 0.100 in.

The use of the *SB* oil allowed higher cutting speeds than dry cutting for all depths of cut, but it was most effective when taking depths of cut of 0.100 in. and greater. For the shallow depth of cut of 0.0125 in., the cutting speed for a 100-min tool life was increased 9 per cent by changing from dry to the *SB* oil. With a large depth of 0.200 in., the corresponding increase in cutting speed was 15.7 per cent, which indicates the advantage of deep cuts when using a cutting fluid.

Values of tool life for various depths of cut when using the emulsion *EmF* 1:50 are shown in Figs. 7 and 8. For short values of tool life, the *SB* oil produces higher allowable cutting speeds than the emulsion *F*. However, for tool-life values of 10 min and more, and particularly for the large depths of cut of 0.200 in., the emulsion gives higher cutting speeds.

The ability of the emulsion to carry heat from the cutting tool is demonstrated in Fig. 8. After the depth of cut exceeds 0.100 in., there is practically no decrease in cutting speed for any given tool life.

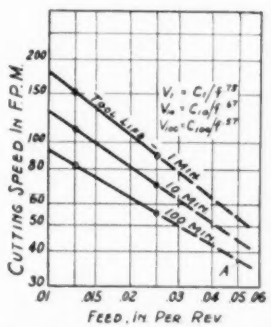

FIG. 13 RELATION BETWEEN CUTTING SPEED AND FEED WHEN CUTTING WITH *SB* OIL

(Depth of cut, 0.200 in. From Fig. 9.)

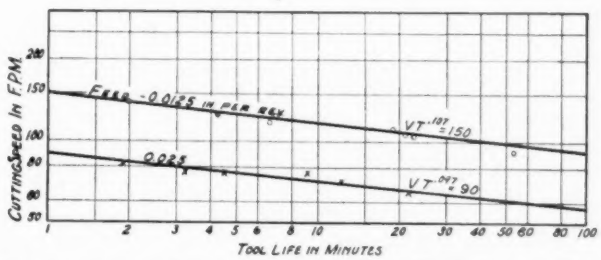

FIG. 14 CUTTING SPEED VERSUS TOOL LIFE WHEN CUTTING WITH *EmF* 1:50

(Three feeds; constant depth of cut of 0.200 in. From Fig. 9.)

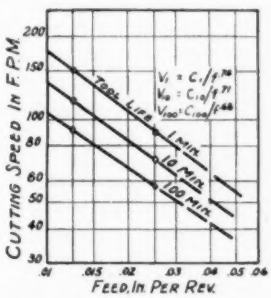

FIG. 15 RELATION BETWEEN CUTTING SPEED AND FEED WHEN CUTTING WITH *EmF* 1:50

(Depth of cut, 0.200 in. From Fig. 9.)

These curves indicate that, on the basis of highest cutting speed for a given tool life, emulsions should be used for the deep cuts and long values of tool life, whereas the sulphurized-base oil *SB* should be used for the smaller depths and shorter tool-life values.

Variable Feed at Constant Depth. In the third series of tests,

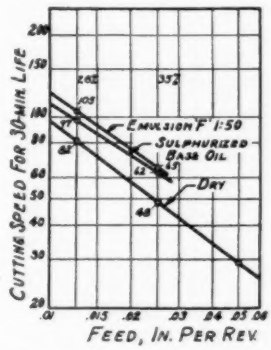

FIG. 16 SUMMARY CURVES SHOWING RELATION BETWEEN V_{30} AND FEED

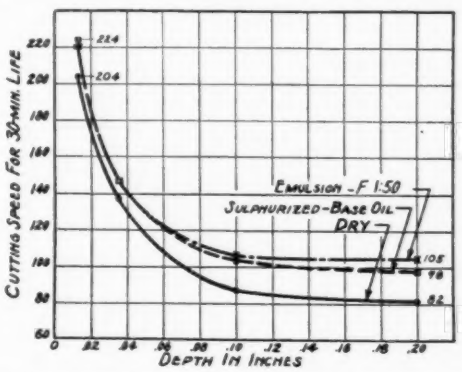

FIG. 17 SUMMARY CURVES SHOWING THE RELATION OF V_{30} AND DEPTH OF CUT

(Constant feed of 0.0125 in.; three cutting fluids; cutting S.A.E. 3140 annealed steel; form of high-speed-steel tools, 8-22-6-6-6-15-3/64.)

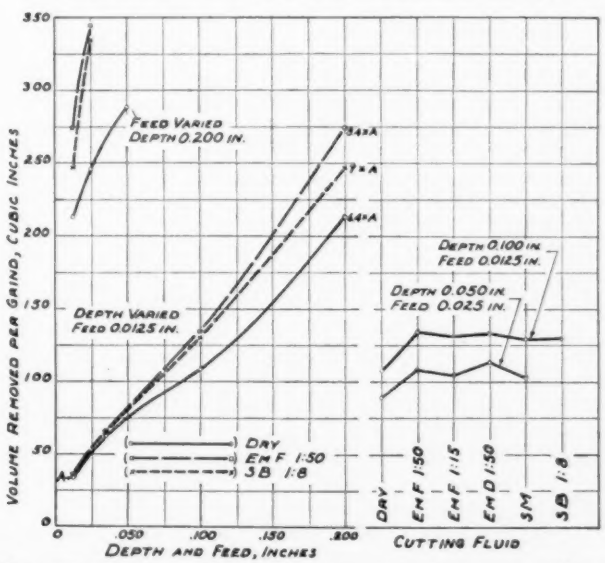

FIG. 18 SUMMARY CURVES SHOWING THE VOLUME OF METAL REMOVED PER TOOL LIFE OF 100 MIN FOR DIFFERENT COMBINATIONS OF FEED AND DEPTH FOR VARIOUS CUTTING FLUIDS

the feed was varied from 0.0125 in. to 0.050 in. per revolution, while the depth of cut was kept constant at 0.200 in. Three cutting fluids, dry, *EmF* 1:50, and *SM* were used. See Figs. 9 to 15, inclusive, and Fig. 18.

This depth of cut of 0.200 in. was selected as, in previous tests in which depth was varied, it was found that cutting fluids are more effective with large depths of cut than with small depths of cut. The results of the experimental data of these tests are represented as straight lines on log-log paper in Fig. 9. The tool-life cutting-speed line is shown for each cutting fluid for the light feed of 0.0125 in. at the top. As usual, the line for dry cutting is lowest, giving a V_{40} of 79 fpm. The line for *SB* is higher but of a steeper slope and has a V_{40} of 93 fpm. The line for the emulsion *EmF* 1:50 is highest, producing a V_{40} of about 99 fpm. The increase in cutting speed of the emulsion over dry cutting is 25 per cent. The three lines for the feed of 0.025 in. are somewhat lower, producing a cutting speed V_{40} of 46 fpm for dry cutting, 61 fpm for the *SB* oil, and 63 fpm for the *EmF* 1:50 emulsion. The increase in cutting speed of the emulsion over dry cutting for this feed is 37 per cent. Only the line for dry cutting is shown for the maximum feed of 0.050 in., for which V_{40} is 28 fpm.

The tool-life cutting-speed lines for the emulsion *EmF* 1:50 do not have such a steep slope as those for the *SB* oil. This indicates that, for longer tool-life values, the emulsion would be superior to the *SB* oil for these sizes of cut.

The lines for dry cutting of Fig. 9 are shown alone in Fig. 10 for each feed of 0.0125, 0.025, and 0.050 in. per revolution. Increasing the rate of feed lowers considerably the tool-life cutting-speed line. The slope of the line, as represented by n in the equation $VT^n = C$, is increased from 0.106 for the light cut to 0.140 for the heaviest cut. The values of C, which correspond with the cutting speeds for a 1-min tool life, are decreased from 117 to 46.7, or 60 per cent, while the feed is being increased by 300 per cent. The cutting speed V_{40} for a 40-min tool life is decreased from 79 fpm to 28 fpm as the feed is increased from 0.0125 in. to 0.050 in. V_{40} is increased from 28 to 46 fpm, or 64 per cent, as the feed is reduced from 0.050 in., to 0.025 in., or 50 per cent. It is increased from 46 to 79 fpm, or 46 per cent, as the feed is reduced further from 0.025 in. to 0.0125 in., or 50 per cent. It is increased from 28 to 79 fpm, or 182 per cent, as the feed is reduced from 0.050 in. to 0.0125 in., or 75 per cent, or an increase of feed to four times, reduces the speed to $^1/_{2.5}$ of that for the light feed.

It was difficult to obtain the exact time of total failure of the tools when the feed was 0.050 in. because a preliminary failure would often be obtained early in the run, but the tool still would cut, getting progressively duller, until the operator's judgment set the time of total failure. The preliminary failures introduced excessive loads on the tools, causing them to be broken off, particularly when using the oil or emulsion.

The relation between cutting speed and variable feed for dry cutting is shown on log-log coordinates in Fig. 11, for three values of tool life, namely, 1, 10, and 100 min. Straight lines are formed, the slopes of which increase slightly as the tool life is increased. These slopes, as represented by the exponent of the feed in the equation $V = C/f^z$, are shown on the figure. Since the tangent of the slope of these curves, that is, the exponent of the variable feed, is less than one, the most efficient cutting speed to remove this material is obtained for the large values of feed. It is seen that the exponents of feed are 0.67 for a 1-min tool life, 0.73 for a 10-min tool life, and 0.78 for a 100-min tool life. The 100-min tool life is the steepest. From this, it follows that a lower exponent is obtained for a lower value of tool life. Therefore, for dry cutting, the most efficient metal removal would be obtained for the largest values of feed when operating at relatively high speeds or short tool life. In Fig. 11, the most efficient metal removal theoretically will be obtained at the point A. For practical reasons, the tool life should be longer than 1 min. The exact time must be correlated with the time for tool replacement and so on.

When using the *SB* oil and varying the rate of feed, it was not possible to use a feed of 0.050 in. and a depth of 0.200 in. because of excessive loads on the tool after the preliminary failure. These loads would cause the $^3/_8$-in. square tools to break off, thereby interrupting the tests. The tool-life cutting-speed lines for feeds of 0.0125 and 0.025 in. per revolution are shown on log-log coordinates in Fig. 12. The slope of these lines is less for the heavier feed. This is just the opposite from dry cutting, Fig. 10, and indicates that the use of the *SB* oil would be more desirable for the heavier cuts at a long tool life. For a tool life of 1 min, the cutting speed is reduced from 152 to 90 fpm, or 41 per cent, by increasing the feed from 0.0125 in. to 0.025 in., whereas for a tool life of 100 min, the same change in feed reduces the cutting speed from 82 fpm to 56 fpm, or 31.5 per cent.

Discussion

M. KRONENBERG.[7] There has been much discussion as to the question when a tool is to be considered dull. Ripper and Burley measured the wear on the face of the tool and considered a blunting of $^1/_{16}$ in. as a criterion. Schlesinger, on the other hand, found as a scientific criterion the sudden rise in the two horizontal components of the cutting pressure, which is not always accompanied by an increase in the main (tangential) component of the cutting force. This behavior may be explained by the fact that the heat which is generated by friction between both tool face and chip and tool flank and work is mainly responsible for the wear of the tool. If the friction due to dulling increases, the horizontal components of the pressure increase too before the vertical component increases. The authors noticed that the breaking down of a part of the cutting edge did not change the quality of the machined surface and did not cause an appreciable increase in power consumption. Thus they allowed the tools to run until total failure which was indicated by the increase of power consumption. It does not seem to be advantageous to run tests until total failure due to the fact that in practice a total breakdown is uneconomical on account of the high cost for regrinding. A rapid change in the horizontal components usually reveals the instant of dulling; viz., between a partial breakdown of the edge and the total failure, provided that a time-recording device is used for measuring the horizontal cutting components.

The writer agrees with the statement that an increase in cutting speed by 22 per cent is possible in the case where the shape of chip cross section is changed from 1:2 to 1:8. Fig. 19 shows the same results for S.A.E. 1035 for various areas of chip and a tool life of 60 minutes. It will be seen however later on that for practical purposes this increase is of minor importance as to the most efficient metal removal on a lathe.

The finding that a shape factor of 1:8 for the area of chip is a desirable proportion of cut agrees with actual practice, where the ratio of feed to depth of cut (= shape factor) varies approximately between the limits of 1:2 and 1:20 and usually only between 1:5 and 1:10.

Formulas for the cutting speed V, in which the feed and depth of cut are given separately are usually presented in the form:

$$V = Cd^{-x} f^{-y}$$

[7] Research Department, Cincinnati Milling Machine Company, Cincinnati, O.

which can be transformed into

$$V = \frac{C}{A^{1/2(y+x)}\ S^{1/2(y-x)}}$$

where

A = Area of cut = $f \cdot d$

S = Shape factor = $\frac{f}{d}$

f = Feed per revolution

d = Depth of cut

x,y = exponents of d and f, respectively

C = Material constant for a definite tool life

This transformation indicates very clearly that the area A of the chip is of considerably greater effect on the cutting speed than the shape S, since the exponent of A is composed of the sum of y and x, while the exponent of S derives from the difference $y - x$.

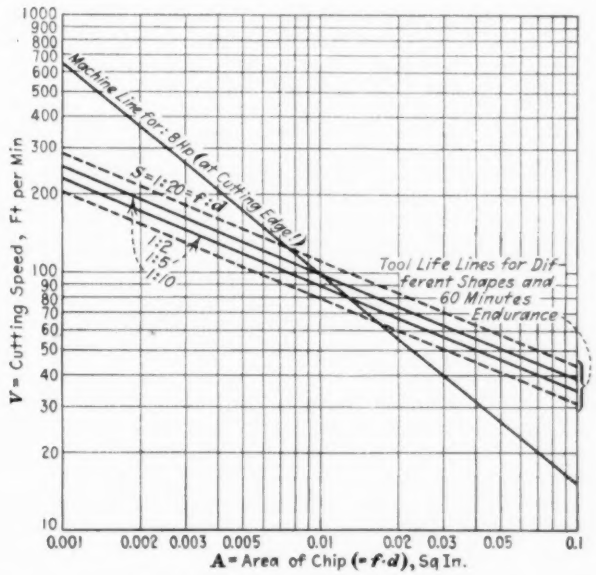

FIG. 19 CUTTING SPEEDS FOR VARIOUS AREAS OF CHIP; EFFECT OF SHAPE OF CHIP CROSS SECTION

(Example for high-speed-steel tool, [18-4-2]; S.A.E. 1035; 20-deg true rake angle; cutting fluid used. f = feed rate, in. per rev; d = depth of cut, in.; $S = f:d$ = shape of chip cross section; $A = f \times d$ = area of chip cross section.)

If as an example, the shape of chip cross section is changed in the ratio 1:4 (viz., from 1:2 to 1:8) then the cutting speed may be increased by 23 per cent, while a change of 1:4 in chip cross section (viz., from 0.004 sq in. to 0.001 sq in.) permits an increase of cutting speed by 270 per cent for the same tool life.

As to the exponent n of the cutting-speed–tool-life relationship, no definite connection with either the chip cross section, the shape factor, or the cutting fluid can be seen from the paper. It is known that the values for n vary approximately between 0.1 and 0.17 and usually between 0.12 and 0.16. The ideal condition would be an exponent $n = 0$, meaning that the tool life would be infinite; since this is out of the question the aim must be to reduce n as much as possible by cooling fluids, etc. On the other hand, care must be taken not to lay too much importance on the change of n within the limits mentioned above. A value of n of 0.12 as against 0.16 results in an increase of the cutting speed (all other conditions unchanged) of approximately only 21 per cent, while a change in the chip cross section has considerably more effect as will be shown. Furthermore the accurate determination of n is difficult. Fig. 3 of the paper indicates this. An exponent $n = 0.111$ occurs twice although no reason is to be seen why this value should be true only for $d = 0.035$ and $d = 0.200$, while the n values of the other lines are different. In the writer's opinion the four exponents shown could be averaged and the lines be made parallel. This averaging would hardly be noticeable on the diagram as it calls only for a minute turning of the lines through 1 deg or less. Thus the value of n averaged from Table 5 of the paper would be 0.127 for dry cutting as against 0.11 for *EmF* 1:50. This indicates a definite improvement, which becomes still more evident if the V_{100} values on this basis are taken into consideration and compared for the same chip cross section and shape. Then it will be seen that the improvement in cutting speed due to *EmF* 1:50 ranges between 15 per cent (for small chip cross sections) and 39 per cent for greater ones.

The most effective combination of the various variables involved in cutting with single-point tools will be explained by

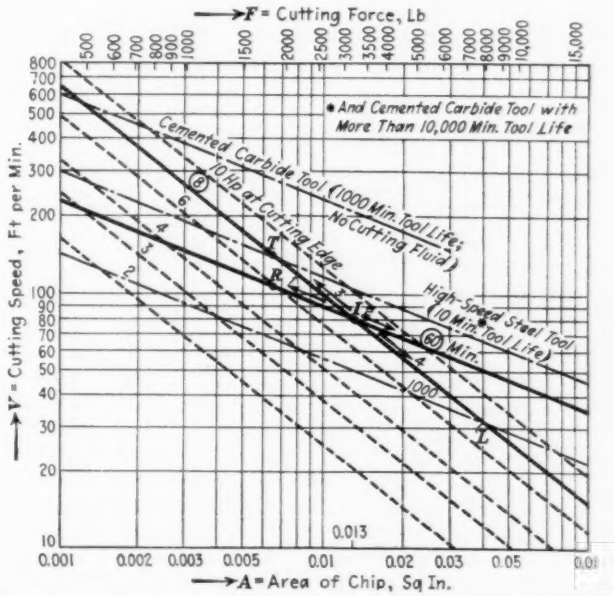

FIG. 20 DETERMINATION OF MOST EFFECTIVE COMBINATION OF CUTTING VARIABLES

(Example for high-speed-steel tool, [18-4-2]; S.A.E. 1035; 20-deg true rake angle; cutting fluid used.)

Fig. 20.[8] It will be seen that two different relationships exist between cutting speed V and chip cross section A as indicated by the lines with smaller slope (lines of constant tool life) and with greater slope respectively (lines of constant horsepower). The lines intersect, for example, in point I where a high-speed-steel tool of 60-min endurance and a machine of 8 horsepower are assumed. Increasing the cutting speed (along arrow 1) by decreasing the chip cross section in such a manner that the kind of tool and tool life is kept constant is not advisable, due to the fact that the productivity is decreased. (The combination at point I gives 12.5 cu in. per min metal removal at point R only 8.2 cubic inches per minute).

Following the tool line in direction of arrow 2 results in an increase in the chip section and a decrease in speed for a constant tool and tool life. Here the 10-horsepower line is approached, indicating an overloading of the machine.

[8] "Science and Practice in Metal Cutting" by Dr. E. Bickel, *American Machinist*, October 1934, page 693. This article is based mainly on investigations made by the writer.

Further combinations of the variables are possible by following the machine line (along arrow 3). Here we increase the cutting speed and decrease area A, but we leave the tool line of 60-min endurance. Thus the tool must be changed and a cemented carbide tool be taken. The production at point T would be 11.2 cu in. per min and the pressure 1800 lb (see scale at top). In spite of the diminution of chip volume per minute, it is often desirable to use small chip cross sections and high speeds due to the decrease of cutting force and consequently less deflection and higher accuracy (no built-up edge).

This will obviously be at some sacrifice in productivity but still considerably more advantageous than in the case of following arrow 1 (tool-life line) where the chip volume was reduced to 8.2 cu in. per min.

Following the machine line in the direction of arrow 4 leads for example to point L, where the productivity is 15.3 cu in. per min and the tool life 1000 min. Thus it seems that the use of a low cutting speed in combination with a big chip results in both a better endurance and a higher productivity. However, it must be borne in mind that the cutting force increases to 8000 lb in this example. This procedure (along arrow 4) is only advisable if roughing cuts are to be taken on stable work pieces.

In conclusion it must be said, that the selection of and changes in the cutting speed should be made in accordance with the machine line (arrows 3 and 4, respectively) and the tool should be adapted to the respective speeds. The machine line is often still unknown, although it is the best guide as to the most efficient metal removal.

Authors' Closure

Dr. Kronenberg has presented charts, the purpose of which is so to generalize the information as to make it applicable for shop use. This was not the primary object of the paper. The authors have emphasized cutting fluids particularly, which are not considered in Dr. Kronenberg's discussion.

The authors, on many occasions, have correlated cutting forces with tool wear and tool failure. They have found and have published data[9] in which the three components of the cutting force are shown to be maximum when a newly ground tool starts to cut, are gradually reduced as the tool is cupped on the face, but are increased perceptibly as soon as the newly formed cutting edge between the cup and the flank of the tool is broken off. The occurrence at this instant has been called preliminary failure by the authors, as the tool will run an additional length of time, ranging up to 60 or 70 per cent, before complete tool breakdown occurs.

By modifying the side-cutting-edge angle and nose radius for a given size of cut, preliminary failure may occur. It will be evident by a burnished ring on the shoulder of the metal being cut but in no way will it affect the size or roughness of the machined surface. The cutting-speed–tool-life line for the preliminary failure, as well as for the ultimate failure, has been determined. Sometimes the line for the preliminary failure plotted on log-log paper is parallel to, but just below, that for the ultimate failure. More often, however, this line has a slope greater than that for the total-failure line. This point is discussed to show that, by determining the time of total failure, using the increase-in-force method, a time of tool failure differing from that of the ultimate tool failure is obtained, which has no consistent relation to the latter in different sets of tests.

When high-speed-steel tools fail in machining cast iron, failure occurs by abrasion on the flank. For some tool shapes this wear is below the side cutting edge. It is gradual in its development. The cutting force will start to increase and become maximum at the time of complete tool failure, at which time there is the first evidence of change in diameter and surface quality on the machined surface. When the wear occurs under the end cutting edge, the diameter of the work gradually increases and it is hardly possible to determine a definite time of tool failure. It would be difficult to obtain consistent values of a certain definite amount of wear by the force method when turning cast iron for these reasons.

Many experimenters have tried to correlate the time of tool failure when taking light cuts with the cutting force. No satisfactory data were published until French and Digges replaced the cutting-force idea with their trailer tool. The authors have used the trailer tool, but have found, even for the 0.0125-in. depth × 0.0125-in. feed in cutting steel, that there is a very definite time of tool failure, as observed by the sudden burnishing of the work shoulder, at which time the diameter and quality of the machined surface is first affected.

The authors believe that the chip-shape factor is of more importance than indicated by Dr. Kronenberg. It is believed that, in the development of curves for guidance in general machining, this chip-shape factor should provide for ratios of feed to depth in excess of 1:5 and 1:10. This is indicated in Fig. 18. It is shown in Figs. 4, 6, and 8 that the chip-shape factor has a greater effect for ratios larger than 1:8. For high ratios, such as 1:16, the formula expressing a relation between V and d no longer holds, as shown by Fig. 3. This would mean that, for large ratios, the depth factor S would become of equal effectiveness to that of area A, as expressed in Dr. Kronenberg's second equation, inasmuch as the value of x becomes zero.

Dr. Kronenberg points out that, as the shape of the chip cross-sectional area is changed from 1:2 to 1:8 (keeping the area of cut constant), the cutting speed is increased 23 per cent, as shown in Fig. 1. He further states that a change in chip cross-sectional area from 0.004 to 0.001 sq in. (giving one quarter the area of cut) permits an increase in cutting speed of 270 per cent for the same tool life. This latter example actually shows a loss in production by reducing the size of cut.

Dr. Kronenberg's Figs. 19 and 20 are very interesting and valuable from a practical viewpoint. It is unfortunate that the material, tools, and cuts are so different from those of the paper. The authors have no way of comparing their data with those of Dr. Kronenberg, shown in Fig. 19, inasmuch as the materials are different and the areas of cut hardly overlap. In Fig. 20 Dr. Kronenberg has used an S.A.E.-1035 steel, presumably annealed, which in general calls for a machinability rating of about 68 per cent, as compared with that of 100 per cent for the S.A.E.-1112 cold-finished screw stock. The machinability rating of the S.A.E.-2340 steel annealed as generally accepted, and used by the authors, is around 56 per cent or only 12 per cent below that of the S.A.E.-1035 steel.

By referring to Fig. 2, the cutting speed for a 60-min tool life for an area of cut of 0.0125 in. by 0.100 in. (equals 0.00125 sq in.) is shown to be about 95 fpm for the emulsion. Fig. 20 shows, for the S.A.E.-1035 steel, that the cutting speed for a 60-min tool life for the same area of cut is about 210 fpm, which is 120 per cent higher than that for the S.A.E.-2340 steel. Dr. Kronenberg used 18–4–2–type high-speed steel, which might increase the cutting speed by 10 per cent over the 18–4–1 type of steel, but even so his values do not seem to agree favorably with those of the steel used in the paper.

The authors greatly appreciate Dr. Kronenberg's contribution and the many oral questions and discussions which brought out numerous interesting phases of the research and added greatly to its practical understanding.

Thin Oil Films

By WALTER CLAYPOOLE,[1] BEACON, N. Y.

A method is described for depositing very thin lubricating-oil films of any specified thickness of the order of 10^{-7} in. on polished metal in connection with experiments on boundary friction. The oil to be deposited is converted into a highly dispersed fog consisting largely of positively charged particles. The oil is readily deposited on a negatively charged metal surface at a rate depending on the nature of the oil, the potential gradient at the metal surface, and the concentration of the oil particles in the fog. The rate of deposition is best determined by observation of the progressive change in the interference color produced over a thickness range between 5×10^{-6} cm and 30×10^{-6} cm. Comparison of color with a standard stepped film of barium stearate laid down by the Langmuir and Blodgett technique gives a high degree of accuracy to the determination of film thickness.

Experiments have been made on the wearability of very thin oil films, and on the determination of the coefficient of static friction. An instrument is described which has been found especially suitable for this work. The author points out that a low value of the coefficient of static friction is a measure of the oiliness value of an oil-metal combination.

THE ENGINEER familiar with the principles of the hydrodynamic theory of lubrication has a relatively simple problem when called upon to design a bearing which will operate satisfactorily under specified performance conditions. His interest is solely concerned with the behavior of the bearing when running under a specified load at a specified speed. He thinks only in terms of full fluid lubrication and sees to it that provision is made for supplying the rubbing surfaces of the bearing at all times with oil of a suitable viscosity. Under these circumstances he is able to state with considerable confidence that the coefficient of running friction of his bearing will be a number preceded by one or two zeros. Although he has theoretical reasons for believing that a correctly designed and properly operated bearing should run indefinitely without visible wear, he is not optimistic enough to expect it to do so in actual operation.

Wear in Bearings Under Normal Running Conditions. A very brief inquiry into the underlying causes for bearing wear will show that although their normal running operation is under fluid-film conditions, the static load when the machine is shut down may reduce the oil film to extreme thinness. On starting, there is a delay in the formation of the full fluid film, and it is during this period that wear of the rubbing surfaces takes place. This wear, however, is not necessarily of a serious type, since no matter how severe the squeezing-out action, the opposed surfaces still carry an adsorbed layer which is at least one molecule thick, and as long as this layer remains attached to the metal no clean contact can take place. An examination of the rubbed areas after long-continued operation will show that the wear has been in the nature of a polishing process, the surface of the metal exhibiting a mirror-smooth patina. Submicroscopic projections have been worn down and submicroscopic valleys have been filled in. This process of running-in combines the agencies of actual wear and surface flow. The wear, however, is to be regarded merely as the result of a slow removal of minute irregularities projecting above the general level, and the total amount of actual metal lost may be very small indeed. Surface flow is generally recognized as the phenomenon responsible for the formation of the desirable Beilby layer.

After the rubbing surfaces have been thoroughly run-in, the rate of wear in normal operation falls to a negligible figure and the question then arises as to the causes for abnormal wear, the visible evidence for which is scuffing and abrasion. If we leave out of the picture such accidental agencies as the presence of abrasive material, there remains only breakdown of the oil film between the opposed rubbing surfaces as the blanket cause for bearing failure. However, oil-film rupture is not likely to occur in a well run-in and properly operated bearing, but when it once starts, the damage to the surfaces is of a very serious nature. As long as the opposed metal parts are at all times separated by at least two molecular layers of oil there can be no wear of the type known as abrasion or scuffing. If the mechanical attack at the contact areas of metals rubbing together becomes severe enough to remove the ultimate protecting film, the clean metals will seize, causing irreparable damage to the surfaces. This seizure is in fact, incipient welding, resulting in the gross removal of metal. Polish wear, on the other hand, is due to the smooth removal of surface molecules, and occurs when the separating oil film has an average thickness less than the average height of surface irregularities. Polish wear is beneficial and is the process made use of in a running-in operation. It is obvious that the better the surface finish, the thinner may be the separating film.

The ideal case, as indicated previously, would be two perfect surfaces separated by a double molecular layer of lubricant. Since perfect surfaces are unattainable, we have to recognize the fact that the working film between rubbing surfaces must be considerably thicker than this. The rise in the coefficient of friction on passing from fluid-film to boundary-film conditions is quite rapid, which means a rapid increase in the rate of dissipation of energy at the rub spots. Unless prompt steps are taken to re-establish fluid-film conditions, the ultimate protecting film adsorbed on the surfaces is likely to be rubbed off, thus bringing clean metal into contact.

What Is a Thin Oil Film? Since it is obvious that the term "thin" is very elastic, it is necessary to set limits for its dimensional value before we can investigate the properties and mechanical behavior of lubricating films of this type. The logical

[1] Research Physicist, Research Laboratories, The Texas Company. Mr. Claypoole was educated in England and after receiving a degree in electrical engineering entered the employ of a firm of electrical contractors. For seven years he was assistant to Sir James Swinburne, F.R.S., working on pioneer electrical and physical investigations as well as on technical patent litigation. Later, he entered government service as senior physicist at the Royal Aircraft Establishment at South Farnborough, England. He came to the United States in 1912 in connection with the early development of bakelite. Afterward he conducted special research work on cable signaling for the Commercial Cable Company. He entered the service of The Texas Company in 1916.

question to ask is: How thin must an oil film be in order that the component oil molecules lose their mobility? The reason for this question lies in the fact that we propose to investigate the protective action of a thin film subjected to severe mechanical punishment. Above a certain minimum thickness we may expect oil molecules immediately adjacent to the high-spot areas, where the squeezing-out action is a maximum, to flow in as soon as the excess pressure is relieved. Below this minimum thickness the protecting film is rubbed off faster than it can be replaced by flow.

Evidence presented later, shown graphically in Figs. 6 and 7, indicates that under favorable circumstances a considerable measure of protection is afforded by films thinner than one millionth of an inch. In this investigation a thin film will be regarded as one having a thickness less than 1/1,000,000 in.

Production of Oil Films of Specified Thickness

It is obvious that if quantitative measurements of thin films be desired, we must be able at will to produce films of uniform and known thickness. Preliminary experiments indicated that the range of thickness desired lay between 10^{-7} and 10^{-6} in., and it was essential that the specified thickness should be obtained with a fair degree of accuracy.

The simple technique described by Langmuir and Blodgett[2] for the production of known thicknesses of metal stearates by picking up successive layers from a compressed monolayer on the surface of water, was unavailable, since it is not possible to produce such a layer of a lubricating oil on a water surface.

Attempts were made to obtain films of specified thickness by driving off a volatile solvent from a weak solution of the oil applied to the metal surface. It is obviously quite a simple matter to leave behind a specified quantity of oil after evaporation of the solvent, but it is quite difficult to devise a method which insures that the deposit shall be uniform. Several other methods were experimented with, but were found wanting in one respect or another.

Oil-Fog Method

The method finally adopted was to deposit the film from a fog produced by fine atomization of oil. Such a fog appears to consist largely, if not entirely, of positively charged particles. Its mechanical behavior may conveniently be observed by feeding it with minimum disturbance into the upper end of a tall, wide glass cylinder. The larger droplets will soon begin to fall out, leaving a dense cloud as a residue which very slowly moves down the cylinder under gravity. A flat metal plate, carefully cleaned and then suspended in a vertical plane in the fog, will remain clean, but if supported at an angle to the direction of motion of the slowly falling fog particles, will acquire a very thin film of oil. The usual water-flushing test serves very well to demonstrate the presence or absence of oil on the metal plate. Gravity deposition of thin oil films from fog offers little possibility, however, for accurate quantitative work, but when advantage is taken of the fact that the oil particles are positively charged, and will therefore readily deposit on a negatively charged metal surface, it is possible to devise a suitable method by which films of specified thickness may be laid down. Preliminary experiments showed that the rate of deposition from fog was different for every type of oil. The addition of a small percentage of a highly polar body to a straight mineral oil, for instance, made the rate of deposition at least ten times greater. It was also found that the rate varied with the density of the fog, with its rate of flow past the deposition surface, and with the potential gradient in the field.

The problem therefore resolves itself into a formulation of experimental details whereby a thin and uniform film of a particular oil can be laid down on a metal surface, together with a method for estimating accurately the thickness of the film. We require a film of a specified thickness, and we have to be able to prove definitely that the thickness is what we intended it to be. Two obvious methods available are as follows:

1 Determination of Film Thickness by a Weighing Method. A metal surface of known area is exposed to standard deposition conditions in the fog, and the gain of weight carefully determined over a series of measured time intervals. The weight gains are plotted against exposure times, which gives the rate of deposition for the particular oil used. Knowing the surface area of the deposition plate, and the density of the oil, we can immediately calculate the thickness of the film laid down per minute of exposure time.

Fig. 1 shows the results obtained by this method for a series of four similar straight mineral oils having different viscosities and of somewhat different chemical types. It will be seen that the rates are linear over the range covered. As an example of the practical application of this method, we see that oil *A* shows a weight gain of 0.8 mg in a total exposure time of 4 min.

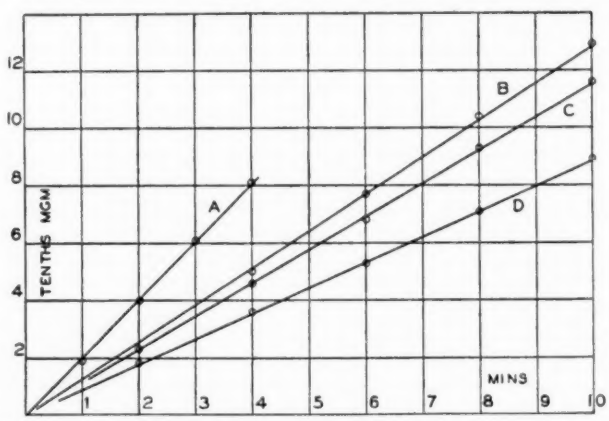

Fig. 1 Varying Rates of Electrostatic Deposition of Four Different Oils Determined by the Weighing Method

This oil had a specific gravity of 0.8735 and the area of the deposition surface was 187.1 sq cm. The thickness T in cm of the film deposited in 4 min is therefore

$$T = \frac{0.8 \times 10^{-3}}{187.1 \times 0.8735} = 4.9 \times 10^{-6}$$

If we assume that the linear relation holds below the lowest determined point, it would appear possible to lay down films, by this method, of thickness approaching molecular dimensions.

2 Interference-Color Method. If we apply to a flat piece of polished chromium plate a continuous film of oil of uniform thickness lying in the range between 500 and say 4000 Angstroms (or 5 to 40 millionths of 1 cm), we have a very accurate method of estimating film thickness by observation of the interference color developed.

In the practical application of this method to the determination of an oil film deposited from fog, very special precautions have to be taken in cleaning the deposition plate. The nature of the difficulties may best be understood by following the work of conditioning the surface. Consider that we have a well-polished

[2] "Monomolecular Films of Fatty Acids on Glass," by K. B. Blodgett, *Journal of the American Chemical Society*, vol. 56, Feb., 1934, p. 405. Also: "Built-Up Films of Barium Stearate and Their Optical Properties," by K. B. Blodgett and I. Langmuir, *Physical Review*, vol. 51, June 1, 1937, p. 964. See also references cited under footnote 4.

chromium plate to be used for the first time. Naturally, it carries an adsorbed greasy film, as shown by the fact that it will shed water. This film can easily be removed by scouring with a paste of fine optical rouge and water, or with a metallographic powder such as Shamva,[3] and water.

Now comes the real difficulty—that of removing the last trace of the polishing powder. It might be thought that scrubbing the surface with a series of absorbent cotton pads under running water would be sufficient, but very surprisingly it is found that a surface finished in this way will not serve as a base on which to lay down a continuous film from oil fog. The deposited film looks hazy, and, of course, no interference colors are seen. The probable explanation is that the surface is still covered with myriads of submicroscopic particles of the polishing powder, since it is known that such fine particles are held very strongly on a clean surface. The use of cotton pads was therefore abandoned in favor of a more vigorous scrubbing medium. The problem was finally solved by the use of rubber gloves, freed from oil by dipping in cleaning solution, followed by thorough washing in water.

The metal plate, held in one gloved hand, is scrubbed with the gloved fingers of the other under hot running water. After a final flushing with distilled water to insure that the surface when dry does not carry traces of salts from the tap water, the plate is put on edge to drain and dry naturally. It is now found that an oil film in the proper thickness range, deposited on the plate prepared in this way, shows brilliant and uniform interference colors.

The statement as to uniformity of color requires modification in the event that surface defects or contamination, however slight, are still present on the plate. The effect of scratches visible to the naked eye is especially pronounced, each scratch being traced out by a color line corresponding to a film thickness greater than that of the surrounding area. For instance, even before the main film has reached the intensity peak of the first order, yellow (thickness about 20×10^{-6} cm), a fine scratch may show as a red trace, corresponding to a film thickness of about 25×10^{-6} cm.

Another defect sometimes observed in the uniformity of the color shows itself as a mosaic pattern of two colors adjacent in the scale, and is believed to be due to some unrecognized surface condition. To sum up the first experimental condition for the deposition of a homogeneous and uniform film of oil from fog, it is necessary to use an extremely smooth and scrupulously clean metal surface.

Method of Preparing a Stepped Color Film. The first operation in the calibration of an oil for rate of deposition by the interference-color method is to prepare a standard stepped color gage by the Langmuir and Blodgett technique.[3] Table 1 gives values computed from data given by Blodgett.[4]

A stepped oil film to match exactly the standard color gage may be prepared in the following manner: A sheet of thin celluloid in which a rectangular hole has been cut, is laid on the highly polished surface of a chromium-plated disk which has been cleaned by the method described. Separated from the deposition surface by a gap of $^1/_4$ in. is another metal plate serving as the second electrode. Fog is flowed through the gap and a standard operating voltage applied for measured times. At intervals the plate is inspected for color. When the first color is brought to a perfect match with yellow-brown on the standard series, a glass slide is moved into position so as to protect a strip about $^1/_2$ in. wide from further deposition. The exposure is then continued on the rest of the plate until the next color, dark blue, is brought to a perfect match, after which the glass slide is moved up as before. In a similar manner the rest of the stepped film is built up.

TABLE 1 THICKNESS AND COLOR OF MULTILAYER STEARATE FILMS[a]

Number of layers	Thickness, cm $\times 10^{-6}$	Interference color
21	5.1	Yellow-brown
41	10.0	Dark blue
61	14.9	Light blue
81	19.8	Yellow
101	24.6	Red
121	29.5	Blue
141	34.4	Green
161	39.3	Red-yellow

[a] Based on 24.4 Angstroms for the length of a barium-stearate molecule.

A graph of film thickness against exposure time is then plotted, as shown in Fig. 2, which gives the results obtained with four oils of the same general type, but of widely different viscosities. Straight lines were drawn from the origin through the determined points, which have been omitted from the diagram for the sake of clarity. It will be noted that these four oils have very similar rates of deposition. In the thickness range in which we are interested when making wearability tests of very thin films, that is, of the order of a few millionths of a millimeter, the required exposure time would be substantially the same for each of these oils.

Assuming, as seems justified, that the linear relation observed throughout the color range continues for films thinner than

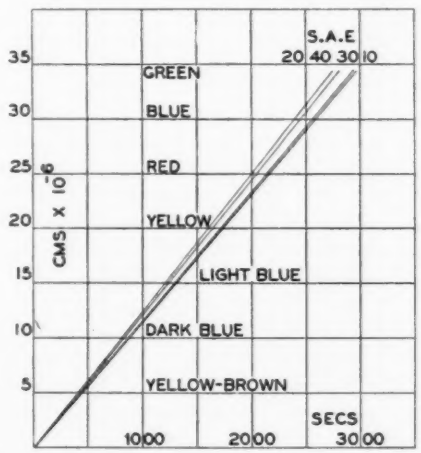

FIG. 2 RATES OF ELECTROSTATIC DEPOSITION OF FOUR SIMILAR OILS DETERMINED BY THE COLOR-INTERFERENCE METHOD

5×10^{-6} cm, the calculation of exposure time required for any specified thickness of the order of a few molecular layers is a simple matter. Suppose we find that 2500-sec exposure under standard conditions is required to match the blue at 30×10^{-6} cm, the exposure for a film three millionths of one millimeter thick will be 25 sec.

The color-interference method is subject to slight error since the refractive index of the stearate used in building up the multilayer stepped film used as a color standard differs from the index of the lubricating oil used to build up the experimental boundary film. Fortunately, the difference is too small to warrant applying a correction factor.

Also: "Properties of Built-Up Films of Barium Stearate," by K. B. Blodgett, *Journal of Physical Chemistry*, vol. 41, October, 1937, p. 975.

Experiments reported by Langmuir and Schaefer[5] on the conditioning of surfaces show that a barium-stearate multilayer surface may be so conditioned as to be strongly oleophilic. Langmuir, Schaefer, and Wrinch have reported[6] further that increments of film thickness of the order of 3×10^{-8} cm produce a noticeable change of color when viewed with polarized light reflected at large angles of incidence from the surface of a multilayer film of the order of 1000 Angstroms in thickness. These observations suggest the possibility of direct measurement of the thickness of extremely thin oil films electrostatically deposited on multilayer stearate films conditioned in the manner described.

Some Experimental Details

1 The Oil Fog. The ideal oil fog would consist of particles alike in size and of dimensions probably of the order of 2 microns in diameter. The actual fog as delivered at the nozzle of the atomizer consists of droplets of varying diameter, as inferred by noting the behavior under gravity settling in a tall glass cylinder. In order to obtain a working fog consisting of small-diameter droplets covering not too wide a range in actual dimensions, the

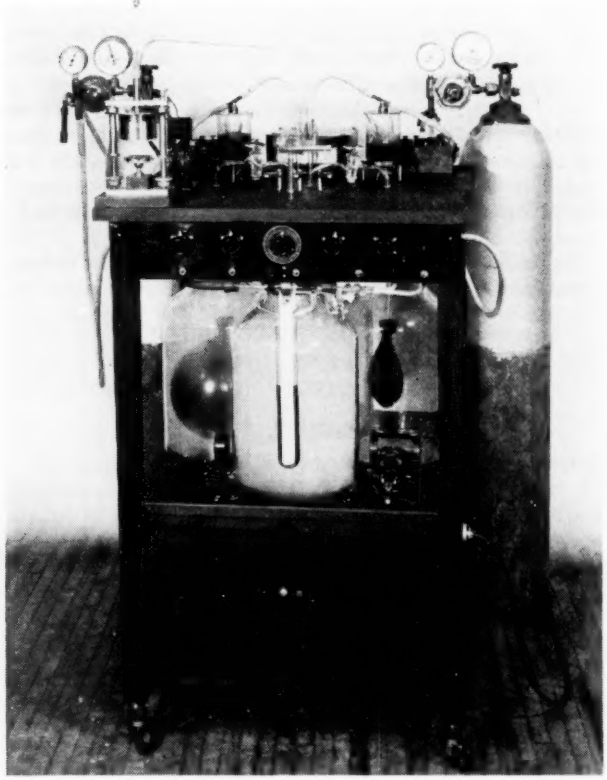

Fig. 3 Apparatus for Production of Oil Fog and for Electrostatic Deposition of Thin Films

fog is first fed into a large settling bottle in series with the working bottle. This arrangement allows the larger droplets to settle out, leaving in the upper part of the second bottle a fairly uniform fog to draw from.

In order to avoid oxidation of the finely divided oil droplets in the fog, an inert gas such as tank nitrogen is used both for atomizing the oil and for flushing out the system. Oils of differing viscosities are brought to the same viscosity while being atomized by immersing the atomizer bulb in a bath maintained at a predetermined temperature derived from the A.S.T.M. viscosity-temperature chart.

Concentration or fog density must be maintained constant. This is easily accomplished by photoelectric means. At opposite sides of the working bottle are arranged a Weston Photronic cell and a 6-volt, 32-candlepower bulb in a reflector. With an

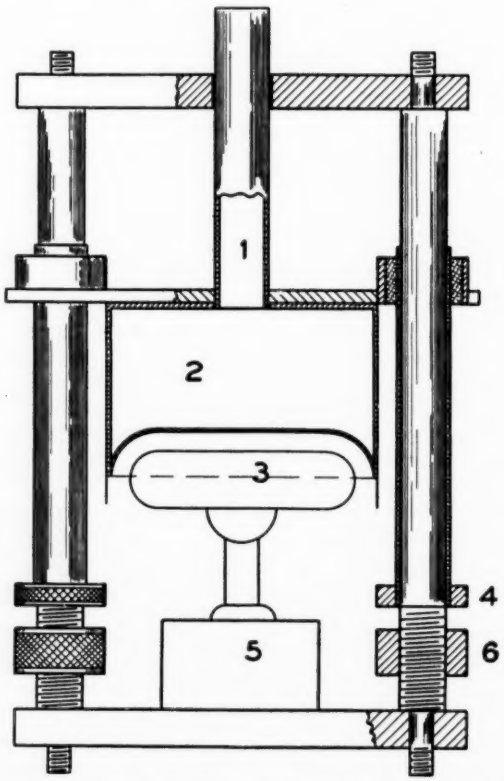

Fig. 4 Details of Deposition Electrode for Thin Oil Films

empty bottle the light is adjusted by rheostat to give full-scale reading on a microammeter. The concentration of the fog is then built up until the reading falls to a convenient, arbitrary figure, such as 40 per cent of the empty-bottle value.

In actual deposition, the fog should flow past the active-metal surface at a constant rate, in order to maintain a constant supply of charged particles in the immediate vicinity of the surface. It was found that 25 cc per sec was a suitable rate of flow, and this was maintained in all deposition experiments.

Fig. 3 shows a portable form of the complete apparatus used for oil-fog production, control, and deposition as a thin film on a polished metal test disk. Three 5-gal glass bottles are used, in two of which are rubber balloons. These are storage bottles for the fog as soon as it is produced in one of the atomizers which can be seen on the table of the apparatus. The bottle in front is the working bottle into which the fog is fed from one or other of the storage bottles, and from which it is drawn to the deposition apparatus shown on the table at the extreme left. This apparatus is sketched separately in Fig. 4 and its construction is described later. In Fig. 3, the fog chamber is shown raised out of position. At the start of a run it is lowered into position over the deposition disk, and at the same instant voltage is applied and a stop watch started.

The purpose of the balloons is to provide a means for flowing fog at a controlled rate, from the storage bottle in use at the

[5] "Improved Method of Conditioning Surfaces for Adsorption," by I. Langmuir and V. J. Schaefer, *Journal of the American Chemical Society*, vol. 59, September, 1937, notes, p. 1762.

[6] "Built-Up Films of Proteins and Their Properties," by I. Langmuir, V. J. Schaefer, and D. Wrinch, *Science*, vol. 85, January 15, 1937, p. 76.

moment, into the working bottle, and then to the deposition apparatus. To do this, nitrogen gas is fed into the balloon at a specified rate which is measured on the flowmeter seen in front of the working bottle. The expansion of the balloon serves in a very simple manner to effect the transfer of fog through the system. Stopcocks enable the operator to shift instantly from one storage bottle to the other during a long-continued calibration run with no interruption of the fog flow.

A simple and very effective means has been incorporated into the apparatus which makes it possible to keep the intensity of the light in the photoelectric density-measuring device always at its empty-bottle value. A second Photronic cell outside the bottle is illuminated by the light bulb and is connected to a second indicating instrument. Both instruments are adjusted to give the same empty-bottle indication. If, therefore, with fog in the bottle, the reading of the outside instrument is kept on this value by means of a rheostat, we can be sure that the fog density as indicated by the working Photronic cell is reliable.

2 *The Potential Gradient.* As previously stated, oil will deposit on a negatively charged metal plate suspended in an oil fog. If the plate be prepared carefully enough beforehand with respect to polish and cleanliness, interference colors will appear as the exposure continues. It will be found that the deposit is far from uniform as evidenced by the variation of color over the surface. At and near the edges the rate of deposition is a maximum, and the reason for this is clear enough when it is remembered that in this region the potential gradient is considerably higher than over the flat central portion of the plate. One obvious way of overcoming this difficulty would be to surround the actual deposition plate with a guard ring at the same potential.

Another and preferable method to follow when calibrating an oil fog for rate of deposition is to shape the deposition surface so that edge effects due to nonuniform potential gradient are eliminated. Fig. 4 shows the deposition apparatus used. Oil fog of controlled density is admitted through tube (1) into a cylindrical metal box (2), the bottom plate of which is pierced with a large number of fine holes. The circular metal disk, on which the thin oil film is to be laid down, forms the upper half of a pancake-shaped electrode (3), the edge of which has a radius of curvature of $^1/_4$ in. The flat bottom of the fog box, and the flat upper surface of the electrode can be set very exactly to a gap distance of $^1/_4$ in. by means of distance pieces inserted between the ends of the sliding members (4) and the adjustable nuts (6). The electrode (3) is carried on an insulating support (5), and is connected to the 1000-volt negative side of a direct-current power pack, the positive side of which is grounded and also connected to the metal frame. Thus, there is a potential gradient of 1000 volts over a $^1/_4$-in. gap through which the oil fog flows at a uniform, slow rate. The fact that during a calibration run the interference color over the whole of the deposition surface is perfectly uniform is evidence that the necessary operating conditions have been attained.

Rupture Tests of Thin Oil Films

Starting with the concept that a thin oil film protects the metal surface to which it is attached, by virtue of its resistance to removal under the stress of high-load rubbing, a test procedure was sought for making quantitative measurements of film strength. The following conditions were formulated:

1 All oils to be tested must be in the form of films of the same thickness.

2 The applied load must have a high and constant unit value.

3 The rubbing throughout the test must be along exactly the same track.

4 The metal base on which the film is laid down must have a high degree of polish, and the actual track to be followed must first be given a run-in treatment to bring the surface to as high a state of uniformity as possible.

5 Means must be provided for measuring the gradual degradation of the film up to the point of breakdown, so that a numerical value may be arrived at which expresses its resistance to rupture.

Considering these requirements individually:

Film Thickness. The procedure already described proved to be suitable for laying down uniform oil films of any specified thickness on polished metal. As previously mentioned, experiments showed that a suitable thickness for a film-wearability test lay between 10^{-7} and 10^{-6} in.

Unit Load. A high and constant unit load can be obtained by using as the rubbing "point" a sapphire formed to a hemispherical contour of small radius. In the tests made, the sapphire was formed to a radius of curvature of $^1/_{16}$ in. An application of the Hertz formula[7] for the case of a steel ball of this radius in contact with a steel flat, under an applied load of 100 g, gives an average value for the unit pressure over the area of the contact circle of about 93,000 lb per sq in. A search of the literature failed to disclose any values for the elastic constants of sapphire, but it is believed that an average pressure at the contact spot of the order of 100,000 lb per sq in. may be expected.

Rubbing Track. The machine built for tests of thin-film rupture made it possible to pass the sapphire rubbing button repeatedly over exactly the same circular track on a rotating steel disk carrying the thin film. Before the oil film is applied, a track about 0.2 mm wide is given a run-in treatment under a diamond which has been formed to a rounded contour and polished smooth. This operation is done dry, both diamond and steel being absolutely free from any trace of oil. Contrary to what might be expected, there is no abrasion or wear of any kind, and the coefficient of friction has a value sometimes as low as 0.02. This remarkable phenomenon does not appear to be connected with the hardness of the diamond. A highly polished boron carbide point which approaches the diamond in hardness will tear up the surface of clean steel even under light loading. Sapphire behaves similarly to boron carbide. Fig. 5 shows, at a magnification of 100 diameters, two tracks on molecularly clean glass. The faint track, which may not be visible in the reproduction, is the result of 100 passages of a diamond under an applied load of 1000 g. The slight image visible is a refraction effect due to distortion of the surface of the glass as a result of surface flow. The other track was made by a single passage of a rounded sapphire under an applied load of only 100 g and shows very severe abrasion accompanied by a skittering progress of the sapphire over the surface.

Measurement of Film Strength. The most logical and convenient method of determining the resistance to mechanical wear of a thin oil film is to follow the progressive rise of friction during the course of a test run. As the protecting film is reduced in thickness the friction rises, usually very slowly at first and quite rapidly toward the end. The initial value of the coefficient of friction for an average straight mineral oil 10^{-7} in. thick is of the order 0.130. After the value has risen to 0.200. the value rises to 0.250 during the course of a very few passages of the sapphire over the track. This value of the coefficient is

[7] Application of the Hertz formula for the case of a steel ball of radius R, in., in contact with a steel flat, under a load L, lb:

Poisson's ratio p for steel = 0.25; Young's modulus E for steel = 30,000,000 lb per sq in.; L = 100 g = 0.2205 lb; R = $^1/_{16}$ in. = 0.0625 in.; radius r of contact circle = $\sqrt[3]{[(3\pi/2)KLR]}$, where $K = (1 - p^2)/\pi E$; and the average intensity of pressure $P = L/\pi r^2$. Inserting values, we have r = 0.000867 in., and P = 93,360 lb per sq in.

FIG. 5 DIAMOND AND SAPPHIRE TRACKS ON MOLECULARLY CLEAN GLASS. ×100

arbitrarily taken as the breakdown value, and when not exceeded no damage is done to the steel surface which cannot be repaired by a light polishing process with optical rouge and water.

Fig. 6 shows the effect of varying film thickness on resistance to mechanical wear. The oil tested was a straight mineral oil of S.A.E. 10 grade, and the three film thicknesses tested were 2, 3, and 4 millionths of 1 mm. It will be noted that a film thickness of 4×10^{-6} mm affords a greatly increased measure of protection against breakdown, as compared with one only 25 per cent thinner. With regard to the molecular thickness of these thin films, it is to be realized that the dimensions and shapes of the component molecules of a material of such complexity as a mineral lubricant have no degree of uniformity. We shall not be far wrong, however, if we assume for working purposes an average diameter of the order of 10 Angstroms or 1 millionth of 1 mm. On this basis it is seen that a considerable degree of resistance to mechanical breakdown was provided in the reported experiment by a film approximately four molecules thick. It must be emphasized that the basic reason for the breakdown of these very thin films under mechanical attack lies in the fact that the mobility of the oil molecules in the area immediately outside the track is exceedingly low. With much thicker films, molecules flow in to replace those removed. Experimental evidence of this phenomenon is given by the dashed curve in Fig. 6. This was obtained in a run in another series, using an

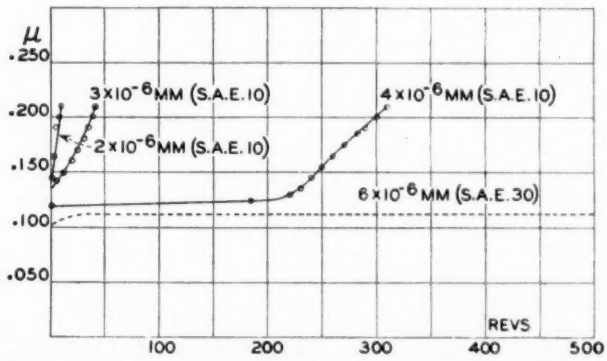

FIG. 6 EFFECT OF DIFFERENT FILM THICKNESS ON THE RESISTANCE TO MECHANICAL WEAR OF A STRAIGHT MINERAL OIL

S.A.E. 30 straight mineral oil, laid down as a film 0.25 millionth of 1 in. thick or slightly over 6 millionths of 1 mm. After a slight initial rise in the coefficient, the value was constant over the entire run, and as a matter of fact remained constant for over 2000 passages of the rubbing point over the surface of the steel disk. This result is believed due to the increased mobility of the oil molecules in the film, new molecules flowing onto the track as fast as removed by the rubbing action.

The curves in Fig. 7 show the effect of an addition agent on the

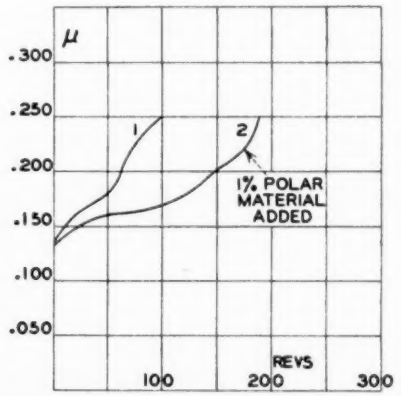

FIG. 7 EFFECT ON THIN-FILM WEARABILITY OF THE ADDITION OF 1 PER CENT OF ACTIVE POLAR MATERIAL

resistance to wear of a thin film, and suggest this means of increasing the protective action of an oil against the risk of failure when fluid-film conditions give place to boundary-film conditions.

Curve 1 shows the progressive rise of the coefficient of friction for a straight mineral oil of S.A.E. 30 grade in a film approximately two molecules thick. Curve 2 shows the effect of the addition of 1 per cent of a material of marked polar activity.

THIN-FILM-WEARABILITY MACHINE

Fig. 8 shows the machine for testing thin oil films set up for operation, and Fig. 9 shows its essential features. A balanced horizontal bar is so suspended as to have only the following two degrees of freedom: (1) It can rock freely in a vertical plane about a line defined by knife edges at right angles to the length of the bar. (2) It can move in the direction of its length, the amount of movement being limited by stops which serve also as electric contacts thus providing a means of indicating departure from a neutral or balanced position.

Near one end of the bar is a holder carrying a round-faced rubbing button which rests on the outer portion of the circular test disk, the latter being fixed on the top of a rotating table offset with respect to the center line of the bar. As the table rotates, the button traces out a true circle on the face of the test disk. The working load is a 100-g weight placed on the top of the button holder. At the other end of the balance bar is attached a silk thread which passes in a left and right direction over two frictionless pulleys to a double chainomatic device by means of which a pull P can be applied to the bar, equal in amount

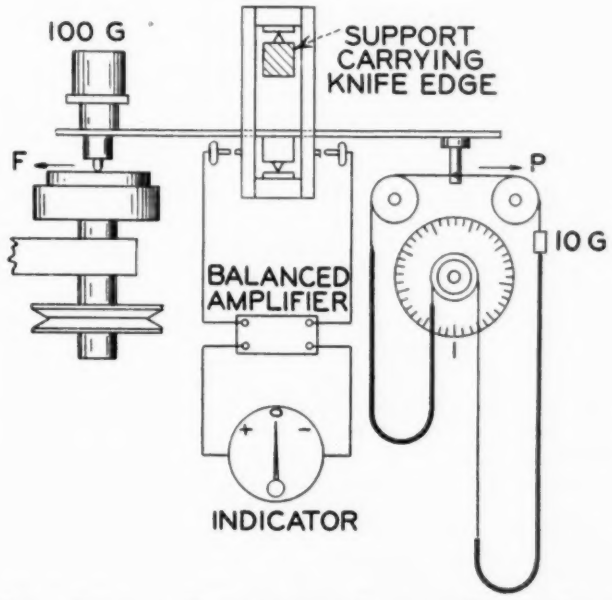

FIG. 9 DETAILS OF MACHINE FOR THE TESTING OF THIN OIL FILMS

and opposite in sense to the drag of friction F between the rubbing button and the face of the rotating test disk. If the frictional drag exceeds 10 g, a 10-g weight is hung on the outermost chain. A simple gear operated by turning the graduated dial allows the chain to be lowered on the right and raised on the left, which operation increases the pull on the silk thread in the direction opposed to the frictional drag. The machine is sensitive to an out-of-balance setting of 0.1 g, which means that with a load of 100 g the coefficient of friction can be determined to better than 1 per cent. The exact point of balance is determined by observing the needle of a microammeter which moves left or right of zero when left or right contacts are made at the limit stops already referred to. The free gap at each of these contacts, which are faced with polished tungsten, is slightly greater than 0.0005 in., and entire freedom from the effect of resistance changes at the contacts is secured by the use of a simple two-tube radiotron circuit, the balance of which is upset when either contact is made.

A scale around the circumference of the rotating table on which the test disk is mounted is divided into 10 equal parts numbered from zero to nine. This scale is useful when determining the value of the coefficient of static friction at various points around the track circle as will be described later.

DETERMINATION OF THE COEFFICIENT OF STATIC FRICTION

A very cursory search into the literature of the subject will show that the determination of the coefficient of static friction for a stated combination of metals and oil is a problem incapable of exact solution. This is hardly surprising in view of the fact that friction between solid surfaces in close contact depends on a number of factors, some of them not permitting control, and some producing effects of an obscure nature. The most difficult factors to control are those connected with the physical nature of the surfaces. No surface, for instance, can be brought mechanically to the state of perfect freedom from minute irregularities such as is exhibited by the surface of quiet mercury. The best that can be done is to reduce the scratches on a carefully flatted surface until they are no longer visible under fairly high magnification. The further we carry this process the lower will be the coefficient of friction, other conditions being the same. It may fairly be assumed that the friction between ideal surfaces would be very low, but since such surfaces can never be produced, the lowest value we can hope to obtain will be notably higher than the theoretical minimum. Another factor of outstanding importance is the change in surface structure produced by cold working. It has been definitely established in the course of the present work that a considerable reduction of the coefficient of friction is found when slip occurs on a well run-in track. Since it is noted that the friction is not only reduced, but is also made uniform around the track, it is suggested that the crystalline structure has been replaced by a Beilby layer. The fact that friction between glass surfaces separated by a boundary film is constant from point to point lends support to this view.

As an illustration of the effect of running-in, the coefficient of static friction under boundary-film conditions between a round-faced tungsten-carbide button and a flat polished steel surface was reduced from 0.132 to 0.114 after running-in dry under a diamond at extremely high pressure.

COEFFICIENT OF STATIC FRICTION—STARTING AND STOPPING VALUE

Consider the case of a rounded button of some very hard material such as tungsten carbide sliding on a surface of polished steel under a normal load of 100 g. Even with a thick film of oil on the steel the unit loading is so high that the surfaces are separated by a boundary film only. If now a gradually increasing force be applied to the button, pulling exactly in the plane of the flat surface, we shall eventually reach a value just sufficient to cause slip. The ratio of this force to the normal load is, of course, the value of the coefficient of static friction. Stated perhaps more precisely, it is the value of the coefficient at the instant of starting to slip. Whether the value of the coefficient at the instant of stopping is the same, is not immediately apparent, and to clear up this point a number of tests were made with the machine described.

Method of Making a Static-Friction Test

The most convenient method of determining the static coefficient is to measure the frictional drag at the exact instant when sliding ceases. Suppose the specimen disk is rotating at its normal speed, and that the balance pull is set for exact balance of the normal running friction. The indicator needle is, of course, at zero. Now stop the rotation and observe the behavior of the needle. As the rubbing speed decreases, there is usually a tendency for the deflection to go to the left of zero, meaning that the friction is higher for decreasing speeds than for the normal speed. At the exact instant of stopping, however, the behavior of the needle provides very exact information as to the relation of static friction to running friction, under the operating conditions. The needle may move to the left, or plus side, which means that static friction is definitely greater than running friction, or it may move to the right, or minus side, which means the reverse. In certain cases no departure of the needle from its zero position is observed from the time the motor is switched off to the instant of stopping. This, of course, indicates that the coefficient of static friction (stopping value) is equal to the coefficient of running friction at the normal rubbing speed of 1.5 fpm.

Method of Taking Observations. An estimate of the probable value of the static coefficient is made, and, while the machine is running, the balance pull is set to a value less than the corresponding frictional drag. The turntable is then stopped at station no. 0 of the divided circle, and the deflection of the needle noted. The starting switch is then closed momentarily so that the table stops at station no. 1, and the deflection again noted. After 10 observations have been made at the 10 stations around the rubbing track, the balance pull is increased by 0.2 g and the whole operation repeated. This is done for as many new settings of the balance pull as are necessary to show definitely that the pull has exceeded the value corresponding to the true static coefficient. Table 2 illustrates the method followed.

Inspection of the results of this run shows that the average value of the balance pull P around the track is 11.2 g, there being five positions where the value is slightly too great and five positions where it is not high enough to cause slip over a distance of 0.0005 in. Since the load is 100 g, the coefficient of static friction (stopping value) is 0.112.

Delayed-Slip Method. By modifying the described method somewhat, the coefficient of static friction at the start of slip can be obtained. The turntable is arrested as before at each of the marked stations around the circle, and the same procedure as before is followed in the setting of the balance pull P on the dial. The working load is the standard value of 100 g, but provision is made for adding an extra load of 20 g by lowering a weight suspended by a thread onto the 100-g weight. Just before the turntable stops at each of the ten stations, the 20-g weight is added, making a total load of 120 g, therefore increasing the frictional drag 20 per cent. The indicator needle, of course, goes to the left or friction side. After the turntable comes to complete rest, the extra weight is gently removed, thus restoring normal conditions. Whether the needle will still remain on the friction side depends on the value to which P has been adjusted. It requires a slip of only 0.0005 in. to affect the needle. After waiting five seconds, the indication, whether plus, zero, or minus, is noted and the operation repeated for the next station. Table 3 will make the method clear. Inspection of these results shows that the value of P necessary to balance the static friction (for start of slip) has a mean value of 11.0 g, so that, for a load of 100 g the coefficient is 0.110 which is a satisfactory check on the value obtained by the standard method.

Oiliness and the Coefficient of Static Friction

The much discussed property of lubrication loosely termed as "oiliness," is without question of considerable importance. However, it is a phenomenon which becomes strongly evident only when the oil film separating rubbing surfaces is exceedingly thin, probably of the order of molecular dimensions. The presence of an oiliness component in a film thick enough to obey the hydrodynamic laws obtaining in viscous-film lubrication has no effect whatever on the friction losses. Conversely, in films of molecular dimensions, viscosity is almost a negligible factor, while oiliness has a paramount effect. Oiliness has been described somewhere as a partnership property of both oil and the surface to which it is attached, and this significant statement may be definitely proved by measurement of the coefficient of static friction for various combinations of metals and oils.

As implied in an earlier statement, it is not possible to obtain an absolute value for the coefficient of friction for any specified combination of metals and oil, principally because of the uncontrollable factor of the physical state of the sliding surfaces. We can, however, with sufficient care, prepare surfaces for use in comparative tests, so nearly alike that relative values of the coefficient will give real information of the oiliness effect for specified oil-metal systems. The figures given in the tests to be

described, while reproducible to better than 1 per cent, represent only the values observed under the specific technique followed in the preparation of the surfaces.

The values given in Table 4 illustrate clearly the effect on the coefficient of static friction of both the surface activity of the metal and the molecular activity of the oil; in other words, they confirm the statement that oiliness is a partnership property of the oil-metal system.

Comparison of the Coefficients of Static and Running Friction

It is generally accepted that the coefficient of static friction for a pair of metals and a thin oil film is greater than the coefficient of running friction. The figures presented in Table 5 show, however, that this belief is subject to radical modification.

In the machine used for this investigation, the rubbing speed was quite slow, being of the order of 1.5 fpm. The values of the coefficient of running friction may, therefore, be expected to lie close to their possible maximum, thus making all the more striking the comparisons shown.

The seven oils tested were of widely different types and it is to be noted that in only one case is the static coefficient higher than the running coefficient. Another quite evident point shown by an inspection of the figures in Table 5 is the part which was played by the metal in emphasizing the difference between the coefficients.

Perhaps the most generally useful deduction is that the oiliness value of a lubricant can best be judged by determining the static, rather than by the running coefficient.

Oils *B* and *G* were known to contain active polar groups, and these two showed the greatest percentage differences between the coefficients of static and running friction.

Acknowledgments

The author wishes particularly to acknowledge valuable assistance given by E. N. Dacus, one of the author's associates, in working out some of the experimental details. Also, the author's thanks are due to L. C. Roess, of the laboratory with which the author is associated, for helpful criticism. The apparatus was built in the laboratory workshop by Allan Jamieson.

Discussion

A. S. Brace.[8] The use of extrapolated weights or color-interference patterns leaves something of a question as to the actual film thickness used.

Time permitting, it would seem desirable to make check tests on identical samples with decreasing time of exposure to oil fog, to the point where the coefficient of friction of the bare button is approached. It is appreciated that this has been done for one oil as illustrated in Fig. 6.

With the wide difference in index of refraction existing between different oils, particularly in the heavier grades, it would seem that a direct comparison of oiliness would be reliable only if a series of runs on each oil were made similar to the three runs shown in Fig. 6.

Another question which arises is that of residual adsorbed film for succeeding tests using the same steel surface. The question here is whether or not the light polishing process removes the adsorbed film or Beilby layer, if present. Shop experience indicates that the adsorbed film or Beilby layer can only be removed by removal of an appreciable part of the surface.

The conclusion with respect to static and running friction suggests that the author is working in a range of surface smoothness which has not hitherto been achieved. It is suggested that measurements of surface smoothness (profilograms) be made before and after test runs.

W. E. Campbell.[9] The author's remarks on cleanliness of surfaces are very important. He may be interested to know that we have found by the electron-diffraction method that surfaces polished with magnesium oxide contain traces of magnesium oxide. However, polish by levigated alumina, followed by scrubbing with cotton under tap water, gives a surface which is free of detectable traces of abrasive.

The results obtained with a diamond bearing are interesting. It has been shown[10] that carbon is a very strong adsorbent for organic molecules. It would appear possible that the results obtained are due to a very strongly held adsorbed layer of a long-chain organic compound which cannot be removed from the diamond surface by the cleaning method employed.

David Clayton.[11] The author obviously has gone far in the direction of obtaining even distribution of the oil, but is it quite certain that the thinnest films are uniform? With reduction of exposure time discontinuity will ultimately be reached. With the films used (2 and 3×10^{-6} mm) each drop of oil has to spread over a relatively large area, and in the process the oil approaches the limit of mobility. Extrapolation of the curves in Fig. 6 shows values of starting friction decreasing with increasing thickness of film. This might be an indication that the surfaces are not completely covered in the case of the smallest quantities of oil. The value of the factual findings is not less even if they apply to minute quantities of oil instead of to very thin films. However, the point is raised because of the direction given to ideas by a paper of this character.

It is interesting to note that the right-hand track in Fig. 5 is similar to that obtained by Tomlinson[12] with a glass bead on a glass plate, and with a hard-steel ball on a hard-steel plate. The remarkable behavior with a diamond recalls to mind the extremely small wear, resulting in low friction, obtained by Stott[13] with unlubricated diamond cups on steel pivots in an investigation of pivots and jewels for instruments and meters. In this instance there was great contrast to the behavior with sapphire cups. Consideration of Fig. 5 raises the question as to the appearance after running-in the tests to the different stages shown by Fig. 6. Was any correlation with the friction behavior apparent?

It is interesting to note from Fig. 7 that so small a proportion of molecules of the polar material in the thin film affected the friction and delayed the breakdown. In the usual use of polar additions to oil, it is considered that preferential adsorption occurs, so in the boundary layer the proportion of polar molecules is high even when the general proportion is very low. No effect of this kind can occur in the circumstances described. Thus the result, while interesting, does not represent the practical case. This would be represented more satisfactorily by similar films of

wholly polar material, if it lends itself to treatment by the method adopted, or at any rate a high concentration.

It would be interesting to know how closely the results in Fig. 6 were repeated in duplicate experiments; also whether or not the coefficients of friction, given in Tables 4 and 5, were obtained with an excess of lubricant or with thin films. It would seem that more information is required to support the statement that at 1.5 fpm, "the values of the coefficient of running friction may be expected to lie close to their possible maximum." Moreover, this statement does not agree with a previous one that as the rubbing speed decreases, there is usually a tendency for the friction to become higher for decreasing speeds than for the normal speed. The general idea that the running friction is less than the static friction probably arises from the fact that in most practical cases there is set up at any rate a partial fluid film when motion occurs. There is little experimental evidence of the comparison for purely boundary conditions. The author's results are therefore valuable additions to knowledge on the subject.

In drawing conclusions, however, it is perhaps necessary to consider that the running friction might be artificially high due to work being done in deformation of the material under the high-pressure conditions of the experiments. High pressure is one way of approaching boundary conditions, but it involves this danger. Further, in connection with the friction results, it is not obvious from the evidence presented that "the oiliness value of a lubricant can best be judged by determining the static rather than the running coefficient." Usually this is true because of the absence of any viscosity effect under static conditions, but if the kinetic boundary friction is different from the static value, it is surely the kinetic oiliness which is of main value for practical application. The present results suggest different degrees of oiliness for static and kinetic conditions.

It is difficult to speculate helpfully on the influence of surface roughness on friction or breakdown. The "wringing" or cohesion of block gages and optical flats, certainly does not support the view expressed by the author: "It may fairly be assumed that the friction between ideal surfaces would be very low;" though not perhaps ideal in the sense visualized, the approach to it is accompanied by enormous increase in the friction.

It is hoped that the author may be tempted to enlarge on the effect of the running-in process. The writer would certainly not have preformulated this condition, if highly polished surfaces were being used. Moreover this particular running-in process is certainly not one that can be used in practice. It would be interesting to see how Fig. 6 appeared without any running-in process. Even though the results might be less consistent, it is necessary to know how ordinary surfaces behave. It is also hoped that the author will be able to work through the range of each of the several important variables to supplement the excellent work already carried out.

G. B. Karelitz.[14] The technique of laying down a thin film of oil on a metal plate will be welcomed by experimenters. It seems that this technique is straightforward and may be easily reproduced by other laboratories. In all tests on boundary friction the researchers were handicapped by viscous action of the pool of oil at the rubbing surfaces. This is the main difficulty in using friction-testing machines of the Deeley type. With a thin film of a predetermined thickness, the difficulty seems to disappear and true coefficients of friction can be measured.

Tests conducted by various investigators have shown that films remain liquid and can be treated as liquid down to a thickness of several millionths of an inch. In actual bearings of good finish the film thickness down to 0.00003 in. was observed. There always has been doubt at what thickness the film begins to obey the hydrodynamic laws of lubrication. In this respect the tests of Claypoole are most significant. It appears that the orientation of molecules, which would prevent their mobility and flow, does not extend beyond five, or say ten molecules, or one half millionth of an inch. It is, therefore, quite legitimate to treat films occurring in actual bearings, no matter how fine, by the usual hydrodynamic theory.

With respect to the value of the static coefficient of friction, Coulomb himself knew, and several investigators have observed that, with due precaution, the coefficient of friction does not drop suddenly when motion takes place. When the speed is very slow, as was the case in the author's experiments, there should be either no increase or very little increase in the coefficient when changing from kinetic to static friction. It is the writer's belief that for this speed the kinetic and static coefficients of friction are equal. It will be of interest to mention tests with huge ball bearings loaded to several hundred thousand pounds, which were made recently for the 200-in. telescope. In these tests the bearings were started and stopped running at a speed of one revolution in 15 min. The starting friction did not differ from the running friction more than 0.75 per cent, in spite of the general rule that the starting friction in ball bearings is twice the running friction. The authors' suggestion that a more exact definition of static friction is in order should be welcomed.

R. J. S. Pigott.[15] Some of us engaged in problems connected with lubrication and bearing design have been conscious, for some time, that there should be a better and much closer cooperation between physicists, engineers, and chemists on this extremely elusive subject. The author's interesting paper is an approach mainly from the point of view of the physicist. Early in the paper the author states: "The ideal case, as indicated previously, would be two perfect surfaces separated by a double molecular layer of lubricant." It should be made perfectly clear that this statement can only apply to academic study on extremely thin films, as of course such a situation is not in the least ideal from an engineering point of view. The ideal bearing, from the engineer's point of view, is one in which the friction torque is the lowest to carry a given load at a given speed. This will certainly not correspond to very thin film conditions. In engineering the principal concern is with moderately thin films, either for flat or cylindrical bearing surfaces, with dimensions which must necessarily remain much larger than two molecules thickness, for any practical operation.

Toward the close, the statement is made: "The presence of an oiliness component in a film thick enough to obey the hydrodynamic laws obtaining in viscous-film lubrication has no effect whatever on the friction losses." The writer is in entire agreement with this statement and cannot urge upon those interested in the subject, too strong a consideration of it. This is particularly true at the present time, since many groups engaged in the manufacture of automobiles, aeronautical engines, and similar devices, have been riding the hobby of oiliness agents added to oils, where this ghostly quality can be of no value whatever except possibly at the start and stop of operation. In most of these cases, the starting and stopping loads are far below the maximum and the oiliness requirements are therefore almost absent. When it is realized that one company is insisting upon rating lubricating oils for use in its internal-combustion engines on the basis of a single bearing test, which is carried to boundary lubrication conditions and therefore benefits by oiliness, one can readily realize how far afield "hunch plays" of this sort can

[14] Professor of Mechanical Engineering, Columbia University, New York, N. Y. Mem. A.S.M.E.

[15] Staff Engineer, Gulf Research & Development Company, Pittsburgh, Pa. Mem. A.S.M.E.

carry investigators. In this particular case, some of the oils which, by operating performance show the best results in the actual engine, would be rejected by this test. Conversely some of the oils rating very highly in this test are worthless, or nearly so, in the engine, due to sludging, lacquering, and other objectionable characteristics.

The idea expressed, immediately following the statement quoted, is heartily supported, that oiliness is a combination property of the oil and the surfaces.

With regard to the ability to prepare surfaces that are physically alike, the advent of the profilograph and other similar instruments will undoubtedly give much better means of standardizing surface conditions, since an examination can now be made on the order of millionths of an inch. The writer has found in all his lubrication testing experience, that the mechanical factors in a testing machine, such as those of operating temperature, trueness of surfaces, clearances, and surface roughness, are very many times more important than any characteristics of the oil or other lubricant. In short, he has found it is necessary to use the utmost rigor in standardizing any piece of test equipment for lubricant ratings in order to obtain results which are continuously reproducible.

This paper is valuable in its approach to the little understood problem of imperfect film or boundary lubrication. This condition obtains mainly in heavily loaded low-speed bearings or in other bearings just before scuffing or failure begins.

Author's Closure

Mr. Brace raises the question of the effect of differences in the refractive indexes of the oils used. As a matter of fact in the work reported, the measured values over a very wide viscosity range did not differ by more than 1 per cent.

An adsorbed film of oil on the surface of polished metal can be completely and readily removed by rubbing with a mild abrasive and water. It is entirely probable that the removal of the adsorbed film is accompanied by the removal of surface atoms of the metal.

The Beilby layer, the formation of which is promoted by polishing, naturally cannot be removed by a fine abrasive such as rouge.

Mr. Clayton suggests that the thinnest films deposited may not be quite uniform. The author agrees that this may be so, but would like to point out that the spreading of droplets hitting the surface is greatly influenced both by the perfection of finish and the state of cleanliness. A pure mercury surface is intrinsically free from surface imperfections and can be kept free from accidental contamination. With vertical illumination, it is possible under a microscope to follow the progress of deposition of an oil film from fog. Droplets can be seen striking the surface and flashing out into a film which quickly becomes invisible. The color presently attained is even and pure. Almost as perfect spreading is observed on a highly polished clean chromium surface. It is not possible, however, to prepare a steel surface having the degree of physical uniformity possessed by a polished surface of chromium plate. For this reason, it may be true that oil films deposited on a steel plate are not as uniform in thickness as those on a chromium plate.

The running-in technique is useful in that it reduces the variations in the coefficient of friction observed with a material having the physical structure of steel. The coefficient obtained on glass is remarkably constant from point to point of the surface.

Many tests similar to those shown in Fig. 6 were made. Some checked surprisingly well. Others were very erratic. The chief causes for poor checking were found to be the presence of accidental dust on the test plate, and wear on the sapphire button.

By "ideal surfaces," the author had in mind the case of two geometrically flat surfaces separated by a double molecular layer of oil. It is to be presumed that such surfaces should slide relatively freely over each other, since in the absence of any surface projections there is no possibility of metallic contact. The friction is measured by the resistance to shear at the slip plane of the film. The component due to the interaction of molecular forces, existing at the actual metal surfaces, is believed to be negligibly small. The case of the wringing together of gage blocks is not analogous, since the separating oil film is ruptured in innumerable minute areas by projecting asperities on an imperfect surface.

Mr. Pigott points out that the academic ideal case of perfect surfaces separated by a double molecular layer of lubricant is by no means ideal from the engineer's point of view. This is, of course, perfectly true. The engineer uses the word "ideal" as synonymous with "perfection," whereas in the paper it was used in the sense of "hypothetical or imaginary."

Wear in Lubrication Problems

By L. M. TICHVINSKY,[1] EAST PITTSBURGH, PA.

Boundary or semifluid friction takes place in bearings of practically all rotating machines when they are started or brought to a standstill. This type of friction, lasting a short period of time, is usually accompanied by the wearing of the bearing surface, the journal surface, or both. Wear takes place also in the case of antifriction bearings due to sliding, rolling, or combined sliding and rolling friction. Many other causes, such as misalignment, dirt, or inadequate lubrication, might be responsible for wearing of any type of bearing. This paper deals with the methods which are employed to obtain the wear resistance of various metals, especially those used in the design of bearings.

MECHANICAL wear, especially of metals, is as important and interesting to physicists as to engineers. The great number of variables which must be considered during this kind of dynamical testing range from very specific and unique properties of materials to the most common and usual. For this reason it is practically impossible to make a wear test during which all variables would be accounted for.

Most of the existing wear-testing machines are built so as to take care of only a few of the numerous variables. The result is that data obtained on a particular wear-testing apparatus are fundamentally related to the type of the machine used, and of course, to the conditions and methods of test.

Mechanical wear is subdivided into two major groups: (*a*) The one in which the wear is caused by abrasion of metal on metal, and (*b*) the one in which the wear is caused by abrasives on metal. A typical example of the first group is the wear of a bearing against a shaft when not perfectly lubricated. The wear of steam shovel teeth or of a grain conveyor belongs to the second group. Very often these two kinds of mechanical wear take place simultaneously. Thus, the rails and wheels of a railway car show wear due to both rolling friction and contamination such as dust and sand. Especially during wet weather the amount of contamination will be very small and most of the wear will be produced by rolling friction, but during dry weather wear due to contamination may be predominant.

These few examples show at once that mechanical wear is one of the most perplexing problems confronting the engineer, and it can be stated that any relative motion between parts in contact is usually accompanied in machines by mechanical wear.

The railroad industry was the first to be confronted with problems of wear. Adams (1),[2] Schwarz (2), Sandberg (3), and others, as long as 70 years ago, observed the wear of rails and reported upon it in current technical literature.

In 1878, Dudley (4, 5, 6) tried to correlate the known physical properties of rail materials with their resistance to wear when the total load which passed over these rail sections was measured. The wear was figured from the decrease of the rail cross section. For this purpose very accurate sketches of worn sections were made, measured by a planimeter, and compared with original cross sections. As a result of such field experiments, Dudley recommended the use of high-strength material with fine grain structure.

Further progress in the study of wear of rails was made when complete records of operating conditions were systematically gathered by railroad companies.

Laboratory wear testing was first mentioned in the literature by Bottone (7) and Bischoff (8). However, methodical experimentation was started only at the beginning of this century.

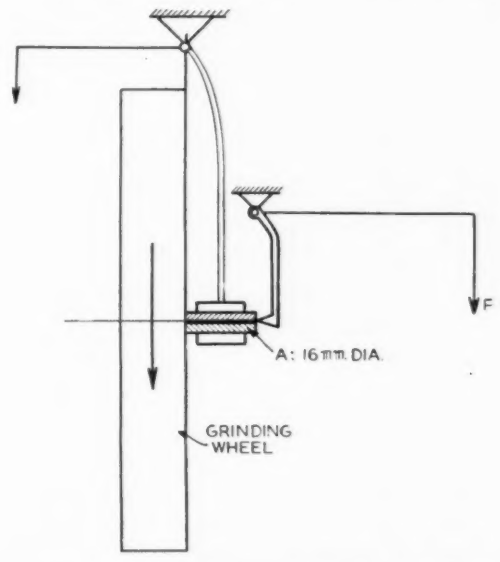

FIG. 1 SELLERGREN'S WEAR-TESTING APPARATUS (1905)—SLIDING FRICTION

In 1905 the Swedish engineer Sellergren (9) reported wear-test data obtained on his wear-testing apparatus. This apparatus is shown in Fig. 1. The test piece *A*[3] was inserted into a bushing fixed to an end of a lever, the fulcrum of which is in line with the plane of the grinding disk. The loading was obtained by another lever system and weight *P*. On account of vibration at very low loads, tests were conducted at pressures above 1 atm. Sellergren performed a great number of wear tests during which he investigated the influence of pressure, velocity, and area. He found that the loss of weight was proportional to the square of the rubbing speed.

The duration of each test was within 1 to 2 min. But during even such a short period of time the surface conditions of the wheel changed so much that no consistent results could be obtained. To some extent this defect was cured by frequent dressing of the wheel surface.

In 1909, Breuil and Robin (10) and Robin (11) obtained wear

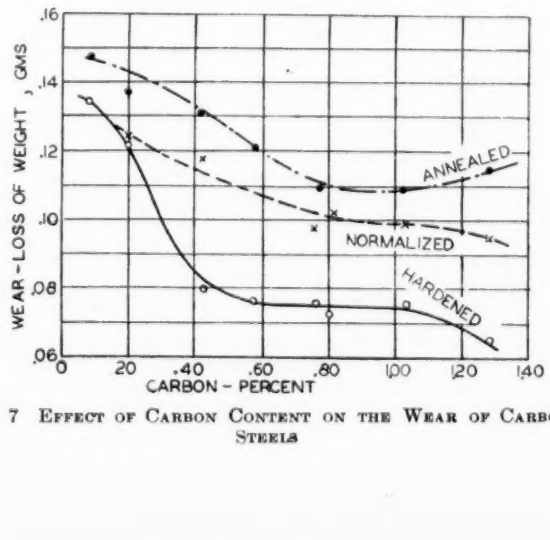

FIG. 7 EFFECT OF CARBON CONTENT ON THE WEAR OF CARBON STEELS

data on the machine shown in Fig. 2. The test piece was pressed against sandpaper placed on a rotating disk. The test piece was prevented from sliding out from the sandpaper by means of a spring. During 3-min tests, on the same piece of sandpaper, the 15-mm diameter sample showed signs of wear under a pressure of 1 kg per sq cm and a travel of 200 m. At 1-min intervals the test was stopped and the sample weighed. The amount of wear was measured as a wear number $(W_1 + W_2 + W_3)/A$ in gr per sq cm, where W_1, W_2, and W_3 are losses in weight after 1-, 2-, and 3-min periods, and A is the contact area of the specimen. Robin made numerous tests for investigating such effects on wear as the size and shape of the end of the specimen, the velocity of sliding, and the mesh of the sandpaper. The most consistent results were obtained when diamond paper was used. He came to the conclusion that test results could be compared only when test methods and conditions were similar. Among other things, Robin was seeking the relation between hardness and wear resistance. He found that a 0.4 per cent carbon steel showed more wear than others. He investigated also the wear as affected by the grain size of steel. His experimental results on rail and wheel materials were in good agreement with the performance of these steels in practice.

Based on essentially the same principle is the design of the wear-testing machine built in 1924 by Honda and Yamada (12), shown in Fig. 3; the horizontal disk covered with sandpaper, the test sample, and the weight W can be seen. The test piece is fixed in a small holder which slides in a slot in the supporting table. The holder is connected by means of a string to a calibrated spring which measures the friction force during the rotation of the sandpaper disk. Thus, on this machine, the effect of friction can be readily observed. A series of tests was made with pure metals and cast irons during which many variables were measured and subjected to changes. Wear of copper, tin, and lead thus obtained is shown in Fig. 4. During these tests the value of the coefficient

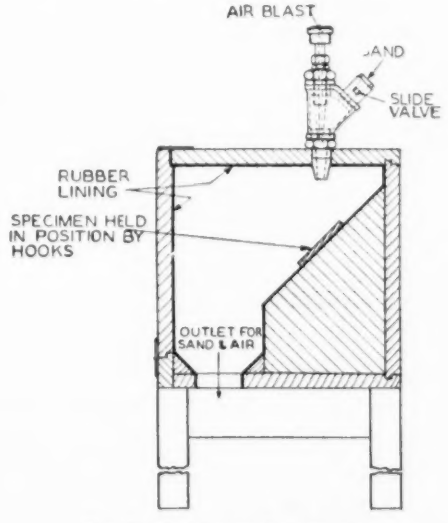

FIG. 8 SANDBLAST APPARATUS

of friction varied slightly. The position of the test piece was changed at each measurement so as to maintain a constant value of the coefficient of friction.

The machine shown in Fig. 5, on which the effect of a lubricant on wear could be obtained, was built by Derihon in 1912. In this machine, the test piece is pressed toward the outside diameter of a disk partly submerged in a lubricant. These tests, as described by Portevain and Nussbaumer (13), were made in order to obtain wear data of bronzes used in bearings. The loss of weight of the specimen was measured after 2000 km of disk travel.

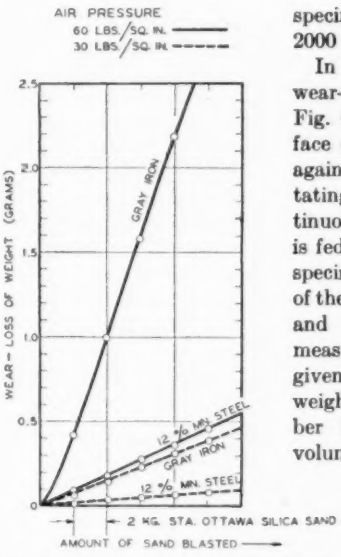

FIG. 9 EFFECT OF SANDBLAST PRESSURE ON THE RESISTANCE TO ABRASION OF IRON AND STEEL

In 1920, Brinell (14) built the wear-testing machine shown in Fig. 6, in which the plane surface of the test piece is pressed against the edge of a slowly rotating soft-steel disk, while a continuous stream of graded sand is fed between the disk and the specimen. After prescribed travel of the disk, the sample is weighed and the depth of impression measured. The wear value is given either in grams as loss of weight or in wear-resistance number $1000/V$, where V is the volume in cubic millimeters of the worn-out segment for 1 mm thickness of the disk. Brinell made a thorough investigation on the wear properties of steel of different chemi-

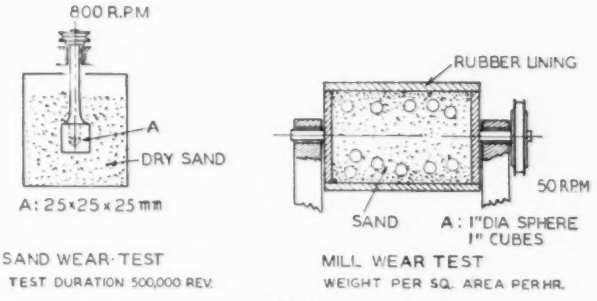

FIG. 10

cal compositions. In Fig. 7 are plotted data obtained by Rosenberg (15) on this machine when the effect of carbon content on the wear of carbon steels was studied.

The wear resistance of metals to abrasion by sand can also be obtained on some rather simple testing machines which might in some cases represent good approximation of actual working conditions. For example, the sandblast apparatus shown in Fig. 8 was used in experiments by Rosenberg (15) during which abrasion by sand of various grades of steel was studied. In Fig. 9 the wear is plotted against the amount of sand blasted at air pressures of 30 and 60 lb per sq in. During these tests gray iron was compared with 12 per cent Mn steel.

To the same class of wear-testing apparatus belong the two machines shown in Fig. 10. The sketch on the left shows a simple apparatus by means of which the wear of a specimen rapidly rotating in dry sand is measured after 500,000 revolutions. The right-hand sketch shows a slowly rotating mill filled with sand and ball- or cube-shaped specimens (15). The wear in these cases is expressed as the loss of weight in grams per square centimeter of surface per unit of time.

Another simple apparatus for similar application was described by Roesch (16), in which a small cylindrical specimen is fixed vertically at the bottom of a sand-filled container and a loaded hardened strip of steel moves back and forth over the specimen. Abrasion by this method was obtained for various grades of wear-resisting metals at pressures as high as 3000 lb per sq in.

In the same article Roesch reports on an experimental pump built with interchangeable vanes. The effect of the amount and

grade of sand added to the water was conveniently studied upon various vane materials. This is an example of a laboratory test which gives rather reliable data on the wearing qualities of various vane materials because these test conditions are very similar to those existing in field service. This small pump with a 150-mm wheel rotating at 3000 rpm was able to deliver water at a head of 35 ft.

There are several types of wear-testing apparatus on which the wear of a flat specimen is produced by the edge of a rotating disk.

Jannin (17) described interesting tests performed with the machine shown in Fig. 11, in which the test specimen was pressed toward the small rotating disk. The indentation produced by the latter on the specimen served as a measure of the wear. In experimenting with journal and bearing material, Jannin explained that (*a*) the cause of wear in bearing metals is due to insufficient shaft polish, and (*b*) the cause of wear of shafts depends greatly on the cleanliness of the lubricant used. Typical results obtained by Jannin are shown in Fig. 12. Phosphor,

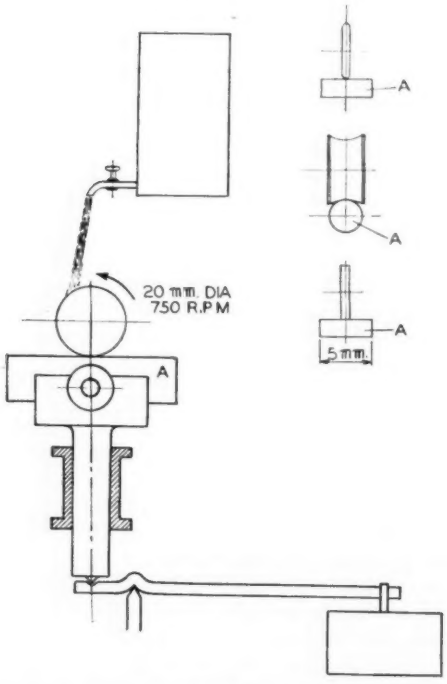

FIG. 11 JANNIN'S WEAR-TESTING APPARATUS (1922)

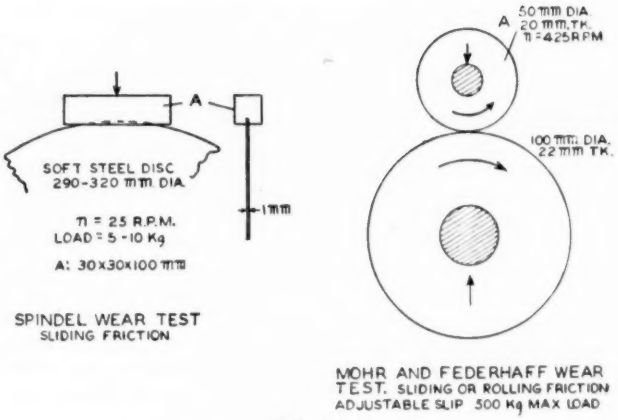

FIG. 13

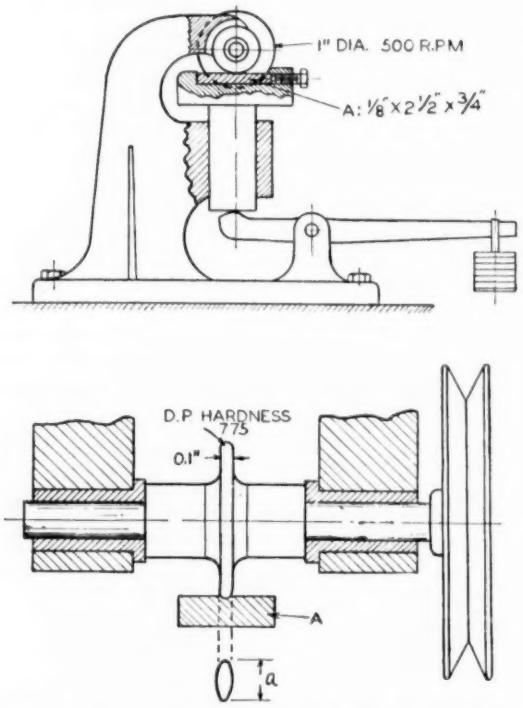

FIG. 14 BROWNSDON'S WEAR-TESTING APPARATUS—SLIDING FRICTION

leaded, and ordinary bronzes were tested and the wear measured; standard mineral oil was used during these tests. Guillet (18), using the same machine, investigated the effect on wear of such variables as speed, polish, and thermal treatment of the disk.

In 1924, Spindel built the machine shown in Fig. 13 for testing wear and grade of lubricants (19), primarily in connection with wear problems of rails and wheels. A great number of experiments made on this machine by Spindel (20), Schulz and Lange (21) for the Austrian Railroads proved to be of great value. A similar testing machine was designed by Sawin (22) for machine-tool applications; very hard materials were tested successfully on this machine.

Over a year ago, Brownsdon also reported on metallic wear (23). His machine, shown in Fig. 14 and consisting of a rotating disk pressed upon the test specimen, belongs to the same type of wear-testing machine used by Spindel. Fig. 15 shows results published by Brownsdon. The effect of various additions

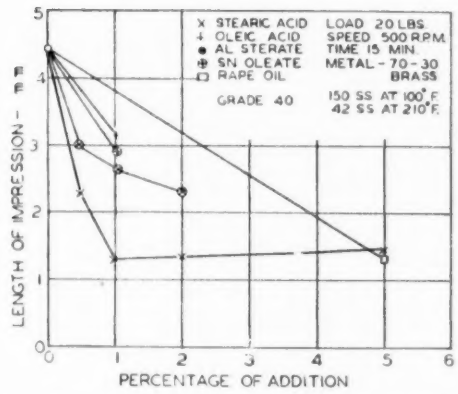

FIG. 15 EFFECT OF ADDITIONS TO MINERAL OIL ON WEAR

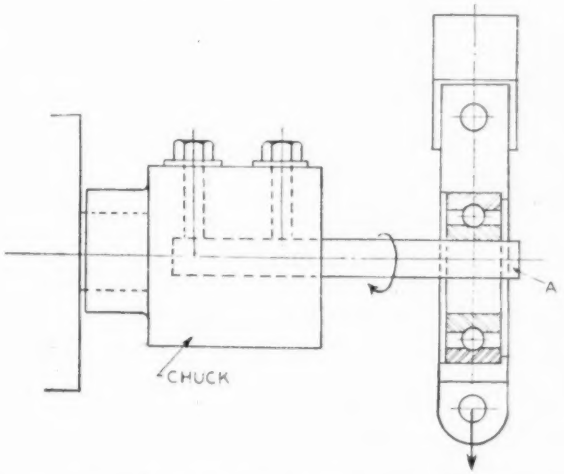

FIG. 16 SANITER'S WEAR-TESTING APPARATUS (1908)—ROLLING FRICTION

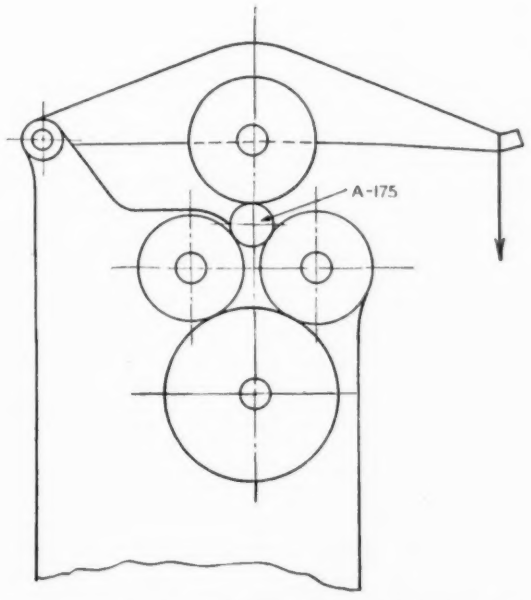

FIG. 17 STANTON'S WEAR-TESTING APPARATUS (1908)—ROLLING FRICTION

to mineral oils changes the properties of the lubricating mixture. Thus, it can be seen from the curves that the addition of all substances used resulted in a decrease in various proportions of the wear value, which is measured by the length a, shown is Fig. 14, of the impression made by the disk on the sample.

Several testing machines were built in order to produce wear due to rolling friction. Approximately at the same time, Saniter (24) and Stanton (25) made wear experiments in which a circular test specimen was subjected to pure rolling friction. Saniter's machine shown in Fig. 16, consisted of a journal specimen fixed in a revolving chuck. The hard inner ring of a large ball bearing served as the member which produced wear on the shaft. The rate of wear was obtained as the decrease in shaft diameter in ten thousandths of an inch after 200,000 revolutions and an application of a load of 205 lb. In Stanton's machine, shown in Fig. 17, the test specimen is pressed radially by three disks located 120 deg apart. The two lower disks are driven through a pair of gears which can be so selected as to produce a certain slip, in which case rolling and sliding frictions can be obtained.

The Amsler wear-testing machine is well known for its wide application when rolling, sliding, or combined rolling and sliding friction must be used during tests. Fig. 18 shows the principle of the Amsler testing machine. The machine by Mohr and Federhaff, shown in Fig. 13, is similar to the Amsler wear-testing machine, the only difference being in the manner of loading. Loading on the latter is obtained by means of a powerful helical spring, while a hydraulic arrangement is used on the Mohr and Federhaff machine.

The application of these machines is rather wide. Tests on it made by Fink (26) and later by Rosenberg and Jordan (27) were run in room atmosphere and in an inert gas. The latter tests indicate that a film of ferric oxide on the surfaces of carbon-steel rollers serves as a medium for preventing metal-to-metal contact. In the absence of these films (tested in nitrogen and hydrogen)

(Brinell hardness = 700.)

severe wear takes place. The effect of removing dust from the lower disk of the Amsler machine is shown in Fig. 19. This test was performed at various rates of slip (28).

The wear-testing apparatus shown in Fig. 20, using ring-shaped specimens, was built by Mayer (29) in 1925. Since the specimen is entirely submerged in lubricant it is possible to control and study the effect of temperature closely. On this machine the torque and coefficient of friction are also measured during tests. Fig. 21 shows results obtained by Kehl and Siebel (30) when pearlitic cast-iron specimens were used during tests.

Zaitzeff (31) and Suzuki (32) also designed wear-testing machines, employing ring-shaped specimens, on which they have obtained good results.

The wear-testing machine, shown in Fig. 22, was built at the Westinghouse Research Laboratories for determining rather high rates of wear. A small cylindrical rotating test specimen *A* is pressed against the 2-in-wide circumference of a large hard-steel disk *D*. The steel disk revolves and also oscillates along its axis, due to which action almost the entire disk surface comes in contact with the rotating specimen. In connection with the selection of a suitable heat-treatment for a crankshaft material, a study of wear resistance of three case-hardened steels was made on this machine; data on the hardness and treatment of these steels are shown in Fig. 23. After each 5-min period of test, the

samples were weighed and their length measured. As shown in Fig. 24, results obtained revealed that the material which received nitrided heat-treatment has a much greater wear resistance than the same material heat-treated otherwise. The curves also show the wear at depths between 0.002 and 0.006 in.

Karelitz and Kenyon (33) reported on tests made with the apparatus shown in Fig. 25, in which flat-faced pieces of several bearing metals were mounted to ride on a small journal lubricated by means of an oil bath. The initial lines of contact gradually developed into grooves until viscous oil films formed between the rubbing surfaces and arrested further wear.

Conclusion

Although this short review of wear-testing methods and apparatus is far from being complete,[4] it shows the variety of methods of testing the wear properties of engineering materials.

All the machines mentioned were developed in view of new service conditions of various machine parts. The most frequently used fundamental methods of laboratory wear testing are shown diagrammatically in Fig. 26.

In making a choice of each type of wear testing, a careful study must be made of the performance of the testing apparatus in order to control at least a few variables or conditions which are also common in actual field application of the material. Thus,

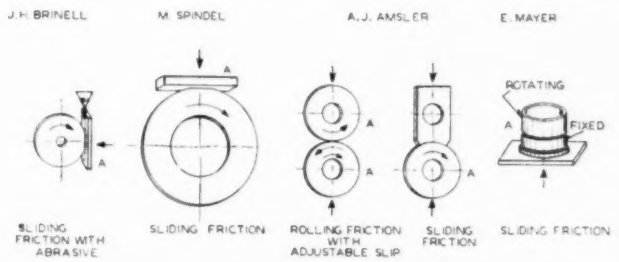

Fig. 26 Important Types of Wear Testing

for example, the sandblast method and Brinell machine will be properly selected for wear tests of materials for water-turbine blades since their wear from sand is sometimes very alarming. On the other hand, this type of test alone will be insufficient because the wearing of these blades is also due to cavitation.

The selection of methods of wear test depends in the first place on the object of the investigation. When the test results are to be applied for practical purposes, the methods must be selected so as to duplicate, as much as possible, the field conditions. When the object of the investigation is to study the behavior of the material under various types of friction, such methods must be chosen which will enable easy alteration and permutation of some of variables and study of influence of segregated factors.

It is the aim, therefore, of the individual experimenters to select such a machine or number of machines and produce such testing conditions as will cause the short-lived performance of the tested material to be representative of its performance in practice.

[4] A good Bibliography on wear, covering the period from 1864 up to 1928, inclusive, can be found in the article by Füchsel (34).

Appendix

In addition to this condensed review of wear-testing machines and methods of evaluating materials from the point of view of wear resistance, it will be interesting to mention another method peculiarly well adapted for the study of surface phenomena, namely, the electron-diffraction method (35, 36).

Unlike X rays, electrons owing to their charge are so easily deflected by the atoms in any aggregate of matter on which they are impinged that their penetration is limited to the surface layers. In practice, a beam of electrons moving at a velocity of the order of half that of light is caused to glance off the surface under examination, and the direction of the diffracted rays leaving the surface are recorded photographically as a so-called electron-diffraction pattern. Since these diffractions are determined by the manner in which the atoms are arranged in the surface layers, it is possible to derive the structure of the surface from the diffraction pattern. The pattern in its details usually reflects the degree of the order of atomic arrangement in the surface.

For example, a smooth single-crystal surface, in which all the atoms are regularly arranged at the points of a space lattice, gives rise to a pattern of spots and regularly arranged parallel pairs of black and white lines, from which the atomic arrangement can be deduced. Thus, Fig. 27 represents an electron-diffraction pattern from a natural face of a diamond. A rough single-crystal surface, on the other hand, may yield only a regular pattern of spots, as shown in Fig. 28, the sharpness of which will depend on the shape of the projections rising from the surface. The spot arrangement is characteristic of zinc blend.

As was first shown by Beilby (34), the surface finish put on a metal by polishing is quite different in its structure from that afforded by abrasive methods. In this case, the surface is smoothed to a state of high finish by smearing over the surface a molten or viscous material formed at the "high spots" as a result of intense heating due to high localized stresses. This fluid material congeals in stress-free regions so rapidly that the atoms

have no time to rearrange themselves into crystal units, but remain in disordered array just as they would be in an instantaneously frozen liquid. This noncrystalline amorphous layer, known as the Beilby layer (1921), gives rise to such a diffuse halo pattern as shown in Fig. 29, which is characteristic of a liquid surface.

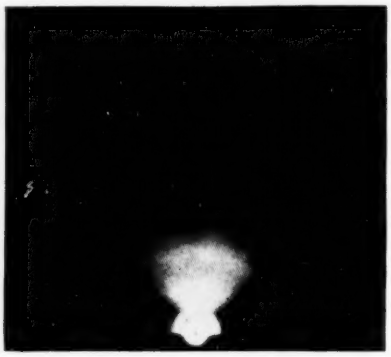

FIG. 29 ELECTRON-DIFFUSION HALO PATTERN FROM A NONCRYSTALLINE AMORPHOUS LAYER, CHARACTERISTIC OF A LIQUID SURFACE

Undoubtedly, such use of the electron-diffraction method will be as much welcomed in industry as it is in physical laboratories.

Discussion

W. E. CAMPBELL.[5] A very useful supplement to the present paper would be one which concerns itself mainly with a critical appraisal of the more important experimental work described. Although it is true that the electron diffraction method has shown itself to be exceedingly useful in studies of surface layers, it should be made clear that the interpretation given by the author of reflection patterns, such as that in Fig. 29, is by no means generally held by experts in the field. Kirchner[6] and Germer[7] have both described experiments indicating that diffuse reflection patterns do not prove that the surfaces are amorphous. Even the leading proponent of the author's interpretation, G. I. Finch,[8] has recently modified his views to admit that diffuse rings produced by electrons scattered from polished metal surfaces are not conclusive proof that the polish layer is amorphous.

B. F. HUNTER.[9] In this paper the author evidently has made a thorough investigation of the wear of metals not lubricated, rather than wear of metals lubricated.

It is the writer's conclusion, from experience, that wear on surfaces of lubricated metals has little relation to the wear on metals with dry surfaces.

In the operation of mechanical equipment, where the surfaces of the metals are lubricated, wear, frequently attributed to lubrication, can be traced definitely to: (1) Improper design; that is, pressures, etc., per square inch beyond the load-carrying capacities of the lubricant; or (2) wear due to an improper lubricant; or (3) improper application of a lubricant.

G. B. KARELITZ.[10] The importance of the wear problem is self-evident. The reporter of *London Engineering*, covering the symposium on wear, held in Atlantic City last spring commented on the bewildering array of testing apparatus presented there, and on the apparent wide divergence of reported results. He concurred and praised the reluctance of the researchers to generalize their findings. The practical recommendation of the author that the individual experimenter should select a machine or number of machines, which would produce such testing conditions as will cause the short-lived performance of the tested material to be representative of its performance in practice, is noteworthy. The difficulty arises of knowing what is its performance in practice.

The 1937 International Conference on Lubrication held in London was remarkable in one respect. For the first time, lubrication was discussed at a joint meeting of engineers, physicists, and chemists. Any further advance in the question of wear must come now from the physicist. It is not sufficient to know how much material is lost by friction or abrasion. As history shows, this road leads in too many directions. It seems that some order would be brought into the picture, if more were known of the physical phenomena taking place during the disintegration of material. It would then be possible to classify the wear and, probably under such classification, results of various tests of the same class could be compared. It is apparent that the author had the same feeling when he added the appendix describing the electron-diffraction method.

Tomlinson in England called attention to the phenomenon of glass being torn up by a sapphire similar to that shown in Fig. 5 of Claypoole's paper.[11] He got it even with a glass bead on a glass plate. He visualized the phenomenon as molecules being knocked out "as teeth by a dentist's chisel." He then developed his molecular theory of friction. Later Bowden presented his interesting work on microscopic zones of extremely high temperatures on the surfaces of rubbing metals. One can easily see that both these physical phenomena have much to do with the question of wear.

In the writer's experiments mentioned by the author, wear occurred under conditions of good lubrication between the rub bing surfaces. (It may be mentioned here that the machine was built earlier for wear tests by Connolly) The test specimens were prepared after the tests so that the cross section of the worn tract could be examined at the surfaces. This work was done by R. M. Sample of the Bell Telephone Laboratories. It transpired that different metals wore quite differently under the same conditions.[12]

Bronze is smeared in the direction of motion to a depth of 0.0015 in. approximately; with babbitt, the matrix is melted away and a pavement of broken tin-antimony crystals is riding on the journal, this material apparently resisting the wear; with pure silver, the crystals break up into something like shreds, these being abraded by the journal; with cast iron, there is no sign of damage to the crystals, apparently the mechanism of abrasion being very close to the "dentist's chisel" scheme of Tomlinson.

It is apparent, that only when the various mechanisms of surface disintegration are studied thoroughly by physicists and understood, that some degree of order in the question of wear testing may be expected. Meantime, such reviews as presented by the author are of real service to the art in guiding those who must give practical answers to current problems brought to them by the industry.

S. KYROPOULOS.[13] The title of the paper has been the subject of a great deal of the writer's research work for the last few years. This work aims at the exploration of the fundamental phenomena of boundary lubrication, oiliness, and wear, including the influence of bearing materials. It consists in a critical examination of existing work on boundary lubrication from the point of view of modern molecular physics, ultimately culminating in the question: Are the phenomena of boundary friction and molecular orientation on surfaces correctly interpreted and consistent with concepts of modern chemical physics, of primary importance for the technical problems of oiliness and wear?

Such studies have been supplemented by experimental studies of the process of wear on varying the physicochemical conditions, including the lubricant. This led to definite conclusions, notably on the role wear particles play in the progress of wear. Other experimental work has thrown light on the questions of polish, wear, and seizure, as influenced by the lubricant.

It may suffice to say that, notwithstanding the greatest appreciation of the experimental work on molecular orientation, etc., the writer has come to the conclusion that the answer to the above question is definitely negative.

The title of the present paper suggests at first sight a more fundamental treatment of the matter and in an appendix two methods which contributed to the studies of surfaces are briefly outlined. This review and bibliography would appear to be useful for immediate practical needs as well as an aid in interpreting practical experience.

S. A. McKee.[14] Because of the present lack of fundamental knowledge of the effects of the various factors involved in any particular wear problem, it is necessary, as the author points out in his conclusion, to simulate actual service conditions as closely as possible. In some cases when this is done, the wear that occurs is so small or the shape of the piece is such, that to obtain a measurement of wear with significant accuracy offers a serious problem in itself. In this connection an investigation is being conducted at the National Bureau of Standards to determine the practicability of an indentation method for measuring wear. With this method the wear is determined by measuring the changes in dimensions that occur to marks or indentations placed in the surface under test. These marks are so shaped that as wear occurs their length is reduced by an amount proportional to the thickness of material removed. These marks might be considered as standardized toolmarks since for a number of years it has been common practice to use the appearance of the toolmarks on a piece of machinery as an indication of wear.

This investigation has been confined to the application of the method to the study of wear on the cylinders and pistons of aircraft engines. A cylinder or piston to be tested is placed in a special fixture and marks at any desired position on the surface are applied to a predetermined depth by means of a specially ground diamond point, which is forced by mechanical pressure through suitable cams and levers into the surface of the piece. The diamond is similar in shape to the Knoop Indentor, which has been recently developed at the National Bureau of Standards for the measurement of the hardness of materials. The mark it makes is in the form of an inverted pyramid with its base lying in the surface of the material.

The viewing and measuring apparatus consists of a conventional microscope and eyepiece scale, except that the tube is lengthened and two right-angle prisms inserted to permit use as a periscope to view the inside of the cylinders. As viewed by the microscope the base of a mark as originally made is in the form of a rhombus with its long axis about five times the short axis. For marks 0.001 in. deep the long axis is about 70 scale divisions (0.028 in.). As the surface is worn away the shape of the mark remains the same but the length decreases in proportion to the thickness of material removed.

The method has been tried in several full-scale engine tests and the results indicate considerable promise as to its practicability and usefulness. Even under the severe operating conditions present, the marks in general retain their shape well enough to provide an accurate determination of wear. The particular advantage of the method in its present application is that it provides an indication of wear only, while the usual measurements of changes in diameters of the pistons and cylinders do not differentiate between wear and such distortion as may have occurred during the test. A further advantage is that it does not require the careful technique and elaborate gaging apparatus necessary to measure the diameters with corresponding accuracy.

At the present time the study of the behavior of the marks in service is being continued. A calibration of the indentations is also being made. The changes in lengths of marks placed on flat blocks of various materials are being compared with direct measurements of change in thickness occurring when material is lapped from the surfaces.

B. L. Newkirk.[15] This paper recalls to mind certain unreported tests made some years ago in the research laboratory of the General Electric Company of the wear of carbon blocks on smooth steel surfaces. In the first tests there was a rotating drum, carrying four rings of $3^1/_2$ per cent nickel steel $20^1/_2$ in. in diameter. Carbon brushes of various compositions, held in brush holders, were pressed by springs against these rings and the drum was run for periods of days or weeks without stopping. Spring pressure and speeds were varied. Rubbing speeds in the longer runs were 125 to 150 fps (7500 to 9000 fpm). The steel rings were well polished and at the start of each run the carbon blocks were faced off squarely and smoothed or polished on the bearing end.

Friction was relatively high in the beginning but this would fall off rapidly as a track was worn in the carbon and, in general, after a period of from 3 or 4 to 24 hr, depending on the material, wear would nearly cease. The area of the track developed by wear depended upon the composition, being smaller for brushes made of flake graphite. Eight pieces were run at a time in eight brush holders, two on each ring. The spring pressures holding the brushes against the rings were different for different brush holders, ranging from $6^1/_4$ to $7^1/_2$ lb. At the end of a run of, say, one week, the areas of the tracks were measured and the unit pressures over these areas were calculated and averaged. The figure so obtained was taken as a criterion of the wearing quality of the carbon. Values of these unit pressures ranged from 6 to 20.7 lb per sq in. In the latter case the worn and polished track was 1 in. wide and approximately $^1/_3$ in. long (in the direction of rubbing).

The friction coefficient was very low (0.001 to 0.003) and of the order of errors of determination, when the brushes were well worn in. Under this condition the load seemed to be supported by an air-film bearing. The wearing quality was determined by the manner in which abrasion occured while the brush was wearing in; i.e., presumably the size and shape of the pits left by the abraded particles.

At a later date, tests were made in which a complete (jointed) ring of graphite was run against a steel collar. In this case conditions were not favorable to the formation of an air-film bearing. With pressures of 1 or 2 lb per sq in., the coefficient of friction was around 0.1. It was found impossible to maintain a polish on the graphite with the 2-lb unit pressure.

At that time small blocks of graphite, having areas of 1 sq in., more or less, were tried as air-film bearings. It was found that they would carry loads of 5 lb or more. These air-film bearings proved, however, to be sensitive to disturbances resulting in loss of the polished graphite surfaces and consequently of the bearing power of the air film.

R. J. S. Pigott.[16] While the paper is valuable in explaining the differences in wear-testing apparatus, the title may prove a bit misleading. The behavior of metals rubbed against each other to produce abrasion, or one metal rubbed against another material to produce the same result, is only, in a very small degree, similar to what takes place in a bearing which has never had any oil or greasy substance in it. Anyone who has been engaged in turning or boring dry cast iron which strikes an oily spot will know what this means, because the tool behaves entirely differently in light cuts, sometimes refusing to enter the work where the oil patch exists.

[15] Professional Engineer, Schenectady, N. Y. Mem. A.S.M.E.

[16] Staff Engineer, Gulf Research & Development Company, Pittsburgh, Pa. Mem. A.S.M.E.

The mechanics of wear in bearings generally follows quite a different path, when there is a lubricant of any kind present, than in dry abrasion. It seems to the writer, therefore, that care must be exercised, in thinking about experimental work on dry abrasion, as to how this is coupled up with lubrication. Aside from the fact that the process of abrasion, or particularly of ordinary wear in a bearing, does not appear to be very closely related to dry abrasion, in any form it is greatly dependent upon the roughness of the surfaces involved, or in the case of a foreign abrasive material introduced between two rubbing surfaces, on the size of the abrasive particle. For example, in testing pumps for oil wells, where sand is present, it has been found that, in a closed system where the sand suffered breakdown to smaller particles, the wear first accelerated (the metal was first roughened), and, if this action was carried far enough, the rough metal did most of the remaining wrecking, regardless of the abrasive. If, however, the abrasive did not roughen the metal much, then as the sand was reduced in size by crushing, wear would again decelerate and finally come almost to a stop and the surfaces would polish instead of abrading.

The practice used thirty years ago in some of the large reciprocating-engine bearings of that day illustrates this sort of effect. After reboring and scraping a large bearing, it was quite often the custom in some of the old reciprocating power stations to feed in Sapolio with the lubricating oil. This is of course a soft abrasive which breaks up quickly, and used for the purpose mentioned, it would rapidly condition the bearing to a smooth matt surface by the time it had practically disappeared, and then would be filtered out in bag filters, practically as a sludge with no appreciable abrasive properties.

In recent accurately made tests, which unfortunately are not yet extensive enough to publish, it has been found that there is wear going on without any metallic contact and certainly with no abrasive present. Further, the places in which this wear takes place, as evidenced by measurable changes of radius of the bearing, are not the same for different speeds and different loads. There is an optimum shape which the bearing will assume in time and this corresponds with the running-in period. Finally, a constant lowest friction coefficient is reached. In some cases this coefficient has decreased to 1 per cent of the initial value and the bearing, when measured, is not round. The out-of-roundness is not a question of deflection, because the bearing housing is rugged and stiff. It is simply a case of some wear or more probably plastic flow in the high-pressure regions.

It is the writer's opinion, therefore, that the study of dry friction testing and abrasion is likely to be only of academic interest as far as lubrication is concerned. It allows us the opportunity of comparing dry frictions with the much lower values when lubricated but it does not seem to have any direct connection with the lubricated bearing.

R. G. Simard and J. C. Geniesse.[17] The author in his résumé of laboratory wear testing shows still more emphatically a truism which cannot be belabored sufficiently; namely, that significance can be attached to laboratory wear testing only in those cases where the method employed simulates closely the particular applications, or where a full analysis or knowledge is available. The latter is seldom if ever true, and therefore the test method must be carefully chosen as to type.

As a specific example of the type of data which must be correlated by careful analysis, the writers will cite some results obtained with three machines in the laboratories with which they are connected, each of a different type which shall be designated *A*, *B*, and *C*. *B* and *C* are the Falex or Cornell machine and the bearing-material machine of Karelitz, respectively. An oiliness, and a film-strength agent were tested on each of these, under comparable conditions. The results are as follows:

Machine	Film-strength agent 1	Oiliness agent 2
Type *A* (reciprocating)	Increased friction	Decreased friction
Type *B* (Cornell)	No effect on friction	Further reduction of friction
Type *C* (Karelitz)	Decreased wear; Smoother surfaces	Ineffective

Conflicting results such as these emphasize the importance of choosing conditions closely simulating those in the type of service under consideration. What is still more important, correlation must be obtained before conclusions are drawn.

Karelitz and Kenyon published data[18] obtained on a wear machine, which indicated that butyl stearate had no effect on the minimum film thickness required to support a given load without wear. This was surprising in view of the oiliness, or friction-lowering effect attributed to this compound. Evidently this is an excellent case showing that oiliness and wear reduction do not go hand in hand. Further evidence of this lack of correlation is shown in the following table wherein minimum film thicknesses, h_0, are given for two oils, one of them containing an E.P. agent. Test procedure was similar to that described by Karelitz and Kenyon.

	S.A.E. 30 oil	S.A.E. 30 oil plus E.P. agent
20-lb load		
No. 62 bronze	0.0000198	0.0000124
No. 67 bronze	0.0000197	0.0000145
Cast iron	0.0000212	0.0000165
60-lb load		
No. 62 bronze	0.0000135	0.0000073
No. 67 bronze	0.0000143	0.0000119
Cast iron	0.0000117	0.0000097

Since for a given load the track width is proportional to the minimum film thickness, the E.P. agent must very definitely reduce the tendency to wear due to excessive loads. This E.P. agent does not exhibit oiliness properties when tested in conventional machines developed for that purpose.

Author's Closure

The author is indebted to Mr. Campbell for his remarks pertaining to the interpretation of the diffuse rings produced by electrons scattered from polished metal surfaces.

As mentioned by Mr. Hunter, wear of lubricated surfaces is due to improper condition of design, lubricant and application. However, a perfectly designed bearing, performing under conditions of fluid-film lubrication, will at some time be subjected to wear, the magnitude depending upon the frequency of stopping and starting the machine. For a very short duration of time, conditions of boundary friction and sometimes even dry friction will prevail. It is the author's opinion that wear properties of practically all materials of bearing and journal combinations must be thoroughly investigated, in order to select such a pair of materials as will cause least wear under unavoidable conditions of boundary lubrication.

The experiments by Bowden, to which Professor Karelitz refers, stress the importance of boundary friction which might be associated sometimes with very high localized temperatures. The author can only support the statement of Professor Karelitz regarding a common front of investigation of wear problems by engineers, physicists, and chemists. This undoubtedly will lead to a better understanding of the complex mechanism of wear.

As pointed out by Mr. Kyropoulos, author of many papers on boundary friction, the fundamental phenomena of semifluid lubrication, oiliness, and wear, including the influence of bearing materials, are not always properly interpreted. Very often practice does not support existing theory.

Mention of unreported experiments by Messrs. McKee and

[17] Members of the Research and Development Department, The Atlantic Refining Company, Philadelphia, Pa.

[18] Bibliography of author's paper (33).

Newkirk indicate that the question of wear is engaging the attention of many institutions and investigators.

Mr. Pigott states that the study of dry friction and wear testing is likely to be only of academic interest in so far as lubrication is concerned. Regarding this, the author can stress the consideration, previously mentioned, of the effect of boundary friction upon starting and stopping. Under these conditions, wear occurs in all types of bearings which most of their life perform in the region of perfect fluid lubrication.

The importance of selecting the type and method of wear test, in order to obtain useful data, is realized by everybody concerned with the wear question. From this point of view, the example of correlating data reported by Messrs. Simard and Geniesse is worth noticing.

Discussion

Rotary Oil Meters of the Positive-Displacement and Current Types [1]

ED S. SMITH, JR.[2] The excellent performance of oil quantity meters, coupled with their moderate first cost, leads to attempts to use them over a wider field of application than can be justified from a consideration of maintenance costs, as has been fairly brought out in the paper. The writer's experience with head meters includes numerous cases involving gassy, dirty, or corrosive liquids where such meters were found more suitable than quantity meters of the displacement type.

The rotary impeller (or current) type of quantity meter promises to have wide usefulness in bridging the gap between the head and displacement meters in the oil industry. However, before it can do so properly, the analysis of performance should be related to another rational operator, in addition to the Reynolds number, instead of the present purely empirical use of the Saybolt viscosity. It is to be hoped that the discussion or closure of the paper[1] will bring out such a rational dimensionless operator.

The quantity meter can be combined with a "speedometer" of one sort or another and thus indicate flow rate as well as quantity. The wide range and practical freedom from viscosity effects make such a combination attractive, at least from a theoretical standpoint. The question of maintenance, always a real factor in practice, moreover, seems to be fairly met with the impeller (or current) meter which may provide one part of the combination more widely in the future.

CHARLES S. HAZARD.[3] The graphs in Figs. 2, 7, and 8 of the paper[1] show the variations in registration of two types of oil meters caused by variations in the rate of flow and in the viscosity of the liquid being measured. At first glance, it would seem that the combined effect of these two variables would produce errors of such magnitude as to make the meters unsuited for the service intended. A more careful analysis of this question will show that this is not the case.

At points to the right of the peak on the registration curves, any of the meters considered by the author will give consistent readings on repeated tests, the deviations being inappreciable at the scale used. A meter of either of these types, used with a liquid of reasonably constant viscosity and operated within a reasonably close range of rates of flow, and which has been calibrated to register 100 per cent at the mean rate of flow and mean viscosity of the liquid used, will give consistently uniform and accurate registration. All commercial types of meters are provided with devices for changing the calibration, consisting either of gearing to vary the ratio between the measuring element and the visible register, or mechanical devices for varying the displacement of the measuring element per cycle. The effect of all such devices is to shorten or lengthen all ordinates of the calibration curve in the same proportion, thereby making it possible to bring this curve into the best possible conformity with the axis of zero error. This will not correct the deviation of the registration curve from a straight line; but the author's results show that a meter tested on a low-viscosity liquid will, in general, show less of such deviation when calibrated for a liquid of higher viscosity.

In actual practice, the necessity for taking into account the variation in registration with variation in viscosity arises in the two following cases: (1) Where a meter originally tested by the manufacturer with a liquid of one viscosity is to be put in service on a liquid of different viscosity; and (2) where a meter which has been used on one type of liquid is transferred to another service involving a different liquid of considerably different viscosity. In the first case, the manufacturer can furnish definite instructions for adjusting the registration of the meter, using the means provided. The second case is ordinarily handled by recalibrating the meter in a standard test measure at the time of the changeover. In the handling of petroleum products there are very few installations in which one meter is called upon to measure liquids of widely varying viscosities, as this would require cross connections between piping handling entirely different products with the certainty of contaminating one or the other product.

In the case of the rotary-sliding-vane displacement meter, the author's statement that "Tests show no appreciable effect of viscosity variation within wide limits," was very interesting, as the writer's tests have shown some variation with viscosity with this type of meter. The same is true of the oscillating circular-piston type of meter, which is extensively used in the measurement of petroleum products, and which was not covered in this paper.[1] This type has a characteristic calibration curve similar to that given for the rotary-sliding-vane type.

The method used in testing the meter should be described. If a standard test measure were used, it should be stated whether tests were made with the inside surface of the test measure dry, or wet with the liquid to be measured. Particularly in the case of extremely viscous liquids, an appreciable percentage of the liquid adheres to the interior surface of the test measure, and, in effect, reduces the capacity of the standard measure. This produces an apparent underregistration on the meter which tends to compensate for the increase in registration due to the increased viscosity. Another interesting effect occurs in the case of low-viscosity liquids which are highly volatile at ordinary temperatures, such as aviation gasoline. In this case, there is an evaporation of the volatile constituents of the liquid while discharging into the test measure, which tends to produce an apparent overregistration on the meter, which compensates for the underregistration due to the low viscosity. The combination of these two effects tends to conceal the variation in the registration of the meter with change in viscosity.

This raises the interesting question as to how a volumetric displacement meter for petroleum products should be calibrated. Should a meter for viscous liquids be calibrated to record the amount which would fill a standard measure to the mark, starting with the measure dry, or should the meter record the amount which would be delivered from a standard measure, filled to the mark? Should a meter for a highly volatile grade of gasoline be calibrated to record the amount actually passing through the meter, or the visible amount delivered into a standard test measure?

M. F. BEHAR.[4] Apart from (1) the intrinsic merit of this

paper[1] as a technical presentation, (2) the light which it sheds upon a field of measurement which had not been explored as thoroughly as adjoining fields, and (3) the interest attending the description of a meter which though employing a new principle is offered in a highly developed state of design and construction, this paper is of importance because what it represents may profoundly affect both the practice of metering viscous fluids in industry and the attitude of the engineering profession toward the choice of methods and the choice of meters.

About the only major criticism that one could make of this paper is that it should have been two distinct papers—one dealing with current meters and one dealing with positive-displacement meters. Each of these, of course, should deal first with the general category and then lead up to the engineering description of the improved specific type.

And yet, it may well be that the author deliberately prepared a unified treatment of related aspects of metering with positive meters and metering with current meters. Although the writer's admiration for many features of the paper and of the devices themselves tempt him to be specific, he will discuss only the broader aspects, that is, those which may have economic significance—tremendous economic significance, one may predict, not only in the metering of viscous fluids but in the automatic control of processes involving flows of viscous fluids. Removal of obstacles toward the complete automatization of these processes will affect not only the petroleum industry but many others.

For 17 years—ever since the publication of its first report—the A.S.M.E. Fluid Meters Committee has laid down a definition of positive[5] meters which specifies that "no fluid can pass through such a meter without actuating the primary device." This rigid definition has created a rather paradoxical situation among engineers concerned with specifying, using, or manufacturing quantity meters, because of the practical impossibility of making truly "positive" commercial meters of certain types that are in demand by reason of their convenience, simplicity, and low cost. In the oil and other meter-using industries, the vague classification and loose terminology of former days are giving way to engineering specifications. Not so long ago, the men who specified positive meters did not belong to engineering societies, did not know that a representative committee had laid down a scientific set of unambiguous definitions in 1922; today they not only know it but some of them have discovered that the report, like certain laws, "has teeth in it" and they sometimes demand the impossible. The greater the proportion of industrial engineers thus "armed" with the report, the more serious the situation grows. Scrupulous sales engineers, who honestly admit that some of their meters are not truly "positive," suffer under a handicap.

Strictly interpreted, the committee's definition implies that no matter how low the rate of flow through the meter, every drop of liquid or every cubic inch of gas must actuate the primary device. While some commercially produced weighing meters can meet this requirement, most of the devices in the great field of commercial, industrial, and public-service volumetric metering, which by usage and custom are called positive-displacement meters, would be excluded if the letter alone of the definition were adhered to. It obviously is impracticable to manufacture and sell against competition a meter of the rotating-disk type (for example) which will register at all when, after a period of inoperation, less than 0.1 per cent of its rated capacity is to be metered. The plain fact is that only such types as the valveless wet drum (for gases) and the tilting tank (for liquids) employ truly positive principles whereby, not only when the meter is new but after working parts have begun to wear, every cubic inch is registered and every drop caught. And even a meter in which buckets are filled and emptied is not absolutely positive, because open vessels permit evaporation, so that in the case of a volatile liquid the totalized quantity at low rates of flow is less than that delivered to the meter and more than that delivered from it. Moreover, spouts and valves are not always absolutely positive in their action.

Most positive meters are quantity meters. Their distinctive characteristic is that they register the total flow passed. If we draw the analogy to the field of speed measurement, positive fluid meters correspond to revolution counters while inferential fluid meters correspond to inferential tachometers such as those of the centrifugal and electromagnetic classes.

But this is all a matter of definition, arising from the historic use of positive meters as quantity meters, that is to say quantity counters. There has arisen lately a demand for fluid meters with primary devices of positive types and secondary devices giving direct readings of rate of flow. Such meters would correspond to the positive direct-reading tachometer—that is to say the integrating chronometric, the conjugating chronometric, and the geometric types (these last in principle only). Such fluid meters would consist essentially of a positive primary device, measuring off isolated quantities, and of a tachometric secondary.

Why not use an inferential primary device in the first place and get a rate reading directly? Because there are required—mostly in the chemical industries—dependable indications and/or records of the instantaneous values of the true volumetric rate at all rates of flow, from practically zero to the full capacity of the meter. The expression "dependable indications" refers not so much to the deflection of a pointer along a scale but to the initiation or "command" of automatic-control functions.

True enough, the new sliding-vane meter described by the author is not the first meter which makes possible the automatic control of various processes on a positive volumetric basis, but the combination of this new meter, together with the author's thorough description of its characteristics, represents a great step forward.

Now as to the piston and disk controversy. The writer was called upon about 6 years ago to act as a sort of umpire between powerful manufacturing interests in a dispute where the placing of orders hung upon the acceptance of disk meters as positive meters—not ideally positive, of course, but positive enough for the purposes in view. The trouble arose from the fact that the A.S.M.E. had rigidly defined the term "positive," but had not defined the piston and disk types. One side held that the distinction between "disk" and "piston" should be ended; the other people claimed that the disk type should be excluded from the élite "positive" class. These two sides still exist, though their personnel has largely changed.

Which is right? To some extent, both—from a realistic standpoint, neither. This is the conclusion reached by studying carefully the liquid-displacement meters that are being produced and considering also those that could be made.

If one were to scrutinize the manufacturer's own blueprints for possibilities of leakage and slippage in the various designs of meters, he would discern that there is no sharp line dividing meters that are of positive design from meters that depend entirely on small clearances between rigid moving elements and rigid walls, that is to say on the closeness of manufacturing tolerances. It will be seen that in design and construction, in theory and practice, *there are degrees of "positiveness."* It would indeed be possible to establish a continuous scale of infinitesimal gradations, from an ideally positive meter to a "displacement" meter with such large clearances that its registration curve has no "flat" portion. ("Flat" could be defined as lying between ±0.5 per cent anywhere along the volume abscissa and ±10 per

[5] This term is no longer used in the fourth edition, received by the writer after presenting this discussion. The writer does not feel that he need alter his discussion, for the influence of the earlier editions is still felt.

cent anywhere along the rate ordinates.) The basis for such a scale of the figure of merit, with regard to positiveness alone, would of course be the registration curve—not necessarily the intrinsic accuracy of the meter being graded. At one extreme would stand a design which has never been commercially produced, namely, a piston meter which could measure any fluid, even hydrogen, without leakage or slippage. The other extreme would characterize an equally nonexistent kind of meter, that is, one having a plunger, a piston, or a disk (but not a velocity-impelled rotary element) with intolerably excessive clearances—a meter, in fine, belonging neither in the "volumetric" class nor in the "current" class, therefore, a meter which is neither positive nor inferential.

All this may sound far-fetched, but a line of reasoning ad absurdum was needed to demonstrate (1) that, since the various liquid meters in question do not arrange themselves into mutually exclusive categories, any scheme of classification must be a compromise; and (2) that to discard the A.S.M.E.'s compromise classification for a purely scientific gradation would be impracticable. The outstanding fact is that no displacement meter is ideally positive. But as long as volumeters are generally considered positive, the nonpiston type seems to be as much entitled to this qualification as is the piston type. Users in the processing industries are interested in the fact that some forms of the piston type depend more on clearances between fixed walls and displaced members than do some forms of the other types.

Finally, positiveness is not the only basis of evaluation; pressure-loss characteristics, possibility of adjusting the register speed, initial and running costs, effects of changes in the physical properties of the metered fluid, the cleanliness of the metered fluid, the presence of abrasive particles, and other considerations should not be lost sight of in the flurry over pistons and other forms of reciprocating, or rotating, or nutating elements.

The author has not failed to discuss these considerations. He is to be congratulated.

Author's Closure

The interest manifested by such quantity of constructive criticism has been very gratifying. Mr. Behar's suggestion that the paper might well have been divided into two distinct papers would be acceptable if the object had been to make a detailed study of the mechanism and characteristics of each type of meter. However, the author's purpose was to treat in a general way the related aspects of viscosity effect on various types of quantity meters. In general, the effect of viscosity on registration is related to the degree of positiveness of the meter. The maximum effect is encountered with orifice measurement at low flow rates, and becomes successively smaller with approach to the final degree of positiveness, as is illustrated by comparison between (1) the free- and confined-impeller meters, (2) the impeller and disk meters, and (3) the disk and piston or rotary-vane meters, which latter closely approach the truly positive. The author avoided delving into the metaphysical problem of the positiveness of positive meters, but is indebted to Mr. Behar for his admirable discussion which emphasizes and illuminates this important point. For example, it is true that the rotary-sliding-vane meter described, or other synchronized-vane meters are positive meters and are as justly entitled to such classification as certain reciprocating-type displacement meters. In the last analysis, the criterion of positiveness is a volumetric efficiency dependent upon clearances and not upon type of mechanism or motion.

Mr. Hazard's discussion is pertinent to some of the problems confronting the users of oil meters. However, the author cannot agree with his simple practical disposition of the problem of treating the variation in registration of a meter on liquids of varying viscosity. From the point of view of manufacture and sales, a desirable meter should have characteristics which do not require special test and adjustment for different oils within wide latitude. Certainly the user would have more confidence in the meter and be put to less expense, when it is necessary to put different oils through the same meter or transfer the meter from one installation to another, if test and adjustment were not necessary within its periodic inspection and maintenance period. This is a practical and important consideration in the measurement of crude oils where viscosity varies considerably. In the case of the rotary sliding-vane meter, the author's statement, "Tests show no appreciable effect of viscosity variation within wide limits," was meant, of course, to convey the idea that the tests were made with liquids of widely different viscosities. Within the working range of the meter curve, i.e., from the beginning of the tangent point on the slip curve to the maximum allowable flow rate, no appreciable translation of the accuracy curve was observed between tests of gasoline and fuel oil. The reason for this lies in the high degree of positiveness inherent in the design. This has also been observed to be true in other designs of synchronized-vane meters. It is true, however, that in the slip region viscosity as well as density has some effect, and it is observed that on a low-viscosity liquid the slip is slightly more than on a high-viscosity liquid. Special analysis of variation in the slip region, which is outside the working range, was not given. However, this meter has a wide working range due to the low slip point, and the variation in shape and amount of the slip is a minor effect which does not materially affect its working range. Of course, test on air would show excessive slip, but on a liquid it would be a much smaller and reasonable amount. The sealing of the clearance between rotor and casing is essentially capillary, and the efficacy of the seal is dependent upon the fluid viscosity and rotor speed. A variation of the accuracy at low flow rates due to viscosity change has also been observed in some piston meters which are of the nonpacked type dependent upon a capillary seal of the clearance between piston and cylinder. Some discussion along this line will be found in a paper by Sylvan Cromer, entitled "Fundamental Principle of Quantity Meters," given at the Petroleum Fluid Metering Conference, University of Oklahoma, 1938. The oscillating circular-piston type meter is well discussed in this paper, also.

Detail description of the test methods cannot be given due to limitation of time and space except to say that the sliding-vane meter was tested by both volumetric-tank gaging and discharge-weigh methods. It is generally recognized that adherence of the liquid to the interior of the tank can have an effect on the test result; however, this can be obviated by actually weighing the discharge. Concerning the effect of highly evaporative fluid in the test result, the writer would call attention to research work done along this line on meter tank trucks as presented in a thesis by E. W. Jackson to the faculty of the Graduate College, University of Nebraska, 1938. The material in the author's paper did not embrace tests on volatile fluids and, hence, the above reference will suffice.

Mr. Smith's remarks are misleading to a slight extent in that the author did not emphasize or wish to point out that quantity meters are being applied "over a wider field of application than can be justified by maintenance costs." This may be so, and Mr. Smith's wide and authoritative experience on head rate-of-flow meters has no doubt brought him to many situations where a head meter was the proper solution. This question is one of application engineering—intelligent selection of type, study of operating conditions, and other problems. Active research is being promoted by both operators and manufacturers within the petroleum industry to improve metering. That this will be fruitful is certain and it can be confidently predicted that new meters, longer-lived and more accurate, and better operating technique

will result. For several practical reasons, the author has not considered important at this time the development of another rational operator in addition to the Reynolds number for analysis of performance of the current meter. Further intensive investigation at the present time does not seem probable as the synchronized-vane type seems to hold forth better promise for the majority of applications due to its wide-range positive characteristics. Such meters have the advantage of the simple rotary motion of the impeller meter combined with a high degree of positiveness. A second reason is the necessity of finding an improved current-impeller form which can be reproduced with the exactness of the orifice plate or venturi meter. This attained, the effect of viscosity would be uniform between different meters and thus some dimensionless operator would be useful in correlating and analyzing results to establish correction factors for viscosity effect at different flow rates. Such an operator would possibly be based on the ratios of kinematic viscosities and the pressure drop to pressure loss through the meter.

This paper was offered in the hope of making some small contribution to fill the gap between the organized detailed information available in head-type meters, such as the venturi and orifice, and the general information available on quantity meters. The A.S.M.E. Fluid Meters Report is a splendid accomplishment, giving complete and authoritative information on head meters, but treats quantity meters in a very general manner. One reason for this contrast is that in order to apply and interpret intelligently the results of head meters requires not only a complete understanding of operating principle and factors affecting performance, but a detailed knowledge of coefficients, correcting factors, and other experimental data. This is not true of the quantity meters which produce a recognizable result on the registers no matter what the operator knows about it. Further, the manufacturer will furnish instructions for installation and repair and, when special problems are met with, will willingly cooperate and work with the user to make a proper installation. Nevertheless, in the interest of extending knowledge and stimulating the progress in this art, it seems to the writer that further attempts should be made to organize available knowledge, giving due deference to proprietary interests when encountered, and stimulate further research on quantity meters. Is not this labor within the province of Fluid Meters Committee? Such meetings as the recent Petroleum Metering Conference specified by the petroleum industry will be helpful and indicate that more information will be available on metering in the petroleum industry in a short while.

Application of Automatic Control in the Oil Industry[1]

ALBERT F. SPITZGLASS[2] AND MAURICE J. ZUCROW.[3] This paper is a worthy contribution to regulation literature and will be of great value to the A.S.M.E. Industrial Instruments Committee in its effort to derive logical methods for analyzing industrial processes from a regulation standpoint. Although the author has concerned himself with a single industry, his story is in a language and form which readily permit correlating his work with problems in other industries.

One of the points of great interest to control engineers is the emphasis placed by the author upon stability for the entire process, and its relation to the individual regulation problems comprising this complex industrial process. The importance of this prerequisite is easy to understand, and it is satisfied only with regulators having specific characteristics. In the paper, nine regulators are described in detail. Of these, only the heater flow regulator is subject to variation in type, the appropriate type depending upon the kind of pump drive. The remaining eight regulators and their types are listed in Table 1 of this discussion.

TABLE 1

Number of regulators	Functional classification	Type
2	Pressure	Proportional narrow-band
1	Pressure	Proportional wide-band
3	Level	Proportional wide-band
2	Temperature	Proportional wide-band (with reset)

It is seen that six of the eight regulators are proportional-wide-band regulators. Although the popular conception is that this type is a necessary evil to be used only when the narrow-band regulator is liable to produce hunting, here the wide-band regulators were purposely chosen. A choice dictated by the problem, which is to balance "supply" and "demand" and regulate the "storage" so that it aids in absorbing shocks caused by sudden "demand" changes. Consequently, their use in this manner does not involve any loss of accuracy. This emphasizes the point that it is dangerous to judge the merits of regulators as devices apart from the particular processes which they are to serve.

In discussing the regulation of the flow of oil to heaters, the author emphasizes the importance of uniform flow; this is a deciding factor in obtaining smooth operation of the cracking unit. He surmises that although the application of the flow regulation directly to the cutoff governor of the engine has advantages it is unjustified. At first blush, the writers were tempted to question the correctness for this resigned attitude, since they have installed many systems where a pressure or flow regulator either shades the action of the governor or replaces it entirely. However, further deliberation revealed that, while this type of problem can be solved satisfactorily, the engineering required, due to lack of standardization, is usually out of proportion to the results obtained. It is unfortunate that cooperation between engine-governor builders and regulator manufacturers is in such a state that it justifies the philosophical attitude displayed by the author; this type of regulation is quite common, however, in the case of turbogovernors. The important point illustrated by this is the existence of a problem which the Committee must attack in its work to coordinate and bring some degree of standardization to the regulation art.

In connection with the regulation of combustion, one finds that a condition exists in the oil industry similar to that which formerly prevailed in the steel industry. Combustion regulation in the oil refinery has found few proponents. In the steel industry, combustion and furnace pressure regulation for open-hearth furnaces have finally proved their value, and now the soaking pit is coming into its own.

While there is a good argument against combustion regulation, the changeable heat content of the refinery gases used for the fuel making this type of regulation difficult and complicated, the argument for furnace pressure regulation is not so easy to refute.

Furnace pressure regulation is valuable because it has a stabilizing effect upon the furnace conditions and incidentally aids in maintaining a uniform combustion rate. Furthermore, it is helpful in directing the flame and in obtaining the correct distribution of gases within the furnace, an ever-increasingly important factor in modern furnaces. The pressure variations which exist in unregulated furnaces have not been apparent until recently, due to the insensitive draft gages which were used. It is only recently that industrial draft gages of high sensitivity

[3] Consulting Engineer, Chicago, Ill. Mem. A.S.M.E.

(±0.1 in. of water for full scale) have become generally available.

In his closing paragraphs, the author points out the direction in which the oil industry is moving. This information should be studied carefully by those responsible for the development of instruments and regulators. In cooperation with the designers of the equipment for the newer processes it will be necessary to establish those factors in process apparatus and regulator design which will produce a well-regulated plant. The new measurement problems which will accompany these newer processes must be solved. Their correct solution will benefit not only the oil industry and the instrument manufacturer but industry in general.

J. B. McMahon.[4] This paper gives a very interesting exposition of the reasons why automatic control has become an integral part of modern petroleum-refining processes. This is particularly true with respect to the discussion of how operators actually use the automatic controls which have been placed at their disposal and how far it is practical to go in the application of automatic control in such plants.

The author's discussion of the various kinds of equipment used for the various jobs involved is probably the most interesting part of this paper. With this discussion there will probably be considerable disagreement in which the writer is going to take some part. For instance, under the subject "Pressure Control on Distillate Receiver" the author states that the application of a simple air-pilot-operated pressure control to the release of the gas in the receiver gave very satisfactory and accurate results. Under most operating conditions, however, the type of controller mentioned will not produce the smooth, uniform gas discharge that can be accomplished by means of a proportional wide-band controller equipped with automatic reset. The difference is illustrated in Figs. 1 and 2 of this discussion, which are taken from an actual installation where the simple pilot-operated type of pressure regulator mentioned by the author was replaced by the latter instrument type of recorder controller. The operating conditions were identical and it is quite obvious that the over-all plant operation would be quite considerably smoothed out by having the gas flows, as well as the gas pressures, as uniform as are shown in Fig. 1 of this discussion, which were produced by the instrument equipped with the wide-band proportional-reset control mechanism.

It seems to the writer also that it is going to be necessary to clarify what is meant by "averaging" level control for discussions such as this. This term was introduced by The Foxboro Company in 1932 to designate a type of level-control results made possible by a combination of very wide-band proportional control with very slow automatic reset. Ordinary proportional wide-band control, referred to by the author, will not produce the results that are designated by the originators of this method as "averaging" control. Ordinary proportional wide-band control should not be designated as being averaging control since the valve movement for true averaging control should be considerably less than that which would be afforded by a proportional wide-band control that just took up the entire range of the instrument or, in terms of former designation, had definitely and exactly 100 per cent throttling range.

The writer does not consider that true averaging control is afforded unless the throttling range is at least several hundred per cent of the scale range in the case of differential-type instruments and several times even that amount for ball-float level instruments which do not have the advantage of the multiplication afforded by the differential method of measuring the level. A

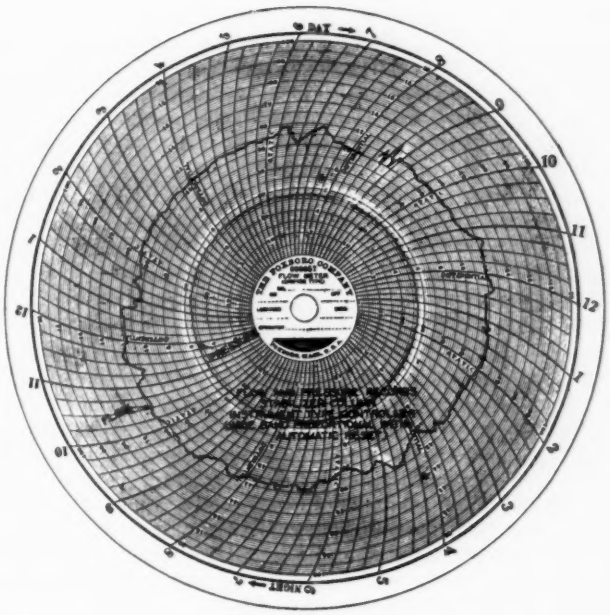

FIG. 1

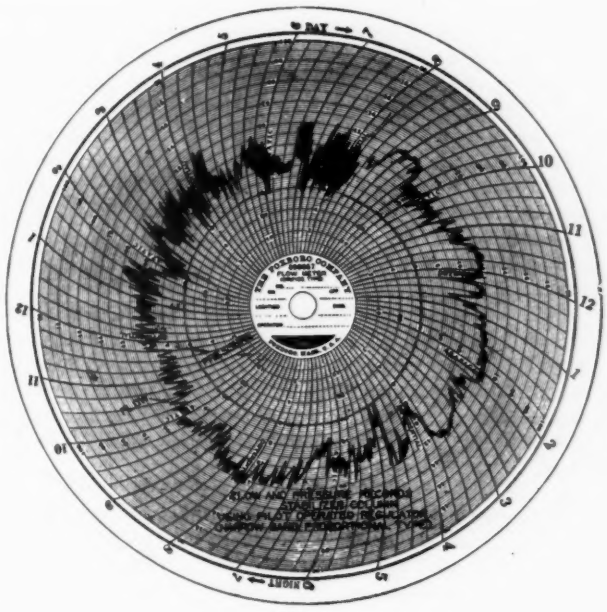

FIG. 2

discussion of this point is brought out in the paper[5] by the writer.

In this connection also, let us point out that in many cases for rather more intricate refining operations than are covered by this paper,[1] a storage capacity of considerably more than the author designates as advisable is necessary to provide the smoothness of operation that will give the best over-all operating results. It is under such conditions of storage relationships that the true "averaging" level controller is necessary and really valuable.

With respect to the control of heater outlet temperatures, the writer would like to point out that the effect of a transient condition such as is shown by the dotted curve in Fig. 5 of the author's

[4] Manager, Controller Division, The Foxboro Company, Foxboro, Mass.

[5] "Control of Liquid Level in Vessels Under Pressure," by J. B. McMahon, *Industrial and Engineering Chemistry*, vol. 29, November, 1937, p. 1219.

paper[1] would make it necessary to use rather highly specialized automatic control to overcome the effect of transfer lag in these furnaces. The automatic temperature control of pipe stills is up front among the very tough temperature-control jobs due to the requirements for very close control under very severe process conditions. This might readily be a fit subject for some of the process analysis work which has been discussed to some extent.

The same remarks with respect to level control in the flash chamber and the level control at the base of the fractionating column apply as they did to the other level-control jobs discussed. The writer would particularly like to draw attention to the fact that the author's statement, "A reset mechanism is not necessary or even desirable in this control since bringing the level back to a normal overcorrects the flow and acts opposite to the damping or averaging effect desired," evidently misunderstands the function of true averaging control. In a true "averaging liquid-level controller," which is equipped with extremely wide-band proportional mechanism and very slow automatic reset, greater variations in flow rate of the uncontrolled flow can be absorbed in a vessel than are possible where the vessel is equipped with an instrument having only proportional wide-band control mechanism. Two things must be taken care of, that is, both the instantaneous upsets and the average changes; simple proportional wide-band control mechanism which does not possess automatic reset will not be able to take care of these as well as the averaging controller since it would not be feasible to set the proportional band as wide without having some provision to take care of average change of conditions. Also, with respect to the level control in the flash chamber, it is quite evident from the author's discussion that it is desirable that the flow remain smooth but that the level should be kept within very narrow limits. Over any appreciable range of change of conditions this can be done only with proportional wide-band control with automatic reset and cannot be achieved by proportional wide-band control alone unless it is very materially assisted by manual resetting which is very much more upsetting to a continuous process than is automatic continuous resetting.

It is to be hoped that the author's paper[1] will be only a precursor for other thoughtful, well-considered discussions along the same line. All too frequently such discussions have revealed a lamentable lack of knowledge by the authors either of instrument mechanisms or of practical plant operation. Mr. Bergman's paper shows a happy combination of knowledge and appreciation of both.

B. R. Carney.[6] The author is well qualified by experience in actual cracking-plant problems involving the use of automatic controls. The title of his paper is broadly inclusive, and the text is confined to cracking-plant problems. This is probably justified by the importance of such problems and the author's preeminent qualifications along this line. Nevertheless, aside from the new processes briefly mentioned, the established operation of crude distillation, stabilization, and chemical treatment have for a long time justified the intelligent use of automatic controls.

The ideas in this paper[1] form a good general policy to guide the use of automatic-control systems. To express this policy in somewhat different words, automatic controls are not intended to replace intelligent operation, but rather are tools provided so that the operator may do a better job and work more accurately than with simple globe valves. This implies, of course, that the controls are subject to the operator's will, and can be conveniently reset to effect the changes in conditions which he finds necessary.

Considering now the specific problem of controlling the raw oil and furnace feed of a cracking unit, the system outlined implies a constant combined or furnace feed and a variable raw feed. Whether right or wrong, many of those responsible for refinery cracking operations like to think in terms of a fixed raw feed. Is it not feasible to make this the control point, absorbing variations (which should be slight) by allowing the combined feed to fluctuate? Admittedly a varying combined feed presents a problem in flow control when it is desired to divide equally the flow in a multipass furnace. For a two-pass furnace, equal division of variable flow would not seem extremely difficult, although the writer does not recall any instances of such a control system. Quite likely the instrument people already have the answer to this; if not, the problem is recommended for their spare-moment attention.

Development of the various throttling-type controls has permitted the use of automatic control in numerous cases where the on-and-off type would have been impossible. The operation of a stabilizer direct from the cracking unit, with only a few minutes surge capacity between, as explained in this paper,[1] is a very good illustration. Six to eight years ago such an arrangement would not have been considered practical. However, in spite of the capability of good controls, there is probably a practical limit to such close interlocking of refinery processes. Thus, it would likely not be desirable to extend further the combined operation by tying the subsequent chemical treatment of the gasoline directly to the stabilizer outlet if for no other reason than because the control problems of chemical treatment differ considerably from those involved in cracking and stabilization. In general, adequate supervision of over-all refinery results requires checks on quantity and quality at intermediate stages, and extensive interlocking of operations makes such checks impossible.

In connection with the control of fractionating-tower top temperature and, thereby, presumably—gasoline end point, the writer remembers an early pyrometer and electrical relay-system installation which was rather unsatisfactory. Controls using a thermometer bulb and air operation have given reasonably good results for many years on crude-distillation units.

The paper includes some pertinent and important hints about practical mechanical details of control and instrument installation. When trying to "line out" the operation of a new refinery unit, there is nothing more exasperating than failure of instruments. Besides the points mentioned the following might be stressed: (1) Instrument lines containing heavy oil have to be protected against low temperature, usually by putting such lines in an insulated conduit along with a small steam line. (2) Flow meters and flow controllers operating on a saturated gas should be protected against low temperatures which will cause partial condensation. (3) A flowmeter or rate-of-flow controller should preferably not be used on a liquid at its bubble point. These three items may seem elemental, but it is surprising how frequently they are overlooked in practice.

J. F. Luhrs.[7] Of particular interest is the author's emphasis on practical considerations in the application of automatic control in the oil industry. The paper serves to illustrate two important points. One is that there are definite limitations to any theoretical approach to the application of automatic control. The other is that empirical methods must be used in the solution of any specific control problem.

The author lists in reference to transfer-line and tower temperature control several independent variables which must be taken into consideration. The writer would like to emphasize the effect which extraneous or superfluous changes in the control agent have on these temperatures. The flow through any regulating valve is dependent upon the port area and the pressure

[6] Shell Union Oil Corp., New York, N. Y.

[7] Bailey Meter Company, Cleveland, Ohio.

differential impressed across the valve. If the port area be varied solely from temperature, changes in the rate of application of the control agent can still occur through changes in pressure differential across the valve. Hence, even though the temperature may be at the normal value, an extraneous change in the rate of application of the control agent may occur which will upset the system. Because such changes are usually quite rapid, their effect is more aggravating than that of any of the other variables listed by the author. It follows that if precise control is to be achieved, such extraneous changes must be immediately corrected, so that the rate of application of the control agent will be dictated solely from temperature.

In the case of a gas-fired oil heater, a change of 1 oz in the pressure at the burners may effect a sufficient change in the rate of fuel supply to change the transfer-line temperature several degrees. Such changes in burner pressure may occur bearing no relation to transfer-line temperature, because of changes in the pressure of the gas supply ahead of the fuel-regulating valve of corresponding magnitude. Such changes in supply pressure may be caused by sudden changes in demand by other equipment, or by changes in gas production. An independent control of the pressure of the gas supply will seldom hold the pressure within the required limits as at the relatively high pressure at which the supply is maintained a change of a few ounces is practically imperceptible. A control operating solely from transfer-line temperature will eventually correct for such extraneous changes in fuel supply, not however without an appreciable departure of the temperature from the normal value.

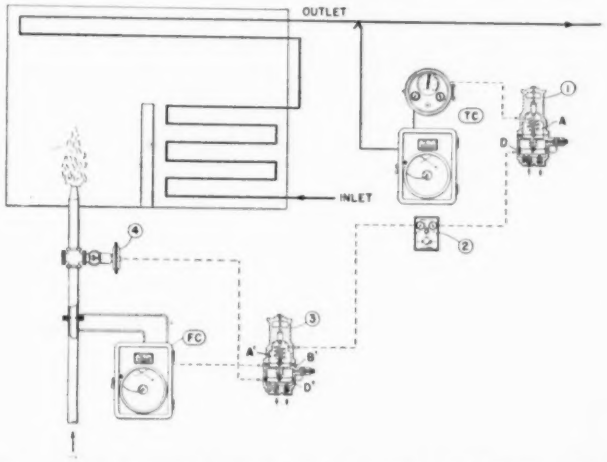

FIG. 3 TWO-ELEMENT CONTROL FOR TRANSFER-LINE TEMPERATURE

Similarly in tower control a slight change in the pressure of the reflux may effect a sufficient change in reflux flow to cause a material deviation in tower temperature from the normal value. Again such changes will ultimately be corrected, but not before an appreciable change in tower temperature has occurred.

A greatly improved control can be obtained if the port area of the regulating valve be varied not only from temperature but from the rate of application of the control agent as well. In a system of this type an element responsive to temperature establishes a desired rate of application of the control agent and a second element responsive to the control agent maintains correspondence between the desired and actual rates of application. Control systems of this so-called two-element type have been used successfully for many years, particularly in connection with boiler combustion and feedwater control. Their use in the last few years in the oil industry has been increasing.

Such a system applied to transfer-line temperature control is shown schematically in Fig. 3 of this discussion. A loading pressure corresponding to transfer-line temperature is established by the recorder-controller *TC* and transmitted to a chamber *A* of a standardizing relay 1. This device acts, in addition to relaying pressure changes, to introduce a floating action so that a loading pressure established in chamber *D* changes both in correspondence with changes in transfer-line temperature and the amount of departure of this temperature from the normal value. The loading pressure established in chamber *D* is transmitted through a selector valve 2 to a chamber *A'* of a standardizing averaging relay 3 which is similar in construction and action to the relay 1. A loading pressure corresponding to fuel flow established by the recorder controller *FC* is transmitted to a chamber *B'* of the relay 3. This device establishes in chamber *D'* a control pressure which is transmitted to a diaphragm fuel-control valve 4.

The pressures in chambers *A'* and *B'* oppose each other and for the relay 3 to be in equilibrium, that is to produce no change in pressure within chamber *D'* and hence no change in fuel flow, it is necessary that the two pressures be equal or stand in predetermined proportion. Hence, for each and every loading pressure established by the relay 1, a definite rate of fuel flow (in distinction to a definite valve position) is established. It will also be apparent that equal changes in loading pressure established by the relay 1 will produce equal changes in fuel flow (in distinction to equal changes in valve position). Any variation in fuel flow not called for by a change in control pressure will immediately be corrected by the controller *FC* before such variation causes a material change in heat liberation in the heater furnace.

The system may be readily transferred from automatic to remote manual control by the selector valve 2. This device also acts to inhibit the floating action of the relays 1 and 3 during periods of remote manual control. As a result, during such periods, if the temperature maintained be slightly different from that for which the controller *TC* is set, the pressures established by the relays 1 and 3 will not go to an extreme but will be maintained at the control pressure established by the selector valve. The transfer from hand to automatic may then be made smoothly without upsetting the system.

The author mentions a few instances where the interlocking of several control points would give improved results, but questions the desirability of so doing in view of the added complication. Such multielement systems have been in use, however, for many years, particularly, as previously mentioned, in boiler combustion and feedwater control. In the writer's opinion, the proper coordination of several variables into one system serves to simplify the control problem rather than to complicate it. It is believed that as knowledge of any particular step in a process advances many instances will occur where regulation of a control agent from several variables will be highly desirable. Specific reference is made, as an example, to the possibility of controlling fuel to cracking units from a proper correlation of time, temperature, and stock characteristics,[8] which in addition to improving heater performance would undoubtedly aid in giving improved results throughout the entire refining process.

AUTHOR'S CLOSURE

Messrs. Spitzglass and Zucrow mention combustion control. It is probable that combustion control has not had greater

[8] "The Determination of Yield per Pass, Time of Treatment, and in situ Density and Instrumentality for Their Control in Commercial Cracking Units," by Robert L. Rude, R. D. Junkins, and C. Barnes, Proceedings of the Nineteenth Annual Meeting of the American Petroleum Institute, Chicago, Illinois, Nov. 18, 1938, Section 3, Refining, pp. 149–167.

application in the oil industry because of two conditions. First, fuel gas is usually available at pressures of from 15 to 30 psi, and changes in combustion-chamber pressure which might affect the flow of gas from burners operating on 4-oz gas have little effect except with regard to change in quantity of excess air. Second, the gas usually has a variable heating value and the setting of fixed fuel-air ratios common in combustion control would not be entirely satisfactory. Furthermore, most refining processes are continuous, and have a relatively constant heat demand, as against boiler operation where demands for power may vary at the whim of a passing cloud.

Mr. McMahon points out improved operation of a gasoline stabilizer by the use of a proportional wide-band controller with reset. It should be noted that the reference in the article had to do with the control of pressure on the cracking-plant fractionating column, which has relatively greater capacity, less drop across the control valve, and probably a lower percentage variability in load, thus making the conditions more favorable to the simple control. However, the wide-band proportional control with reset is of advantage in many of these cases, though not vitally necessary.

With regard to the definition of "averaging," control, this is left to the Subcommittee on Terminology. As a suggestion, an extension of Mr. Haigler's idea might be the classification of proportional controllers, as follows, in terms of instrument scale range:[9]

Narrow band	less than 4 per cent
Wide band	4 to 20 per cent
Full band	20 to 100 per cent
Extreme band	over 100 per cent

Regarding the comments on level control, when the basic factor of flow through the heater is held constant, the entire process is stabilized, variations in other flows are minimized and the necessity of reset or other additions to simple controls is likewise minimized.

Mr. Carney questions the principle of control of furnace feed versus control of raw-oil feed, expressing a preference for holding raw-oil feed constant. It is possible in a fully automatic system to change combined feed rates as he suggests, to correspond to variations in combined-feed ratio. However, this further requires changes in the flow of fuel to the heater, and finally adjustment of the reflux return to the top of the tower to balance the increased heater load. Maintenance of constant combined feed at constant outlet temperature under control of the operator is generally felt to result in more stable and uniform plant operation.

With regard to Mr. Luhr's comments, it is surprising to note the representative of an instrument company expressing the thought that control of fuel-gas pressures to almost any desired limit is difficult, and this view is not generally shared in the industry. Constant pressure drop across a control valve and burner orifices will usually result in a satisfactory control of flow of fuel gas to meet the demands of a temperature controller. However, if it be desired to set up a proportionality with the loading pressure of a wide-band temperature controller with reset, a simple and relatively inexpensive method is the provision of an instrument-type flow controller on the fuel gas, the control point of which is adjusted by the loading pressure from the temperature controller. Such instruments are in standard production by several manufacturers.

With specific reference to the paper presented by Messrs. Rude, Junkins, and Barnes,[8] while this represents an excellent case of carrying research and development through to a satisfactory conclusion, it is probable that the comments of Messrs. Spitzglass and Zucrow on control of speed governors apply in this instance also, and the cost of equipment and engineering necessary is disproportionate to the results which can be obtained through the use of simpler standardized controls available.

With reference to the general problem of separate direct versus interlocking controls, it is noticeable that the latter have been quite generally adopted in connection with boiler control as compared to refining. Perhaps this is because, considered as a process, a boiler is certainly much simpler than an oil still. With water, pressure and temperature are definitely dependent variables, while with oil they are practically independent. Latent heat is dependent upon temperature in the case of water, while in oil it is also dependent upon molecular weight, and a variable "heat of cracking" may further complicate matters. With the greater complexity or additional number of degrees of freedom in oil, the principle is usually followed in experimental work of holding all variables but one constant and noting the results with changes of that one variable. Simultaneous changes of two or more variables cloud the issue as to which change is responsible for the results.

It is on this basis that preference is expressed for the method of taking up the "slack" with one variable. In the case of a transfer temperature controller this would be fuel to heater, while in a tower temperature controller the variable is the return of reflux to the top of the tower.

This does not mean that interlocks for safety are not desirable. For instance, in the case of a transfer temperature controller, a continued slow rate of coking of the tubes would call for an increase of fuel to maintain the transfer until such a furnace temperature is reached as to result in overheating and rupture of a tube. An interlock to prevent admitting fuel beyond a given furnace temperature would minimize such a possibility.

[9] "Application of Temperature Controllers," by E. D. Haigler, Trans. A.S.M.E., vol. 60, 1938, paper PRO-60-5, p. 633.

Pressure-Responsive Elements[1]

KENNETH S. M. DAVIDSON.[2] This paper is a valuable contribution to the literature on the subject. What impresses the writer particularly is its direct approach to the problems of pressure measurement, as that problem is encountered in the ordinary course of events in present-day engineering work. Previous contributions have usually related either to highly specialized problems of pressure measurement, or to abstract analyses of instruments. Mr. Exline covers the whole field of engineering pressure measurement, starting with a rational physical approach, which will permit special problems to be treated as extensions of the basic groundwork, rather than as isolated investigations. There has been a need for a paper of this type.

The fact that this paper treats certain types of measuring instruments more fully than other types is not a very serious matter, for it helps to set up a background into which fuller considerations of other types can be fitted. In particular, it treats of bellows-type elements almost to the exclusion of Bourdon tubes. The bellows-type element has received increasing attention in recent years, and it appears to have very desirable characteristics. It has by no means displaced the Bourdon type, however, and a paper purporting to describe pressure-responsive elements in general should certainly compare the characteristics of these two types of elastic elements. At any rate, such a comparison is a logical next step in a study of the subject as a whole.

[1] Published as paper PRO-60-4, by Paul G. Exline, in the November, 1938, issue of the A.S.M.E. Transactions, vol. 60, p. 625.

[2] Associate Professor of Mechanical Engineering, Stevens Institute of Technology, Hoboken, N. J. Mem. A.S.M.E.

The bellows-type element has enjoyed a certain advantage over the Bourdon tube from the fact that, because of its comparative newness, it has been studied by the more refined methods customary at present; the Bourdon tube on the other hand has received less recent attention. However, a not inconsiderable array of useful data regarding the Bourdon tube are available, and its analysis at this time would be interesting.

A comparative analysis of bellows and Bourdon elements would naturally consider their relative stiffness (that is, their relative ability to move indicating or recording mechanisms) as a function of the maximum stress in the element, and of the maximum pressure for which the instrument is designed.

GEORGE H. LEE.[3] The wide discrepancy between the calculated and the observed bellows stiffness apparently results from a neglect of the curved sections of the bellows and from the boundary conditions of the flat annular plate assumed by the author. By computations briefly described in the following paragraphs, the writer arrives at results in close agreement with the experimental values.

One half of one convolution of the bellows is considered; the calculation of the deflection for this section of the bellows is divided into three parts: The deflection of the flat annular plate, and the deflection of a unit width of each of the two curved sections adjacent to the plate. The curved sections considered are in effect quadrants of circles in an axial plane. The flat annular plate is subjected to the following boundary conditions: A force, normal to the plate, equally distributed over the outer boundary, with an equal but opposite force distributed over the inner boundary; a moment, due to the adjacent curved sections, distributed over the outer boundary of the plate, and a similar, but not necessarily equal, moment distributed over the inner boundary. The deflection of the inner boundary is measured relative to the outer boundary. The deflection of the curved sections of unit width is determined using Castigliano's theorem. The ends of the curved sections next to the flat plate are subjected to the same forces and moments per unit length, as the boundary of the plate; the tangents at the other ends of the curved sections remain vertical, due to the symmetry of the system, and so are assumed fixed. The deflections of the curved sections are measured from these fixed ends.

The total deflection of one convolution of the bellows then is twice the sum of the three deflections. The bellows stiffness per convolution is the applied axial load divided by the deflection per convolution.

The bellows stiffness is calculated for bellows Nos. 3 and 5 of the author's tables. These values are found to be 4100 lb per in. and 4300 lb per in., respectively, against the observed bellows stiffness of 4347 lb per in. and 4938 lb per in., respectively.

The deflection of the flat annular plate is obtained from the solution of the differential equations[4]

$$\frac{d^2\phi}{dx^2} + \frac{1}{x}\frac{d\phi}{dx} - \frac{\phi}{x^2} = -\left(\frac{1}{D}\frac{P}{2\pi x}\right)$$

and

$$\phi = -\frac{dw}{dx}$$

where ϕ is the slope of the plate along a diameter, x is the radial variable, D is the flexural rigidity of the plate, P is the total applied force, and w is the deflection. The arbitrary constants are evaluated from the boundary conditions just given.

[3] Sibley School of Mechanical Engineering, Cornell University, Ithaca, N. Y.

[4] "Strength of Materials," by S. Timoshenko, D. Van Nostrand Company, New York, N. Y., 1930, part 2, p. 491.

The moments existing at the boundary of the plate and either curved section are evaluated from the condition that the slope is the same for the curve and the plate at their common boundary.

The behavior of the pressure bellows under actual operating conditions suggests that the bellows stiffness in terms of an applied internal pressure would yield information more pertinent to the design of bellows gages than the bellows stiffness in terms of the applied axial force. The bellows stiffness in terms of the applied internal pressure could be calculated by a modification of the method outlined in this discussion. The deflection of the flat annular plate may be obtained from the solution of the differential equation[4]

$$\frac{d^2\phi}{dx^2} + \frac{1}{x}\frac{d\phi}{dx} - \frac{\phi}{x^2} = -\frac{1}{D}\frac{qx}{2} + \frac{P}{2\pi x}$$

where q is the applied internal pressure. The deflection of the curved sections due directly to the applied pressure could be neglected in comparison to the deflections due to the axial force.

ED S. SMITH, JR.[5] This paper forms an excellent basis for a "Section on Instrument Elements" for ultimate issuance under the auspices of the A.S.M.E. Industrial Instruments

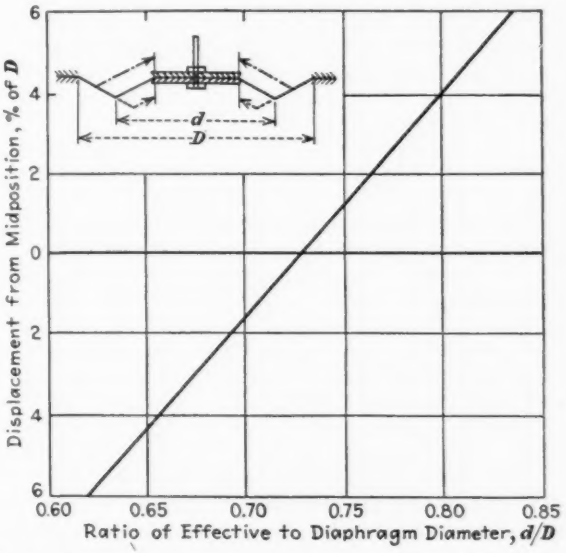

FIG. 1 PERFORMANCE OF FLAT DIAPHRAGM WITH SLIGHT SLACK

Committee, and in which the treatment of other elements, such as the Bourdon tube, would receive as full development as the present paper's section on bellows.

For bellows, and other instruments having substantially lineal response, the use of stored energy may be permissible as indicating the probable effects of friction. However, for the more general case where the response may be in other than lineal relation, it is more accurate to consider forces due to friction and to deflection of a resilient portion.

Another noteworthy point is that the maximum error of the bellows, as in Fig. 16 of the paper, is practically ten times the probable error, and that the probable error is established by practically all of the observations while the maximum error is determinable with far less accuracy due to its almost accidental values; both of which considerations lend weight to the use of the probable error in preference to the maximum error, and es-

[5] Hydraulic Engineer, C. J. Tagliabue Co., Brooklyn, N. Y. Mem. A.S.M.E.

pecially as a fair basis for guarantees. It would be interesting to have a least-squares analysis of these same data in the closure.

Under materials, (*a*) plating of resilient instrument members has been resisted in several fields, (*b*) silver is a valuable metal to use where reasonable size resilient parts must handle weak forces (W. W. Frymoyer of the Foxboro Co. is to be credited with this), and (*c*) some difficulty has been experienced in obtaining beryllium-copper bellows from some sources. It would be helpful in the treatment of instruments generally if the closure were to include a fundamental analysis of hysteresis in terms of the characteristics of materials with emphasis on the relation between low error and the economy in the use of material by the selection of one having a high yield point.

A noted omission is that of the limp flat or slightly formed diaphragm. Where a flat circular diaphragm is mounted between flanges having a slightly smaller diaphragm, and then stressed axially to take up the slack to give as much travel as possible without stretching, before clamping, such a diaphragm rolls and unrolls as a very flat cone in service thereafter within the limits of slack, accurately following a lineal relation between axial travel and the diameter of its effective area. Fig. 1 of this discussion shows the large but dependable change of effective diameter with even small travel. Although obviously such a basic characteristic should be adequately compensated for in design, still in the literature the writer, offhand, remembers only a brief note by the late J. H. Hodgson. Flat limp metal diaphragms, commonly used in diaphragm tops, have an even greater change of effective diameter with much smaller limits of travel. On the other hand, formed diaphragms having substantially cylindrical, instead of conical, shape have a nearly constant effective area and ample travel, their chief disadvantages in comparison with the slack flat limp diaphragm being that they are deformed at full travel while the latter merely roll and unroll without stretching and that they cannot be cradled as effectively as the latter which, when cradled nearly completely, can withstand surprisingly high differential pressures.

M. F. Behar.[6] In the field of measurements it has become a habit to publicize far and wide the new methods—the utilization of new physical principles—and to greet in more or less perfunctory fashion the appearance of all new instruments utilizing old methods. Sometimes this uniformity works a cruel injustice toward an inventor or a company, for whereas the majority of new instruments using old methods represent relatively small advances in the art, there are exceptional instances representing each a tremendous amount of research followed by painstaking development and culminating in a masterpiece which does advance the art.

"Another pressure recorder of the spring-loaded bellows type, and direct-writing at that!—oh, why bother?" Such would be the usual reaction.

But not in this instance!

Both this paper[1] and the new pressure recorder which it describes deserve an extraordinary reception. They mark the turn of the tide with regard to the attitude of physicists and engineers toward the various classes of pressure-measuring elements.

In considering the field of pressure instruments, one is struck by a strange paradox: On the one hand a great proportion of physicists and engineers manifest a preference for gravitational-method instruments that almost amounts to a prejudice against elastic-member instruments; on the other hand, a great majority of the instruments sold every year for pressure measurement depend on curved flattened tubes, helical tubes, diaphragms, metallic bellows, springs of various shapes, and other elastic elements that deflect in more or less exact proportion to the applied pressure.

Certain it is that easily read dials are preferable to visible liquid columns. Equally certain it is that perfect elasticity and total absence of hysteresis and variance have never been attained. All metals and alloys are imperfect. The best of springs fail sooner or later.

Evaluation of the properties of metals and alloys to resist static stress at normal temperatures has become a well-understood matter. But when it comes to methods of evaluation of resistance to repeated stress, to abnormal temperatures, or to wear, neither the methods of test nor the engineering application of the information are so well understood. And with regard to the "service life" or "accuracy life" of elastic members, as distinguished from their life until actual failure occurs, there is little exact information and there appears to be no accepted criterion. There was not even a set of accepted definitions until about three years ago.

This deadlock is nobody's fault. Users being convinced that elastic members can't be improved, they don't demand extreme-precision models and gage manufacturers don't have the necessary incentive to carry on lengthy and costly research. It has remained for a great oil company to subsidize Exline's work.[1] The demand was created by the unusual problems surrounding the measurement of bottom-hole pressures, where extreme accuracy is really worth millions of dollars to the oil industry. A great oil company comes to the rescue and the deadlock is broken.

This paper[1] greatly enriches the literature on elastic-member pressure gages. It will focus attention on the subject and some forgotten articles will be brought to light. The writer particularly likes the author's final paragraph calling attention to the importance of the energy term in mathematical analyses of elastic-member elements—a viewpoint deplorably neglected in most texts, yet one which we cannot overlook when we compare, for instance, the kinetic behavior of a small-diameter bellows and that of a large-diameter diaphragm—the former being of the "medium-force high-energy" class and the latter being of the "large-force small-energy" class.

And the extraordinary precision and accuracy of the new gage itself—exceeding the precision and accuracy of many gravitational instruments now used as secondary standards—will focus attention on the possibilities of elastic members. There will no doubt be a widespread demand for extreme-precision elastic-member gages of various other forms for various other important applications. A widespread demand having come into being, there will be the incentive; the gages will be manufactured and they will be put to important uses by physicists and engineers.

The deadlock is broken. The tide is turning. History is being made by a "development," praiseworthier than a "discovery."

Author's Closure

The author is in complete agreement with Mr. Davidson regarding the desirability of a sound exposition of the performance of the Bourdon tube and a comparison of its characteristics with other pressure-responsive elements. The Committee on Industrial Instruments and Regulators is endeavoring to secure such a paper.

Calculation of maximum stresses in both Bourdon tubes and bellows is unsatisfactory because of the incomplete state of the theory. For practical purposes an approximate value of this can be obtained by determining the pressure required to cause a given permanent deformation. Some work of this nature has been done in this laboratory on bellows but the results are so

[6] Editor, *Instruments;* founder and director, The Instrumentation Manual Project, Pittsburgh, Pa.

variable that they do not warrant publication at the present time.

Mr. Lee's method of calculating the bellows stiffness is distinctly superior to the approximate method used by the author. It is felt, however, that his statement that "the bellows stiffness in terms of an applied internal pressure would yield information more pertinent to the design of bellows gages than the bellows stiffness in terms of the applied axial force" is not true. Equation [3] of the paper represents the physical behavior of the bellows under pressure and shows that the bellows stiffness K_b is simply added to that of the restraining spring K_s. If no restraining spring is used the value of its stiffness will be zero.

Mr. Smith has suggested that consideration of the forces developed by an instrument element would be more useful in indicating the probable effects of friction than the stored energy and that the linearity of response of the element determines the applicability of the energy term. As Major Behar points out, the equivalent systems can exist using large force with small displacement on one hand and small force with large displacement on the other. Their equivalence can be shown only by considering their total stored energy or the change in the stored energy over a selected small region of their stroke. In the case of pressure elements the integral of Pdv over any part of the response curve would be equal to the integral of Fds, where F and s are the developed force and the displacement, respectively.

It is not quite clear what Mr. Smith expects in a least-squares analysis of the data presented in Fig. 16. The errors shown are deviations from true values which need not be evaluated by statistical methods. The probable error which was given was 0.6745 times the square root of the sum of the squares of all the errors divided by one less than the total number of observations. The author agrees with Mr. Smith that the probable error would be quite valuable in specifying instrument accuracies.

A discussion of the limp diaphragm was not included in the paper in order to save space for a more complete description of the bellows which the author felt was justified by the lack of other published material on this subject. The analysis of Eaton and Buckingham, reference (9) of the paper, fully covers the limp diaphragm. The author was not familiar with the work of Hodgson.

The author appreciates the work of the discussers in calling attention to the omissions and emphasizing certain points in the paper.

Corrections

Page 629, Table 2. A, a, B, and b are radii corresponding to the diameters given the same symbols in Fig. 6, except that B is the outside radius. In line 2 the values for B and b are interchanged.

Page 629, Equation [2]. The last term in the numerator should be changed to $\frac{16c^2}{c^2-1}(\log_e c)^2$.

Page 632, reference 15. The added term should be changed to read

$$+\frac{16a^2b^4}{a^2-b^2}\left(\log_e\frac{a}{b}\right)^2.$$

Pressure-Type Thermometer Systems[1]

Paul G. Exline.[2] The author presents a readable and interesting exposition which fills another gap in the broad program of the A.S.M.E. Committee on Instruments and Regulators. As with any well-written paper, this one leaves the reader with a desire for more information on the subject. In this case, the writer would like to see a treatment of the suitability of the various systems described to individual applications, together with the reasons why some ten different systems are necessary. This is by no means a criticism of the paper under discussion but a suggestion for future consideration.

The growing use of the word "spring" to designate any form of a Bourdon tube seems unfortunate to the writer. There is a large group of devices for storing and releasing energy transmitted mechanically to them, for which this term is entirely appropriate. Except for its shape, there is no more reason for calling a Bourdon tube a spring than for calling a diaphragm or bellows a spring.

The writer fully concurs with the author that there is need for further work on Bourdon tubes, both theoretical and metallurgical. Most of the theoretical work at present available is of little practical value since it deals with certain cross-sectional shapes little used in practice.

R. D. Webb.[3] From the user's point of view, this paper[1] is a very welcome one for apparently too many of us have accepted pressure-type thermometers without question. The reason for this can probably be laid to the fact that this type of instrument has been available for many years and long association has caused us to take it for granted. Too many engineers have operated their plants, taking engineering data with this type of instrument without any doubt in their minds as to its accuracy.

As we study the five major points into which the author has divided his analysis, we find that every one is of great importance to the thermometer user.

Point No. 1, the pen, which refers to the recording mechanism, is a rather fascinating one to study. The first reaction you get upon looking into the modern thermometer is that the manufacturers have retrogressed by going to the light, apparently flimsy, type of construction which so many of them now use, but years of constant observation of the heavier linkage type and of the lighter linkage type wins you over to the side of the modern trend. The light parts give the instrument a sensitiveness not otherwise obtainable, and wear is practically unknown. Where vibration is present, the lighter parts again show their superiority. The incorporation of a virtually rectilinear linkage on liquid and gas-filled thermal systems appears to be a logical means of achieving uniformly graduated charts; nevertheless, several companies produce instruments of excellent accuracy without resorting to it, although all too often three-point calibration of an instrument is difficult or impossible simply because of bad linkage angularity.

In the author's second point, the Bourdon tube, the user is naturally interested in the type of element used and, of course, the vital importance of such things as creep, set, hysteresis and endurance are recognized. The type of spring winding, whether it be spiral or helical, apparently has much to do with the linkage and its angularity just mentioned and also with the convenience of installing one or more thermal systems in a recording case. The helical winding apparently gives the high rotation necessary to use one-to-one linkage ratio between the spring and the recording-pen lever while the spiral-type winding offers the advantage of compactness. This seems slightly contrary to what the author has said in regard to the spiral spring's offering greater deflection.

The capillary connection tubing, part 3 of the paper, becomes of interest to the user mainly from one point of view, that is, durability. If of the type that uses a single heavy tube with no protecting armor, then the ability to stand flexing and also resistance to corrosion are the major considerations. The small capillary types with protecting armor usually have greater flexibility, and the use of Monel or 18–8 stainless-steel armor generally solves the

[1] Published as paper PRO-60-8, by L. G. Bean, in the November, 1938, issue of the A.S.M.E. Transactions, vol. 60, p. 657.

[2] Engineer, Gulf Research & Development Corp., Pittsburgh, Pa.

[3] Carbide & Carbon Chemicals Corp., New York, N. Y.

problem of corrosion resistance. This last type of construction seems to have a mechanical weakness usually to be found where the flexible armor is fastened to the case and to the bulb.

The subject of bulbs has been nicely covered by the author and here the user comes to realize that the main consideration is that of conveying the exact temperature of the medium being measured to the bulb; in other words, securing proper immersion. The subject naturally overlaps with point No. 5, the filling medium, simply because the size of the bulb, which greatly influences the ease of immersion, is governed by the nature of the filling medium.

The trend of the manufacturers appears to be toward smaller bulbs, this being clearly shown by the author's own company adopting the name "Small Bulb Type" for their compensated class-III system.

The second notable trend is one toward longer tubing lengths. This trend is governed a whole lot by the filling medium and the method of compensating it for tubing and case error; furthermore the use to which the thermometer is to be put in a large degree governs the type of filling that must be incorporated. If uniformity of graduations on the chart were a factor, the vapor type would be eliminated. As yet, ranges above 500 F are generally limited to the mercury and gas-filled systems. The low temperature range, that is, below —40 F, is restricted to liquid- and gas-filled instruments and here the power of the gas-filled type is questionable. The fluid in which the bulb is to be immersed sometimes becomes a factor in deciding the filling medium when separable sockets cannot be used. The mercury-filled systems are naturally restricted to bulbs made of ferrous metals, although the somewhat recent practice of making mercury-filled bulbs of 18–8 stainless steel has greatly widened the field of use for this type.

The writer agrees with the author that further work should be done on pressure-type thermometers. He names definite fields where this is most needed, but to the user the two things that are most important are accuracy and durability. Generally speaking, both of these will stand considerable improvement.

Some Fundamental Considerations in the Application of Automatic Control to Continuous Processes[1]

W. D. Wood.[2] As recognized by the authors, their paper is not an exhaustive presentation but furnishes a definite group of basic terms, which may well be acceptable to the A.S.M.E. Committee on Industrial Instruments and Regulators. Further terms could be appended from time to time as the literature on the subject grows. At present, a more complete listing would lead to confusion.

Although the paper is admirably presented, there are a few terms which warrant discussion. It is suggested, at the outset, that automatic-control terminology be divided, for clarity, into the three following classes: (1) Terms describing process or plant characteristics; (2) terms describing controller characteristics; and (3) terms describing performance. Discussion of the authors' items of terminology follow.

Item 1. The writer agrees with the authors' suggestion that this subject be referred to as "automatic-control technology."

Item 12. The term "set point" or "control setting" seems more descriptive than "normal" alone.

Item 13. This is affected by the comments regarding *Item 12.*

Items 14 and 15. The term "sensitivity" still seems to the writer to be best adapted to relate the ratio between cause and effect. It is logical and accurate to use the term "proportional sensitivity" to represent the coefficient of the second term on the right of the equation on page 647 of the paper. "Control band" is, however, an excellent descriptive term and might well be used in describing the characteristics of proportional control. The use of "sensitivity" is widespread in England and it is used here by at least two manufacturers.

Although the authors have discussed both proportional and floating control, they have neglected to present a term which describes the amount of floating-control action as their "control band" describes the amount of proportional-control action. That is, they have not described the coefficient of the first right-hand term of the equation on page 647. The term "floating sensitivity" seems logically adaptable here.

The term "sensitiveness" seems to the writer to describe adequately what the authors mean by "ultimate control sensitivity."

Item 16. "Droop" has evidently been chosen for want of a better term. There is no consensus of opinion here, but it seems to the writer that it ought not to refer equally to a proportional-control characteristic and to a two-position control characteristic. The writer suggests three terms to be used in describing this characteristic of proportional control: (1) "Set point:" the desired value of the "controlled variable" at equilibrium. (see *Item 12*). (2) "Control point:" the actual value of the "controlled variable"at equilibrium. (3) "Drift:" the difference between the actual value and the desired value of the "controlled variable" at equilibrium. "Drift" is a specific characteristic of proportional control resulting from load or demand changes. With these terms the "droop" characteristic is completely described without the use of a word which seems out of place in scientific nomenclature.

Item 17. To avoid confusion would it not be best to dispense with the term "throttling control" since it is here used to describe several types of control and has already been used to describe proportional control?

Item 19. The term "proportional control" alone seems adequate.

Items 23, 24, and *25.* Ought all these three terms to be called lags? "Velocity-distance lag" is entirely different in character from "transfer lag" or "demand-side storage lag." Each term affects the performance of a controller differently, that is, "demand-side storage lag" is generally advantageous, whereas "velocity-distance lag" is not. The writer suggests that the three terms be replaced successively by "storage response" or "capacity response," "transfer response," and "flow lag."

Item 26. "Controller response" is suggested. The word "controller" seems better here than "control" since the latter hints of a performance characteristic.

Item 27. "Measuring response" or "metering response" is suggested.

Item. 28. "Controller agent response" is suggested.

Item 30. "Controller dead time" seems preferable.

C. E. Mason.[3] The general qualitative analyses, as presented by the authors, and the recent paper by Haigler,[4] are valuable in developing an appreciation of the fundamental factors affecting the physical reactions of process lag. Although the ultimate object of the efforts of the A.S.M.E. Committee on Industrial Instruments and Regulators may be to formulate rules applicable to quantitative analysis, it is essential that all members of the Committee working on this phase of its work have a thorough and common understanding from the viewpoint of qualitative analyses.

[1] Published as paper PRO-60-6, by E. S. Bristol and J. C. Peters, in the November, 1938, issue of the A.S.M.E. Transactions, vol. 60, p. 641.

[2] Engineering Research Department, Taylor Instrument Company, Rochester, N. Y.

[3] Chief Engineer, The Foxboro Company, Foxboro, Mass.

[4] "Application of Temperature Controllers," by E. D. Haigler, Trans. A.S.M.E., vol. 60, November, 1938, paper PRO-60-5, p. 633.

It seems possible that some of the rules developed from pure qualitative analyses may require some revision or qualification after studying quantitative analyses, because the actual value of the effect will be the algebraic sum of several influences. However this possibility should not discourage the development of rules suggested by qualitative analyses alone.

The authors' definition of the term "normal" seems to have possibilities of confusion due to the presence of the word "desired." However, omitting it would apparently change the intended meaning. Controllers with "drooping characteristics" will function to maintain different values of the controlled variable if the demand or the conditions of the supply were changed. The desired value of the controlled variable does not change with these changes in demand or supply, except in a very few special cases where a temporary change may be desirable in order to effect what commonly has been called "averaging control."

It seems to the writer that two distinct terms must be used—one definitely representing the single-point mechanical setting of the controller, and one representing the actual or average final balanced condition of the variable resulting from the characteristics of the control system and certain specific conditions of the supply and demand. The authors' definition actually defines neither of these, but if the word "desired" be omitted it would define the latter. It was understood of course that these two terms would become synonymous for controllers not having a "drooping characteristic."

In order for the work of the Committee to be of material value to the industrial designing and control engineers, these qualitative analyses must be extended to quantitative form. The need of these two distinct terms, referred to previously by the writer, will be apparent when attempting quantitative analyses.

The writer is preparing, for future presentation to the Committee, a paper dealing with quantitative analyses of the effect of process lag. The results of this work indicate the desirability of introducing new definitions which are not necessarily apparent from the qualitative viewpoint. In some instances it will be desirable to reconsider definitions so as to be equally practical in both methods of analysis. It is the writer's opinion that final decision on recommended definitions be withheld until some work has been done from the viewpoint of quantitative analyses.

Reconsideration of the term defined by the authors as "normal" will affect the definitions of "deviation from normal."

"Control band" or "throttling range" seems to apply only to the proportional characteristic of a controller and becomes meaningless when other functions compensate for "drooping characteristics."

Since the term "throttling control" has been used commercially to designate a proportional control, it seems to the writer that the term should be completely discarded. However, if we disregard the possible confusion, it could be defined as "a general classification of control employing a corrective action which is capable of maintaining all intermediate values of the final control element." It seems also that this definition would be in accord with Haigler's suggestion.[4]

Storage lag retards in the sense of slowing down, but it does not effect a lost-time reaction, as might be inferred by using the word "delay." This comment also applies to the authors' definition of "transfer lag." Although the retardation is of a different nature, it is in reality the compound effect of two or more capacities separated by a potential.

"Velocity distance lag" in the same sense is not a retardation, but a definite time delay. The retardation which might be observed is due either to the storage lag which is always present, or to some small effect of transfer lag.

It must be appreciated that storage lag is the only process lag which might be considered as existing alone. Storage lag exists in all applications. The presence and proportions of the other two—which are also always present, at least to some small degree—constitute the actual difficulties encountered in automatic control.

It would seem practical to consider that the other lags defined by the authors as "control lag," "measuring lag," etc., are really one of the three major lags located in various parts of the complete system. It is the writer's opinion that these can, without confusion, all be defined by one of the first three general definitions.

Referring to Fig. 6 of the paper under discussion, it might be interesting to note that, if a sudden change had been made in the flow or temperature of water entering the tank (demand), the resultant temperature curve would be very similar to the dashed curve shown in the figure, although transfer lag does exist. This analysis is suggested only to prevent the impression that the absence of the S-curve characteristic is indicative of no transfer lag.

From a quantitative viewpoint, the curves of Figs. 13 and 14 of the paper might justify some comment; however, since they are qualitative only, they should be drawn as shown in order to illustrate the important characteristic which the authors wish to emphasize.

[The following is a discussion of the papers by E. S. Bristol and J. C. Peters[1] and by E. D. Haigler,[4] respectively. Editor.]

M. J. Zucrow.[5] The paper under discussion is in a large measure complemental to Haigler's.[4] For this reason, it is difficult to discuss it without making some reference to the one by Haigler.

The authors are to be congratulated upon their clear presentation of the fundamentals of a difficult subject. Their openmindedness in subordinating their own preference for the term "regulation" to the word "control" is praiseworthy. It raises a question, however, regarding the name which should be adopted for the art under consideration. Since the standardization of terminology is one of the main activities of the A.S.M.E. Committee on Industrial Instruments and Regulators, it might be of value to have the question of control versus regulation settled at an early date. Like the authors of the paper, the writer prefers the word "regulation," which is more consistent with the Committee's name. Furthermore, the definitions indicate that "regulation" more closely describes what is of interest, even though these words are synonyms. The definitions are as follows:

Regulation: To adjust to or maintain at a desired, required, or standard condition or action; put or keep in good order; adjust according to circumstances or requirements; as, to regulate a watch or mechanism; to regulate the ventilation of an apartment.

Control: To exercise a directing, restraining, or governing influence over; direct; counteract; regulate; as, to control the engine of a motorboat by a lever; to check by a duplicate register; verify or rectify, as an account.

The authors have treated with brevity a large amount of subject matter. To discuss all of the topics mentioned in their paper would make this discussion too lengthy. Consequently, the writer has confined his remarks to only a few of them.

The authors' discussion under the subtitle "The Automatic Control System Applied to the Process" warrants amplification to increase its generality.

Most physical processes to be regulated involve plant capacity. There is a flow of energy (or fluid) into the capacity and a flow of energy is being continuously withdrawn from it. The inflowing energy is termed the "supply" and the outflowing energy the "demand." Conditions can be such, however, that these terms should be interchanged. The conventional regulation

[5] Consulting Engineer, Chicago, Ill. Mem. A.S.M.E.

problem is one where the regulation apparatus must so vary the "supply" that it will always equal the "demand." Ordinarily, it is difficult to measure the "supply" and the "demand" directly. Instead, some new variable which is an index of the balance between these energy flows is measured. The object of the regulation is to keep this index at its proper value, because then there will be a balance between the "supply" and "demand." This index, which may be a temperature, pressure, or speed, is really a measure of the potential energy contained in the regulated system. For example, if the heat supply to an electrically heated furnace were to be regulated, this index would be the temperature of the furnace in the system. Similarly, when the steam flow through a pipe is regulated by a pressure-reducing valve, the steam pressure, used for influencing the opening of the valve, is taken as the index of balance. In this example, even though the steam flow through the reducing or supply valve equals the flow through the demand valve, the object of the regulation is not achieved unless there is no increase or diminution in steam pressure. It has become common parlance in some fields of regulation to call this index of potential-energy level the "storage" as distinct from "capacity." Using the aforementioned terms, the general statement of the regulation problem is the equating of "supply" and "demand" and the maintaining of a constant "storage." It should be noted here that there are problems where the "demand" can be measured and the "supply" adjusted directly from this measurement, but the problems discussed by the authors and by Haigler[4] are not of that type.

Owing to the frequent use of the term "storage" in the sense described by the writer, the Committee should consider the value of reserving this word for such usage. The word "capacity" could then be restricted to describe or measure the physical dimensions and characteristics of the process equipment. Capacity involves not only the physical size of the equipment but also the maximum energy supply which is available. This has not been clearly pointed out by the authors. It is a measure of the time required to produce a definite temperature change with the heat-supply valve in its wide-open position. Storage on the other hand defines the heat contained in the system when the supply and demand heat flows are equal.

Although the writer, like others, has used the term "capacity lag" indiscriminately, he now questions the appropriateness of this term unless it is given a definite meaning. Lag is the "retardation of movement for any cause;" it also means "any specific amount of such retardation." Since this property of the plant must ultimately be evaluated in a quantitative manner, some distinction must be made between the term "capacity lag" when used to denote the characteristic temperature curve of a plant and its use when referring to a definite time interval. Since the designer of the process equipment must be provided with specific values of criteria as a guide in design some simple evaluation of the foregoing factors is required. Since, as pointed out, the temperature reaction of the plant involves not only its physical dimensions, but also the maximum energy flow available, a criterion similar to the "time constant" used in the regulation theories developed for combustion control might be serviceable; this is discussed later.

It is well known that, in the usual case, when the position of the regulating valve is changed, the value of the regulated variable (temperature in this case) does not assume a new value immediately. Ordinarily, the plant temperature changes in some such manner as that shown in Fig. 1 of this discussion. When the valve is opened instantaneously from its initial opening m_0, to a new position m_1, the temperature changes slowly at first, then it increases at a more or less constant rate, and finally approaches a new equilibrium value asymptotically. The following question naturally arises: What is the "time lag" as a unit of measurement? Callender and Stevenson[6] define it as the time, in seconds, which elapses between the instant the valve was moved and the beginning of the constant rate of temperature change. They base their definition upon the fact that, with instantaneous response of the regulating valve to a temperature deviation, the deviation will grow unchecked for the duration L, defined as unit time lag. This deflection bc may be regarded as inevitable. According to this, the automatic regulator "should be able to stop a fluctuation before it has developed to more than twice its inevitable value, and subsequently damp the oscillations to comparatively small values in not more than two complete cycles." This definition of time lag is presented merely to illustrate that there is a problem still unsolved; a simple method for determining the result of the combined action of the regulator

[6] "The Application of Automatic Control to a Typical Problem in Chemical Industry," by A. Callender and A. B. Stevenson, Society of Chemical Industry (London, England), Proc. Chem. Engg. Group, vol. 18, 1936, pp. 108–117.

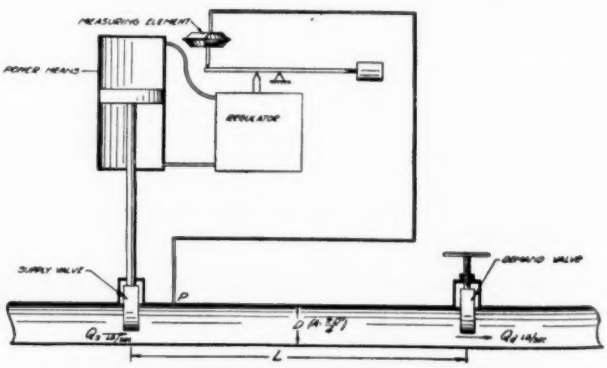

FIG. 3. PRESSURE REGULATION FOR A PIPE

and process equipment before the latter has been designed. Since the temperature response characteristic due to plant capacity and thermal resistance cannot be modified by anything in the regulator, some simple criteria must be established and means devised for evaluating the total time lag and maximum deviation, to aid the designers of process equipment.

C. E. Mason of the Foxboro Company has made an excellent beginning in this direction.[7] He utilizes the analogy between the conventional heat-flow problem and capillary fluid flow to give a picture of the process. As an example of the analogy, Fig. 2 of this discussion, which corresponds to Figs. 1 and 3 of Haigler's paper,[4] is presented. The areas of the tanks a and a_1 represent the demand-side and supply-side capacities. The resistance R_1 is the thermal resistance between the two capacities, it being assumed that the liquid flow rate q corresponding to the heat-energy flow is given by

$$q = \text{const} \times (T/R)$$

The problem is for a given change $(Q_d - Q_s)$ or $(Q_s - Q_d)$ to find the variation of the storage T as a function of time. It is unfortunate that Mr. Mason has not published more of his work.

It was mentioned earlier that in fluid-flow problems, such as are encountered in steam-power-plant practice, it is convenient to express plant capacity in terms of what is called a time constant. Stodola, who introduced this constant, calls it the "Anlaufzeit," which literally means "starting-up time" or "traversing time." The significance of this term is illustrated as follows:

Consider a conduit such as that shown in Fig. 3 of this discussion and assume that a compressible fluid is flowing through it. If the demand flow Q_d exceeds the supply flow Q_s, then the deficiency is obtained from the fluid stored in the volume LA, with a corresponding drop in the absolute pressure P. If the unbalance $Q_d - Q_s$ is 1 per cent, then the absolute pressure drops at the rate of 1 per cent per sec. Conversely, if the pressure increase by 1 per cent per sec, then the excess flow into the pipe would be 1 per cent. Consequently, if it were conceivable that this relationship continued for all flow changes, up to 100 per cent, then the time required for a pressure change of 100 per cent would be that required to add or remove the volume of fluid LA (cubic feet) from the pipe with a flow rate q; this would be given by the ratio LA/q. The dimensions of this ratio are those of time and it is a measure of the capacity of the system. If Q be that value of q which corresponds to the maximum difference between the supply and discharge flows (for example, supply = Q and demand = 0), the supply valve will have been instantaneously opened from 0 to its full-load position and for this condition the ratio is LA/Q and may be termed the "capacity–time constant."

Thus, if the "capacity–time constant" be 2 sec, it means that after a sudden change in the position of the regulating valve from zero to full-load flow, it will take 2 sec before the pressure in the pipe changes 100 per cent. This means that the rate of pressure change is 50 per cent per sec. This relationship is truly valid only for small pressure changes, since these basic relationships do not apply to large changes in pressure. However, in the quantitative analysis of regulation problems, the pressure changes are small and these relationships are applicable.

For conduits or containers which have fixed volume it is seen that the "capacity–time constant" is merely the ratio of the volume between the supply valve and the demand valve divided by the maximum flow for the system. There are cases, however, where the unbalance in flows is accompanied by a change in volume as well as by a change in pressure. Detailed discussions of this subject can be found in the books of Th. Stein[8] and Wünsch.[9]

The last part of the paper contains many definitions of important concepts pertaining to the art of regulation. The authors have given this particular phase of their material considerable thought, and these definitions should be of great help to the Subcommittee on Terminology in carrying out its program. The writer feels that the appropriateness of the definitions is something for the Committee to determine and he has, therefore, refrained from discussing them.

ALBERT F. SPITZGLASS.[10] This paper, together with Haigler's,[4] opens up the subject of qualitative approach to control problems and their relation to the processes.

While indicating a preference for the terms "automatic regulation" over the terms "automatic control," the authors have used the latter terminology throughout their paper as a concession to general practice. Such an attitude is obviously a very laudable one, but in the present case it does not seem as though the usage of either term has become well enough established to justify the selection of any but the most suitable term. The discussion by Zucrow[6] has emphasized this point and by reference to accepted definitions of these terms has indicated that we are not faced with a choice of words but a choice of ideas. A regulator is not the same thing as a controller, if we are to give any weight to the definitions in standard dictionaries, but obviously a regulator is a specific form of controller whose object is to maintain some condition at its normal value.

Therefore, if we use the term "regulation" and use it in the sense of maintaining normal values, then we do not have to distort our theory of regulation to take into consideration problems pertaining to program controllers, safety devices, interlocking mechanism, and starting-up operations. It is not that these problems do not play an important role in the general problems of control. It simply is a fact that the fundamental principles we are trying to study and classify now all have to do with the maintenance of normal value of continuous phenomena within certain limits and there is no way to stretch our theory to include this other type of problem, which is always discontinuous in some respect or other. It would not be necessary, therefore, to make the exception noted by the authors, namely, that demand-side storage may be disadvantageous when it is desired to establish promptly a new normal temperature. True enough, it is a disadvantage but that is beside the point, just as a question of the safety involved in large demand-side storage might be beside the point.

In both this paper and that by Haigler,[4] emphasis is placed on "factors favorable to control." The Haigler statement is qualified by "as reflected by smaller cycles with on-and-off control and narrower control bands with proportional control." The present paper[1] makes no definition. The conclusions of both the papers are accurate if referred to the definition of favorable factors advanced by Haigler.[4] However, there is a natural tendency to generalize from such a statement and while no such intent exists on the part of the authors, it is possible to get the impression that these factors are favorable to all types of regulation.

Since these authors[1,4] divide regulators into four general classes, it seems more logical to refer all factors, favorable or unfavorable, to the classification and the specific type of regulator, rather than to make a general rule and then make exceptions. The

floating regulator cannot be considered a mere exception to the rules applying to regulators in general. It embraces a tremendously important field of activity and its theory has been propounded at great length, especially in the foreign literature. Among the most able treatises on the subject of industrial regulators, and one which treats at great length on floating regulators, is that by Th. Stein.[8] The point of view that he presents has received too little consideration in this country, even though G. W. Smith and Dr. Zucrow both discussed this work at great length last year in connection with the paper by Ed S. Smith, Jr., on automatic regulators.[11]

In order to refer these qualitative statements to regulators, they should first be divided into a broad classification of a type which lends itself to a comprehensive qualitative treatment. This might be accomplished by dividing automatic regulation into the following main groups.

1 *Stabilized Regulation* (*follow-up reaction always included to give stability*). (*a*) Inherent follow-up—for systems with sufficient back pressure or flow-head reaction (self-regulation) to give inherent stability. (*b*) Mechanical follow-up—for systems having insufficient follow-up reactions to render them inherently stable.

2 *Unstabilized Regulation*. In this class the problems of expediency are controlling factors, as with two-position regulators.

For convenience, a complete tabulation of classifications presented by recent authors is given in Table 1 of this discussion to indicate the relation of this approach to that of other authors.

Authors' Closure

A considerable proportion of the discussion presented comprises different opinons with respect to terminology suggested by the authors and serves to fulfill one of the objects aimed at in the preparation of the paper. Such opinions are believed to constitute material suitable for review by the Terminology Subcommittee and it is felt that not much would be gained by attempting detailed replies to the various comments submitted. These closing remarks, therefore, refer to only a few of the more important points of difference in terminology.

Mr. Wood suggests that the term "response" be substituted for "lag" in most cases where the latter is employed in the paper. However, response of a process or control system is a reaction or effect having several characteristics such as magnitude, total duration, and lag. The latter term is merely one of the several characteristics of "response" and was broadly defined as "retardation *or* delay in response" in order to allow for just such differences as exist between "velocity-distance lag" and "demand-side storage lag." Lag may consist of an initial time delay before any appreciable response can be detected, a reduced rate of response, or both.

The authors are in complete agreement with Mr. Mason's view that both qualitative and quantitative analysis should be considered in setting up terms and definitions. The Committee will no doubt welcome further specific suggestions in this direction.

It is to be emphasized that the designer of a process may achieve marked improvements in its operating characteristics without quantitative analysis if he understands the fundamental factors involved in making it easy to control.

At present, quantitative analysis is in a nebulous state and, in the case of temperature control at least, cannot be readily applied except to the simpler cases. It is to be expected that as work continues this situation will be improved upon.

The point made by Mr. Mason in connection with the curves of Fig. 6 warrants enlargement. For purposes of discussion it may be considered that the rate of water flow, in Fig. 5 of the paper, is to be varied to maintain constant the temperature of the water within the tank, and that the degree of electric heating is an independent variable. The varying rate of electric heating may then be considered as the demand (for cooling) and the flow of cooling water as the supply. With supply and demand reversed as thus considered, the system of Fig. 5 will be at least as easy to control as that of Fig. 2. Transfer lag between heater and tank is helpful in that it retards the effect upon the temperature of demand changes. Of the response curves of Fig. 6 it may be said that, in the absence of measuring lag, the one which best indicates the relative ease of control is that obtained in response to a change in flow of the control agent. From this viewpoint, the important transfer lag is that between the point of application of the control agent and the point of measurement.

Nearly all of the curves contained in the paper, including those of Figs. 13 and 14, were taken from the results of laboratory tests with a commercial controller, using a heater of the form shown in Fig. 5. The exceptions are those of Figs. 3, 6 (dotted line), 7, 12*c*, and 12*d*.

Dr. Zucrow's conclusion that more is required of a controller than to maintain equality between supply and demand seems to hinge upon the definitions of these terms. If, in his Fig. 3, the demand is considered to be for steam at a specified pressure, the requirement of "constant storage" is automatically taken care of.

The apparent slighting of floating control noted by Mr. Spitzglass is the result of concentration on temperature control to which this type is rarely applicable. The authors are well aware of the importance of floating control in other fields. They believe

[11] See G. W. Smith's discussion of the paper "Automatic Regulators, Their Theory and Application," by Ed S. Smith, Jr., Trans. A.S.M.E., vol. 59, February, 1937, p. 125. Also, see M. J. Zucrow's discussion of the same paper, p. 132.

that a discussion of the application of automatic controllers outlining the fields in which each type is used would be well worthwhile.

The authors did not intend to imply any personal preference for "automatic regulation" as opposed to "automatic control," as inferred by several discussers.

Application of Temperature Controllers[1]

JAMES L. KIMBALL.[2] The writer believes that control problems could be simplified greatly if a definite maximum band could be agreed upon for both pressure and temperature, say 10 per cent of the total, and that such a band be specified as adjustable between zero and full range. For cases where drift is objectionable, the more expensive types of controller, involving reset, would be indicated.

Such an approach would be comparatively simple, and would relieve the manufacturer of the responsibility for unfavorable factors of the system or process over which he had no hand in the making. At the same time, it would place in the hands of the prospective user definite information as to the characteristics of the equipment manufactured in conformity to an accepted code.

A standard of this kind would give a basis for determining the degree of area when adjusted to its maximum band, whereas at present with fixed bands varying in percentage of the total, no definite comparison is possible.

These two factors, taken together, would give the complete story of any regulator. On the other hand, if the author were to rewrite his paper to apply to pressure control, it would assist materially in straightening out our present-day control problems.

J. B. MCMAHON.[3] The approach to this problem outlined in this paper[1] is a hopeful sign that our large users of automatic controllers are becoming very much aware of the coordination necessary between designers of equipment and builders of automatic controllers. Except in amazingly few instances this feature of design, designated as "controllability" by the author, has been entirely neglected by designers of processes and process equipment.

It is noteworthy that the author designates this only as an approach, not as a solution. Practical experience in the application of automatic controls soon shows that at the present time most of our analyses of control problems must of necessity be based on what amounts to almost nothing more than hunches, as it is impossible to evaluate the factors involved accurately enough to be able to call most of our analyses anything more. The conditions which the author sets up are susceptible to this inadequacy, and should not be used quantitatively on that account.

In the author's analysis of the various kinds of process lag, the effect of transfer lag is not discussed very fully, nor is a really adequate definition of transfer lag made, although it is a very bothersome factor in any problem where heat must be transferred through a wall. Transfer lag is due to two factors, i.e., thermal resistance and heat capacity. It exists only because of the simultaneous presence of these two factors, and would not be bothersome if either were absent. Any heat-transferring material possesses both. Thermal resistance makes necessary the presence of a temperature gradient in order to transfer heat. Heat capacity delays the establishing of changes of temperature gradient. The two in combination give rise to some very queer results when present in combination with other types of lag, as they almost always are.

One type of heat-exchange problem occasionally encountered is not mentioned by the author; that is, where it is desired to extract heat from a fluid without interfering in any way with its flow, which makes it necessary to control the flow of the fluid whose temperature is being controlled. The diagrammatic layout would be the same as Figs. 2 and 3 of the paper under discussion, except that the controlled valve would be in the demand line along with the temperature bulb. Generally speaking, such applications are very difficult to control, except over a very limited range, and are to be avoided wherever possible. By-passing part of the supply fluid around the exchanger by means of a three-way valve is often a happy solution to this problem.

It is to be hoped that this paper[1] will be the forerunner of many more approaching this matter from this standpoint. A series of papers such as this will hasten the time when mathematical analysis will make it possible to prove to equipment and process designers that "controllability" is just as vital a factor in design as any of the other factors with which they have to deal.

WALTER C. WAGNER.[4] While the author of the paper under discussion presents an effective approach to the general solution of a familiar subject of limited scope, the writer believes that the author has opened up a method of attack that will lead to broader applications. Although the subject specifically is applicable to process control, the writer finds in it principles involved in the elements of temperature control as applied, for example, to the related subject of temperature control of buildings purchasing steam-heating service from a public utility. The control of living conditions obviously departs widely from conditions predetermined by a process engineer, inasmuch as he determines the character of the demand for temperature, whereas in the case of meeting the varying demands of the public, a new control variable enters into the picture. Basically, however, the method of attack of a problem, based upon certain assumptions of normal average conditions, also requires instruments for research and their application to determine finally control requirements.

While there is not included in the paper[1] the recognition of the economics of the liquid or gaseous forms of supply, the ideal maximum quantity, and duration, of flow may be such as to affect the cost of supplying such heating (or cooling) service sufficiently to justify the modification of the demand for ideal requirements for such heating service. Similarly, the measurement of the quantity of flow and of its sustained demand must be measured with an acceptable accuracy. Should, for example, a change in rate of flow of steam service be great or its frequency be such as to affect this accuracy, the designing engineer must give that serious consideration.

The importance of systematic response in the control systems for process control closely parallels that for steam-service control. In general, therefore, while the writer's discussion has been concerned with the application of temperature controllers to other than a process control, it is hoped that others concerned with the subject of steam-heating service will give a wider application than intended by the author to the principles involved in his paper.

M. F. BEHAR.[5] Eight years ago someone prefaced a classification and discussion of the "objects" of measurement or control

(such as, processing conditions, composition, and properties) with the following declaration: "Industrial instruments are definite means of attaining definite ends. From the viewpoint of the industrial engineer the *application* of an instrument is of far greater importance than the instrument itself." This theme was then elaborated in opposition to a school of thought—then in the majority among manufacturers and users of industrial instruments—which held that process-control devices had reached such a state of development that process-control engineers need no longer worry, for the marvelous new robots would not only do the work of human eyes watching dials and human hands operating valves, but would do it with far greater accuracy however difficult the application.

The author of the paper under discussion belonged to what was the minority school of thought eight years ago. That it is now the majority school of thought is due in no small part to the quiet, unassuming influence of the author. In this paper he has epitomized his philosophy. Wisely indeed, he has not attempted to compress into the limitations of a "paper" his approach to the analysis of controllers in general and of applications in general, but has restricted his treatment to one of the numerous entities which are controlled automatically in modern industry, that is, temperature, the most important processing condition.

The only other nonmathematical analytical discussion of temperature controllers and temperature applications considered together as one problem appeared seven years ago. In these seven years, there has been so great a spread of the recognition of the view that the application is as important as the controller, that one naturally expects a corresponding improvement in the treatment. This paper[1] comes up to these expectations. It is open to only one major criticism—it is not long enough. The author has had so much experience with the automatic control of conditions other than temperature, and with the automatic control of physical and chemical properties, that he could have written an extremely useful introduction, comparing temperature-application problems with these other purposes of automatic-control devices. There are not only interesting differences but interesting analogies. Temperature is distinguished from most other conditions by time elements which follow definite laws—a body of laws summarized by the expression "thermometric lag." This lag is so definite a phenomenon as compared with the elusive entities often met with in application engineering that the author might well have inserted a brief treatment of it in relation to automatic control. This cannot be done adequately without mathematics, so perhaps this is the reason why the author refrained from doing it in this particular nonmathematical paper.

The originality of the section entitled "Classification of Problems" is striking, and one may express the hope that this same approach may be followed in dealing with parallel subjects, that is, humidity control and the continuous control of physical properties such as viscosity. The author no doubt could do so if he had the time, but this is an age of specialists and, the author having shown the way, parallel discussions along the same line of approach would enrich the engineering literature if written by specialists in these other control problems. For example, one cannot help but notice in this paper a little slip in a passing reference to humidity measurement and control by the psychrometric method, where the author says that the dry bulb must not be shielded—which is bad advice, for it is extremely important to minimize radiation effects when using psychrometers with dry bulbs, and the "true" psychrometers are those in which both the dry bulb and the wet bulb are surrounded by two shields, that is, two pairs of concentric tubes with surfaces highly polished in order to eliminate all radiation effects.

Methods of classification can be discussed endlessly without arriving at universally acceptable conclusions. The only scientific basis of dividing a number of entities is to formulate a scheme of mutually exclusive and collectively exhaustive categories, based upon the easily recognizable characteristics of the entities and upon actual relations between them. Now then, when dealing with such entities as the kinds of behavior of automatic controllers in their active state, it is extremely difficult to formulate a valid scheme. To put it in another way: It is relatively easy to classify controllers in their inert state, as mere dead things, and it is relatively easy to classify furnaces, ovens, fractionating towers, and other applications in their inert state, but it is infinitely more difficult to classify the phenomena of what might be called "life"—the things that happen when a controller is engaged in controlling an application.

The author has chosen a compromise classification—a dual classification; he does not attempt to go into the infinite variety of these modes of behavior, but he classifies controllers as such—dead controllers, not hooked up to applications—according to five general classes of modes of which they are capable by reason of their design. Then he classifies problems (as discussed by the writer), and in so doing he classifies also the favorable factors that make for controllability. Finally, he gives examples showing how his original method of classification can be applied to various pieces of industrial processing equipment.

The writer's admiration for this original treatment is deep and sincere, for he had tried to work out in 1927 to 1930 a classification of the infinite number of kinds of behavior exhibited by "living" temperature controllers (controlling their applications) into twenty-odd classes of modes of control, starting with the on-and-off modes and working up to the mode which recognizes the rate of change of the controlled temperature. The writer is the first one to acknowledge that this qualitative and almost "popular" classification is obsolescent, but he nevertheless continues to maintain that the only perfect approach to a thoroughly scientific treatment of the problem is along the trail which he then blazed. Such a line of approach, however, is beset with mathematical difficulties, for these modes of control, the phenomena of "life," so to speak, which may be observed when a controller is at work, are relatively easy to classify qualitatively but difficult to classify quantitatively in the exact language of mathematics. That they are relatively easy to classify qualitatively is amply proved by the fact that it was done seven years ago; that they are difficult to classify into mathematical categories was demonstrated in Le Corbeiller's paper.[6]

A. F. Spitzglass[7] and M. J. Zucrow.[8] Recent years have witnessed a broad extension of the field of automatic regulators in industry. This has been accompanied by much confusion due to the lack of a common language for the art and to misconceptions regarding the purpose and abilities of automatic regulators.

In former years the actuation of the final control element, such as valve, damper, or rheostat, was done manually by an intelligent workman who based his actions upon observations and judgments derived from his familiarity with the process. The basic reasons for applying the automatic regulator was to relieve him of the many repetitive adjustments he was wont to make and to provide the process with a constant attendance independent of the human equation. These functions are usually well served by automatic regulators.

The fact that a regulator cannot exercise human judgment is frequently overlooked. As a result, many contradictory conclusions exist regarding the merits of automatic regulators.

---

[6] "Sur les Oscillations des Régulateurs," by Le Corbeiller, Proceedings Third International Congress of Applied Mechanics, Stockholm, 1930, vol. 3, pp. 205–212.

[7] Consulting Engineer, Chicago, Ill. Mem. A.S.M.E.

[8] Consulting Engineer, Chicago, Ill. Mem. A.S.M.E.

This is in large part due to misguided efforts to evaluate their merits as devices per se, without taking into account the characteristics of the process equipment to which they are applied. For, to reach intelligent and correct conclusions, it is fundamental to consider the process, its equipment, and the regulator, as an entity. The differences in regulator characteristics are merely the different laws of control-valve movement built into them by the manufacturer. No such standardization exists, however, for the process equipment or the process itself. Consequently, since these latter exercise an important influence upon the controllability of the process either manually or automatically, the designers of such equipment should pay particular attention to the factors which will make the process easy to regulate. For it is wishful thinking to suppose that a process which is so designed that it is difficult to regulate with human supervision can be well regulated by a machine which has no brain.

The author, a user of automatic regulators, is to be complimented for his unbiased recognition of the importance of correctly designing the process equipment. His qualitative analysis of heat-exchange processes will do much toward pointing out to process designers the factors which must be given consideration if good regulation is to be obtained. While his paper[1] is limited to a discussion of heat-exchange equipment, the fundamental principles, which have been frequently overlooked or misunderstood, have a much broader application. Although he has limited himself to qualitative analyses only, the solutions are so clearly defined that designers should have no difficulty in applying them. Until the physical picture of the regulation of process has been correctly painted and is well understood, quantitative analyses may be of doubtful value.

The paper presents a classification of automatic regulators which is worthy of consideration. In spite of the great number of different commercial regulators on the market, it becomes obvious that the number of basic types is relatively small; therefore, the subject lends itself to basic classification quite readily. This is due to the fact that fundamentally the regulator involves only two functions: (1) The measurement of a physical variable and (2) positioning of a control element in accordance therewith.

Ivanoff[9] points out that, by classifying the methods of measurement the regulator is classified at the same time, since fundamentally the regulator positions the control element in proportion to the measurement function to which it is responsive. This is a slightly more basic method of classification than mentioned in the present paper and it might be well to compare the two, as in Table 1 of this discussion. The on-and-off or two-position methods are usually treated as a separate class as noted in this table, but actually these are limiting cases of the proportional or floating method. Thus, a very high-speed floating control and a proportional control with an extremely small band can be considered as on-and-off or two-positioning controllers.

TABLE 1 COMPARISON OF IVANOFF'S AND HAIGLER'S CONTROLLER CLASSIFICATIONS

Ivanoff	Haigler
(*a*) On-and-off method	(*a*) On-and-off method
(*b*) Actual temperature deviation	(*b*) Proportional wide-band, and proportional narrow-band
(*c*) Integral of temperature deviation	(*c*) Floating type
(*d*) Deviation plus integral (proportional plus floating)	(*d*) Proportional-reset
(*e*)[a] The rate of change (first-derivative method)	.....
(*f*)[a] The rate of change plus integral (first-derivative plus floating)	.....

[a] Ivanoff also adds these two types of specialized controllers which are not in very great usage.

The concept of supply-side capacity and demand-side capacity is important, although it only applies to a system that can be defined in terms of two capacities. The logical extension of this type of distinction is to define the system in terms of as many capacities as actually occur, with each capacity defined and bounded by the resistances which separate it from the next capacity. This has been done by recent writers and the author deserves commendation for emphasizing this concept.

In using the qualitative analysis of the author, the difficulty lies in the fact that it is impossible to think in terms of more than two capacities without some sort of mathematical definition. Furthermore, such concepts as high speed and low speed, wide band and narrow band, and large and small capacities are all relative and are only valuable in showing trends. Unfortunately, if the qualitative approach only be used, exceptions begin to be found which would not appear if the terms were defined quantitatively, as in the method of the hydraulic analogy. Until such quantitative solutions are available, an analysis such as the author's is of great assistance to the users of equipment.

S. D. Mitereff.[10] In so far as the paper elucidates the factors facilitating the application of temperature control in process industries, it is admirable. In so far, however, as it directs the attention to the necessity of "tailoring" the process equipment to make it easily controllable with the simplest types of regulators mentioned in the paper, the writer believes the paper to be somewhat misleading.

With the present tendency toward ever-increasing sizes of equipment, made often of special material, any change in either projected or existing plants is extremely costly. Moreover, the annual value of product passing through a given piece of equipment is sometimes enormous. Under these conditions, the process equipment should be designed almost entirely from the standpoint of efficiency consistent with capital cost and not from the standpoint of easy controllability. If two of these objectives be compatible, so much the better. If not, then it is up to the control engineer to select control apparatus which is "tailored" to the plant. It should be stated here that controllability is not an absolute term, depending as it does upon the type of control equipment contemplated. The process which is not controllable with one type of regulator might be, and usually is, easily controllable with some other type.

On the basis of his own study, as well as of a perfectly general theorem of Minorsky (discussed later by the writer), the writer can state a priori that there is no temperature-control problem, however involved, which could not be solved to any desired degree of accuracy by the use of the rate-of-change-responsive regulators, provided that by and large the process is one of systematic behavior. That such regulators are more complex than ordinary types should not bar their wide acceptance. The only valid criterion aside from cost, for selection of a piece of equipment is its reliability, using this term in its broad application to the process as a whole. Cost is a factor, but the incremental cost of modification of any good regulator to make it respond also to the rate of change of temperature consists of the cost of few simple additional parts and this cost is vanishingly small compared with saving in capital and operating cost resulting from the use of such advanced regulator characteristics.

Reliability of equipment depends to a great extent upon its designer. With the multitude of ideas made available recently, there is no reason why any good designer, given time, resources, and opportunity, could not design a reliable rate-of-change-responsive regulator.

The author of the paper should be congratulated on bringing to light the concept of systematic versus unsystematic behavior of controlled process. For the practical purposes investigated

[9] "Influence of Characteristics of a Plant on the Problems of an Automatic Regulator," by D. A. Ivanoff, October 16, 1936.

[10] Petersburg, Va.

in the paper this concept needs no elaboration. Scientific significance of this concept, however, merits its further discussion.

Strictly speaking, unsystematic behavior is a systematic response to such a multitude of causes, often unknown and interdependent, that the analysis of such causes becomes impossible. Although the reasoning from cause to effect is impossible in predicting an unsystematic behavior of a function, there exists another no less scientific method of prediction of such a function. This method, disclosed in a recent U. S. patent of Minorsky's, consists essentially in finding the series of higher time derivatives of a function, prefixing it by the value of the function, and multiplying it by the time interval desired. The sum of this series then becomes the value of the function which it will have at the expiration of this time interval. The number of terms in the series, and, consequently, the highest order of derivative, depends in some fashion on the number of distinct causes affecting the function.

It follows from this that the systematic behavior, by its nature, can be predicted with reasonable accuracy by the use of few terms. On the other hand, the prediction of unsystematic behavior may require the use of such great number of terms as to render this method inoperative in a practical sense.

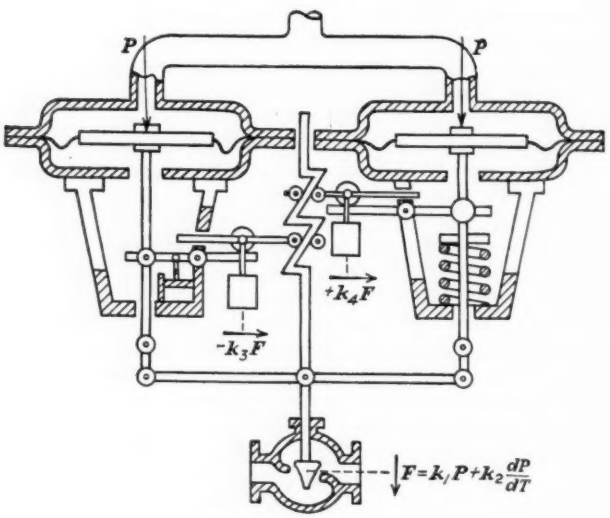

FIG. 1

The writer would like to suggest, as a research problem of some scientific institution, the development of a curve-extrapolating machine based upon this theory—this machine in effect would be a predictor of events plotted on the curve, be it weather data, or other examples of both systematic and unsystematic behavior. Since such a machine can be easily reversed, its accuracy can be checked against known past variation of the function.

In concluding his series of contributions on the subject of automatic control, the writer would like to remark that he greatly regrets the injection into the discussions of an unnecessary argument as to what is more important, theory or practice. The writer was working on the assumption that theory is just an explanation of the facts from the standpoint of basic laws of physics and mechanics and that the theory is therefore very valuable in preventing practice from straying into fallacies resulting from imperfect understanding of observed phenomena. Of course, the difference between a carefully worked out engineering theory and a mere hypothesis ought to be known to engineers.

Another value of a theory is that if it be expressed in mathematical form an advance in the art can often be made by mere manipulation of equations and analysis of the physical meaning of the results. A simple rate-of-change-responsive regulator can be designed by this method as follows: The desired characteristic equation[11]

$$F = k_1P + k_2\frac{dP}{dT} \quad [1]$$

can be rewritten as

$$(F - k_2k_4F) + k_1k_3\int FdT = k_1\int PdT + k_2P \quad [2]$$

provided $k_1k_3 = k_2k_4 = 1$.

Equation [2] can be put into the form

$$F = k_1\int (P - k_3F)dT + k_2(P + k_4F) \quad [3]$$

Examination of Equation [3] discloses that it refers to a regulator of characteristic $F = k_1\int PdT + k_2P$ provided with opposite-sign adjustment of primary impulse P in proportion to final effect F. The simplest form of such a regulator is shown, purely schematically, in Fig. 1 of this discussion.

An equivalent electric vacuum-tube circuit can easily be designed, based on Equation [3], so that adjustment of primary impulses is accomplished by use of the familiar feed-back principle.

One of a number of rather dramatic applications to electric circuits of the rate-of-change-responsive characteristics is in correcting the distortions in phonograph records made by the old-style mechanical methods. If these old records are reproduced by a carefully designed rate-of-change-responsive electrical-reproducer circuit, most of the naturalness of the original music or voice can be resurrected, especially if special compensation is made for distortion of recording caused by solid friction.

Even more spectacular results can be obtained through application of Minorsky's basic invention of the rate-of-change-responsive electric circuits to television. Depending on the degree of continuity and "systematicity" of the viewed scene, a preview of future events can be achieved in video amplifiers. In slow-changing processes, such as the growth of grass, the accurate advance in time can be as much as days or even weeks, and the importance of this invention in such cases cannot be overestimated. The field of medical prognosis and research might be interested in this invention, and it is hoped that an active development is being carried out to make its benefits available to the public.

ED S. SMITH, JR.[12] The qualitative treatment used by the author is consistent with the exploratory nature of the paper and fits in ideally with the chief aim of the A.S.M.E. Committee on Industrial Instruments and Regulators, under whose auspices it was presented, which is the cooperative sharing of experience and of knowledge of the engineering fundamentals involved, mainly for the use of those who are studying the subject without benefit of adequate personal experience.

Practically all of the paper consists of useful observations analytically coordinated; these portions will not be further dealt with in the writer's discussion. The author's main contribution in a practical sense is the example set by his own independent and courageous engineering of process conditions so as to be most favorable for control, an example that accelerates the present still-new era in successful and economic process control. On the economic side though, the writer presumes to call attention

[11] See "Principles Underlying the Rational Solution of Automatic-Control Problems," by S. D. Mitereff, Trans. A.S.M.E., vol. 57, 1935, paper FSP-59-9, p. 159, for definition of terms used in this discussion.

[12] Hydraulic Engineer, C. F. Tagliabue Mfg. Co., Brooklyn, N. Y. Mem. A.S.M.E.

to the fact that modern controllers having automatic reset are relatively inexpensive in comparison with even simple piping changes in old plants and give improved control out of all proportion to their surprisingly low cost, considering the improved performance under difficult conditions. It is of course recognized that there is no one best controller for all installations.

On the side of terminology, the paper's terms are likely to be generally understood by initiates, but it should be brought out that "corresponding" is more accurate than "proportional" and that "regulation" is possibly more widely accepted as being broader than "control" in related fields. The literature is more readily integrated if the more accurate usages are followed.[13]

Much of the paper emphasizes the fact that off-and-on control benefits by enough storage to iron out the variations due to violent attack on the controlled variable. Starting with simple assumptions as the heat H_1 equals the heat output H_2, that the load L in Btu per deg F per sec, and that the temperature change T is proportional to the heat change for a given load, the equations may be readily set up for off-and-on control in most of the heat-exchanger cases discussed in general terms in the paper and the conclusions immediately proved or disproved. It is to be hoped that the next meeting of the A.S.M.E. Committee on Industrial Instruments and Regulators will result in a subgroup that will share the work of such investigations so that the full burden will not fall on any one individual and so that the results will be available to all. This is only one of the jobs that such a group could do to the advantage of all, and with comparatively little effort. Another task would be the stating of the simple static and dynamic relations involved, so as to bring out the interrelations of capacity and other lags, relative speeds of valve travel, reset speeds, dead zones, and sensitivities.

In the author's discussion of his Fig. 1, a reference to hunting appears which seems to be based upon some unfortunately common experiences with a too-large valve. In considering the differences between off-and-on and proportional control, it seems to the writer that more care is needed in separating the effects of process and instrument lag, i.e., lag in sensing the changes of the variable, which is relatively more serious with proportional control than with off-and-on control, in view of the smaller potential changes existing with proportional control.

As to these "lags," the term itself is misdescriptive, when thought of as so many seconds between one event and its result, except in the case of transportation lag where it does apply. In the cases of metering lag and process lag due to capacity, it seems handier to the writer to use the "interval," which is the number of seconds for a value to respond to within one tenth of the ultimate change, following a sudden upset.

In the author's description of Fig. 4, first paragraph, there appears to be some implied contradiction in the average temperature differences in regard to the efficiencies of the heat-transfer surfaces.

In conclusion, it appears that the paper brings out clearly the advantages and disadvantages, from a control standpoint, of a number of common cases. This is now available as a portion of the material required for a complete treatment. However, it would seem that it might be well to take the next steps by formulating the simplest and most concise statement of the basic principles involved, and then carrying forward the mathematical analysis for both static and dynamic relations. The writer appreciates the author's courageous gesture in writing a paper for the sake of settling in open discussion what are more or less debatable points, in which he deliberately chose the *ex cathedra* presentation and with full understanding of its inherent vulnerability. The fact will remain, after the discussion is closed, that the present paper has performed an outstanding service in its field.

[13] See "Fluid Measurement and Control," by Ed S. Smith, Jr., *Chemical and Metallurgical Engineering*, vol. 44. no. 5, May, 1937, p. 178.

Author's Closure

The author wishes first of all to call attention to two typographical errors in the paper which escaped correction. On page 635, first column, line 7, the word "or" is omitted at the end of the line following "on-and-off" and preceding "narrow-band instrument" on the next line. On page 637, Figs. 9 and 10 have the correct figure numbers, but the legends are interchanged. Incidentally, while the printed text incorporates a number of minor changes from the preprint text, where misinterpretation seemed possible, it is believed that none of these changes affect the discussion.

Mr. Kimball has suggested a simplification of control problems through standardization of the specifications of controllers. It is entirely possible that, within certain fields of pressure control in which he seems to be most interested, some such standardized specifications might be workable. However, it seems to the author that, in the general field of process control and particularly in the field of temperature control, such limitations would never be possible. On the one hand, the majority of industrial control problems in most fields of application are best handled by simple on-and-off or two-position control. On the other hand, many control problems require throttling ranges of not less than from 20 to 50 per cent of convenient instrument-scale ranges, and at least one type of proportional reset controller is regularly built and used with throttling ranges as wide as 3000 per cent. Obviously, customers whose applications require only on-and-off control will not wish to pay for more complicated constructions, providing throttling range which is useless to them. Neither could users nor manufacturers be limited to any maximum throttling range, 10 per cent or any other value, if a considerable portion of the process problems could be satisfactorily solved, provided wider throttling ranges were available.

Mr. McMahon is to be congratulated on picking out and filling in one fundamental weakness in the paper. The author's experience with control problems involving considerable transfer lag had been rather limited, and this subject was barely mentioned. It is fortunate that one with so much experience in such problems has filled in this point in the discussion.

Many other arrangements of heat exchange will occur to readers in accordance with their own experience. The by-pass controlled exchanger mentioned by Mr. McMahon is certainly an important type, although one rarely met in the author's own experience.

Incidentally, it has come to the author's attention that, in the minds of some readers, the term "heat exchanger" was not sufficiently broad, and did not cover simple electrically heated units in which there was admission but no discharge of heat units on the supply side. It was intended that the term "heat exchanger" should be extremely broad, covering everything from such simple heaters—and the common steam heaters closely approach the electrically heated case, since heat losses in the condensate are relatively rather small—on to the most complicated heat exchangers.

Mr. Wagner is to be particularly thanked for discussing an application of the paper in fields far from the author's industrial experience. It is certainly true that building heating involves some of the most complicated temperature-control problems, and only the considerable tolerances permitted by the human organism have made many methods of control passable.

In regard to the question of economics raised by Mr. Wagner, it is the author's belief that, in the words of Professor Marks, "A good engineer is always aware of the economic problem."

The same economic factors are present in this temperature-control problem that exist in problems of process temperature control, but the weighting may be entirely different.

Mr. Behar's discussion opens with some statements indeed flattering to the author. It is believed, however, that they do not give due credit to the collective efforts of engineers associated with the various manufacturers. It was the author's impression as a customer that leading vendors have long been aware of the fact that wider use of instruments was limited more by application problems than by design and construction problems. Progress is in no small measure due to the collective efforts of their factory and field engineers who have been working quietly but nonetheless effectively toward enlightenment of the user.

Mr. Behar questions the author's statement that the dry bulb of a psychrometer must not be shielded, in the passage: "At the same time the adjacent dry bulb must not be shielded or spattered." It was perhaps unfortunate that the word "shielded," having also a specialized meaning, was used, since simply blocking off the representative air stream is meant. Radiation shields are, of course, frequently used in psychrometers.

The author is aware that classification of controller mechanisms without their associated processes does not tell the whole control story. Nevertheless, it is felt that the method of classification used in the paper, listing separately the control mechanisms to be purchased and the processes to be equipped, is the only one of much practical help to the user.

Messrs. Spitzglass and Zucrow have discussed at length the paper of the author and that of Bristol and Peters.[14] They point out clearly the limitations of qualitative analysis, both in regard to inexactness and in regard to inapplicability to processes involving more than two capacities; yet, at the same time, they declare the usefulness of a qualitative picture in leading to later quantitative work. The author will be entirely satisfied with the qualitative scope of his paper if it does help in understanding quantitative work which may follow.

It should be mentioned in passing that since this paper was written and presented in 1937, although only recently printed, it antedates the mathematical papers of Mason[15] and of Spitzglass.[16] Being based, therefore, necessarily entirely on observations and intuitive judgments, without benefit of exact checking by mathematical methods just now coming into use, its use for indefinite extrapolation of the conclusions far beyond the scope of the original observation is not advised without some form of checking.

Mr. Mitereff questions "the necessity of tailoring the process equipment to make it easily controllable with the simplest types of regulators," while Mr. Smith raises the same question "when modern controllers having automatic reset are relatively inexpensive in comparison with even the simple piping changes in old plants, and can improve control out of all proportion to their surprisingly low cost." The author would not for a moment advocate uneconomic changes in existing plants or even in new plants, merely to permit the use of a simpler and cheaper controller. But he does wish to emphasize that design for controllability is usually of considerable economic advantage when over-all investment and operating costs for the process are considered. It must not be overlooked that the initial response of even the best proportional reset controllers now available is the response of a simple throttling controller. While the reset mechanism will correct deviation of the control point which has occurred as a result of load changes, it does not prevent that initial deviation. Hence, any process which requires wide throttling ranges must unavoidably operate with considerable deviation following upsets. If the process is designed for improved controllability permitting a much narrower control band or throttling range, a simple proportional narrow-band, or even an on-and-off, instrument may give better control than the best reset instrument on a process improperly designed. There is no doubt in the author's mind that design for controllability will in the long run extend rather than circumscribe the application of control instruments.

Discharge Temperatures From Pulverizers

By OLLISON CRAIG,[1] WORCESTER, MASS.

In view of the fact that the temperature of discharge from coal pulverizers was of interest because of the effect that it might have on the amount of air passing through the preheater, and on the amount of uncontrollable air through the furnace, data were taken in a number of plants covering temperature of air entering pulverizers, temperature of air in coal discharge, moisture of raw coal entering the pulverizer, moisture of discharged coal, and weight of coal pulverized per hour.

Two sets of points were plotted, one showing the temperature of discharge for given entering temperatures, and the other the temperature drop through the pulverizer for given entering temperatures. In plotting the data no consideration was given to the size of pulverizer, amount of coal pulverized, or the moisture content of the coal. The plotted points fell in a straight band having a width of approximately 65 deg. A straight line drawn through the band shows the average variation within 35 deg.

Sufficient information was obtained in the cases of two plants to calculate heat balances. From these heat balances leakage of uncontrolled air into the pulverizer was calculated. It was found that this amounted to about 2 per cent of the total air for combustion.

WHEN UNIT pulverizers are used for grinding coal and coal is discharged directly from the pulverizers through piping and burners into a boiler furnace, air is required as a conveying medium for the coal. This air is usually referred to as primary air. It would be desirable for a number of reasons to pulverize coal in a unit pulverizer and discharge it into the furnace without the use of any primary air. If this were possible the power required to propel the air would be saved; all the air of combustion except furnace leakage air would be introduced through the burner as secondary air, providing more accurate control of combustion conditions, and making possible the use of smaller discharge pipes between pulverizers and burners. However all existing designs of mills in use require air for conveying coal through the pulverizer and through the discharge pipe and burner. This primary air, being mixed with the pulverized coal, is of further value in obtaining initial ignition of the coal and in securing proper mixture of the coal with the secondary air. The fact remains that primary air is necessarily used, and primary air must be taken into account in determining performance of pulverizers and design of burners, air heaters, and air ducts.

Occasion arises in all plants when it is necessary to pulverize and burn coal containing more than a normal amount of moisture. When the coal is more than normally wet it is desirable to supply primary air to the pulverizer at a temperature higher than that of the surrounding atmosphere. The extra heat available in the hotter primary air is then available for evaporating moisture from the coal. Drying of the coal during the process of pulverizing has the effect of increasing the capacity of the pulverizer, decreasing the amount of power which is required to drive the pulverizer, and increasing the fineness to which the coal is reduced.

Many boiler installations are equipped with air preheaters and in such cases it is customary to take air from the hot-air duct and introduce it into the pulverizer as primary air. This method is satisfactory and effective, providing that the temperature of the preheated air is sufficiently high for the amount of moisture contained in the coal and for the amount of coal to be pulverized. There are, on the other hand, boiler installations which use pulverized coal but which do not have air preheaters. In these cases it is usually desirable to provide other means for heating the air going into the pulverizer. Steam-air heaters are often used for this purpose. With steam-air heaters the temperature of primary air that can be obtained is limited by available steam pressure. In other cases hot gas is taken from the back pass of the boiler or from the breeching, mixed with air, and introduced into the pulverizer. This method has the disadvantage of requiring too large a proportion of gas in the primary-air mixture, thus diluting the primary air with inert gas and interfering with ignition at the burner. Sometimes gas is withdrawn directly from the furnace, mixed with tempering air immediately outside of the furnace, and the mixture is introduced into the pulverizer as primary air. This last method has a number of advantages. Any desired temperature, subject to the limitations of the pulverizer, may be obtained. The amount of inert gas so used is usually of insufficient amount to interfere seriously with ignition.

Frequently air preheaters are designed to give rather high temperatures, that is temperatures of 500 F or more. Temperatures as high as this or higher can also be obtained by the use of hot gas from the boiler furnace. In general it would be desirable to take advantage of the highest temperature available and thus improve pulverizer performance. Oftentimes a limitation is placed on the temperature of air entering the pulverizer, or the temperature of the mixture leaving the pulverizer. This limitation may be established to protect bearings or casings but usually it is to prevent fire in the pulverizer, in the classifier, or in the coal-discharge pipe. If ignition of coal occurs, flame cannot be produced nor can there be an explosion unless the velocity of travel of the coal-and-air mixture is less than velocity of flame propagation. This is illustrated by flame action at the burner. The reason flame does not travel back into the burner is that the velocity of discharge from the burner is greater than velocity of flame propagation. In those pulverizers in which coal-and-air velocities exceed the velocity of flame propagation, for any ratio of coal-and-air mixture that might exist, ignition of coal could occur without danger of fire or explosion. This has been demonstrated by actual tests. In case the velocity of the mixture be less than velocity of flame propagation, it is necessary to take such precautions as possible to prevent ignition, since, should ignition take place, flame would result and an explosion occur.

Reference has been made to "velocity of flame propagation, for any ratio of coal-and-air mixture that might exist." Velocity of flame propagation is the rate at which flame travels through a combustible mixture and may be expressed in feet per minute. This velocity is not constant for all mixtures of powdered coal and air, but varies with the kind and condition of the coal and with the ratio of coal and air in the mixture. The curves of Fig. 1 illustrate this. Each curve is for a different coal containing a particular percentage of volatile matter and of ash. It is to be noted that the greater the percentage of volatile matter and the less the ash the greater is the velocity of flame propagation.

[1] Engineering Manager, Riley Stoker Corporation. Mem. A.S.M.E.

Contributed by the Fuels Division and presented at the Fall Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Providence, R. I., October 5–7, 1938.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Each curve defines the relation between the coal-air ratio and the velocity of flame propagation. It will be noted that for each coal there is a coal-air ratio which results in a maximum velocity of flame propagation. Other factors affect velocity of flame propagation, but the factors used in the curves are of major importance and are sufficient for the purpose of this discussion.

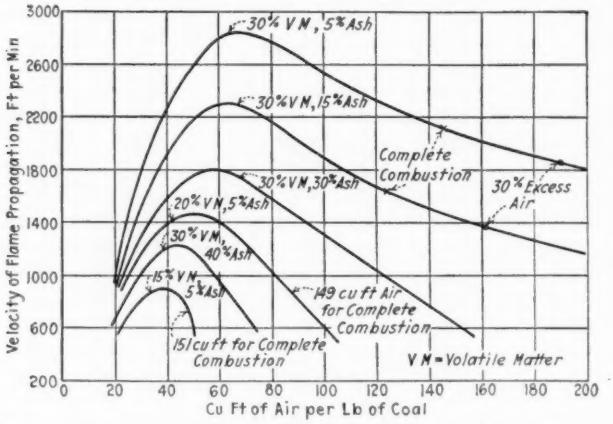

FIG. 1 VELOCITY OF FLAME PROPAGATION FOR MIXTURES OF PULVERIZED COAL AND AIR

(Coal dust through 200-mesh sieve. Curves reproduced from *Revue de Metallurgie*, November, 1922. Experiments at Taffanel Experimental Galleries, Lievin, France.)

In the course of changing rates of coal pulverizing and rates of air supply to a pulverizer, some ratio of coal and air will occur which will result in the maximum velocity of flame propagation for that particular coal. For example, assume that coal having 30 per cent volatile matter and 5 per cent ash is being pulverized. From the top curve of Fig. 5 it will be seen that if 1 lb of this pulverized coal is mixed with 67 cu ft of air, the velocity of flame propagation through the mixture would be 2820 fpm. Any other coal-air ratio would result in a slower velocity of flame propagation with this particular coal. The amount of air in this mixture is about 47 per cent of the amount of air theoretically required for complete combustion. For other coals, maximum velocities of flame propagation occur with other ratios of coal to air. In any case there is a probability of a coal-air ratio occurring in a pulverizer, at some time, which would result in the maximum velocity of flame propagation. The velocity of travel through the pulverizer must be greater than this velocity of flame propagation to avert danger of fire and explosion, or the temperature within the pulverizer must be maintained sufficiently low to prevent ignition.

The terms "explosion" and "explosive" as used here are relative. A mixture which is more explosive than some other mixture, is one in which the velocity of flame propagation is greater. Explosion is the rapid burning of a mixture in a confined or partially confined space with a resulting building up of pressure in the space. In a partially confined space, such as in a pulverizer, the faster the mixture is burned the greater is the resulting pressure and the more explosive is the mixture. The velocity of flame propagation is thus related to explosiveness.

Various manufacturers have determined from experience what temperatures of discharge from their particular pulverizers are permissible without danger of ignition within the pulverizer. In certain cases this discharge temperature is regulated by the admission of cold or room air into the pulverizer with the hot preheated air. There is of course a disadvantage in this method since the cold air, which becomes a portion of the combustion air, does not pass through the air heater. The effectiveness of the air heater is thereby reduced and consequently more expense is entailed for a larger air heater to compensate for decreased effectiveness. Also, in such cases, since all the gaseous products of combustion pass through the air heater, either the air is heated to a higher temperature than otherwise or the temperature drop of the gas is reduced.

It is probable that all pulverizers, with the exception of those which are operated under a positive air pressure, take in some cold air other than that which comes through the primary-air ducts. This leakage air may enter through joints and cracks or through the coal and feeder. Its effect is the same as that produced by tempering air which is admitted under control and is greater or less as the amount of leakage is greater or less than the amount of the controlled tempering air.

The temperature at which a mixture of coal and air is discharged from a pulverizer and its relation to the temperature of the air which is admitted to the pulverizer as primary air, is of interest, because of its bearing on the amount of primary air required, effectiveness of coal drying, amount of tempering air, and elimination of possible burning of coal within the pulverizer.

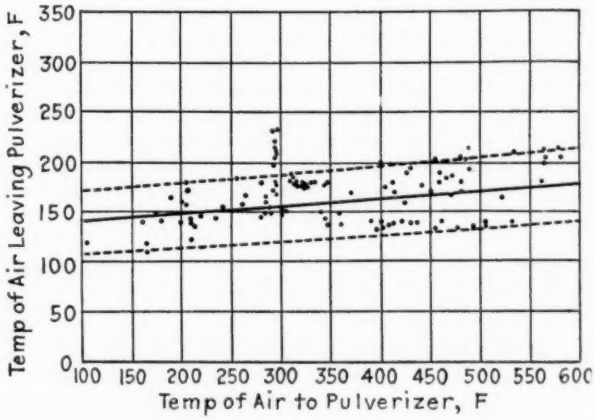

FIG. 2 AIR TEMPERATURES FOR COAL PULVERIZERS

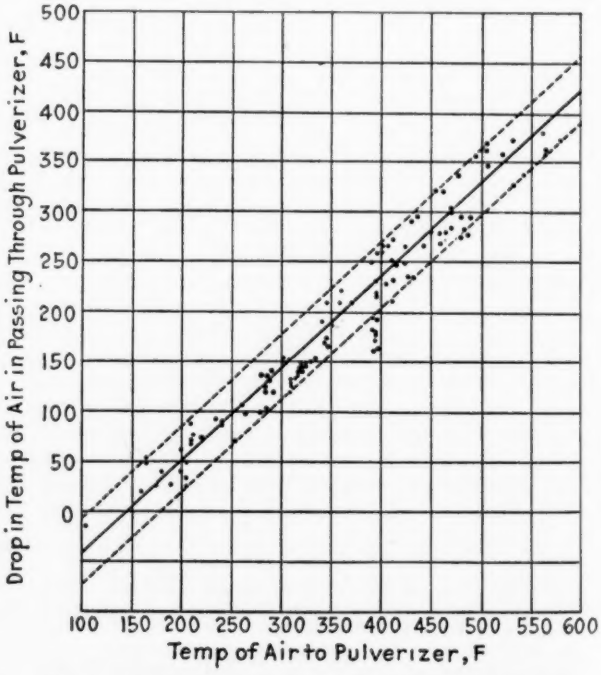

FIG. 3 AIR-TEMPERATURE DROP THROUGH PULVERIZERS

TABLE 1 COAL-PULVERIZER TESTS

Coal pulverized, lb per hr	9070	9450	9950	10850	11250	12000
Air temperature, pulverizer inlet, deg F	470	430	483	465	450	480
Air temperature, pulverizer outlet, deg F	170	195	205	185	170	185
Temperature drop through pulverizer, deg F	300	235	278	280	280	295
Moisture in raw coal as fed, per cent	3.10	3.50	3.06	3.75	2.93	3.08
Moisture in pulverized coal, per cent	0	0	0	0.57	0	0
